Exploiting microalgae as feedstock for biofuel production is a growing field of research and application, but there remain challenges related to industrial viability and economic sustainability. A solution to the water requirements of industrial-scale production is the use of wastewater as a growth medium. Considering the variable quality and contaminant loads of wastewater, algal feedstock would need to have broad tolerance and resilience to fluctuating wastewater conditions during growth. As a first step in targeting strains for growth in wastewater, our study isolated microalgae from wastewater habitats, including urban stormwater-ponds and a municipal wastewater-treatment system, to assess growth, fatty acids and metal tolerance under standardized conditions. Stormwater ponds in particular have widely fluctuating conditions and metal loads, so microalgae from this type of environment may have desirable traits for growth in wastewater. Forty-three algal strains were isolated in total, including several strains from natural habitats. All strains, with the exception of one cyanobacterial strain, are members of the Chlorophyta, including several taxa commonly targeted for biofuel production. Isolates were identified using taxonomic and 18S rRNA sequence methods, and the fastest growing strains with ideal fatty acid profiles for biodiesel production included *Scenedesmus* and *Desmodesmus* species (Growth Rate (d^{-1}) > 1). All isolates in a small, but diverse taxonomic group of test-strains were tolerant of copper at wastewater-relevant concentrations. Overall, more than half of the isolated strains, particularly those from stormwater ponds, show promise as candidates for biofuel feedstock.

Screening microalgae isolated from urban storm- and wastewater systems as feedstock for biofuel

1   **Abstract**

2   Exploiting microalgae as feedstock for biofuel production is a growing field of research

3   and application, but there remain challenges related to industrial viability and economic

4   sustainability. A solution to the water requirements of industrial-scale production is the use of

5   wastewater as a growth medium. Considering the variable quality and contaminant loads of

6   wastewater, algal feedstock would need to have broad tolerance and resilience to fluctuating

7   wastewater conditions during growth. As a first step in targeting strains for growth in

8   wastewater, our study isolated microalgae from wastewater habitats, including urban stormwater-

9   ponds and a municipal wastewater-treatment system, to assess growth, fatty acids and metal

10   tolerance under standardized conditions. Stormwater ponds in particular have widely fluctuating

11   conditions and metal loads, so microalgae from this type of environment may have desirable

12   traits for growth in wastewater. Forty-three algal strains were isolated in total, including several

13   strains from natural habitats. All strains, with the exception of one cyanobacterial strain, are

14   members of the Chlorophyta, including several taxa commonly targeted for biofuel production.

15   Isolates were identified using taxonomic and 18S rRNA sequence methods, and the fastest

16   growing strains with ideal fatty acid profiles for biodiesel production included *Scenedesmus* and

17   *Desmodesmus* species (growth rate $(d^{-1}) > 1$). All isolates in a small, but diverse taxonomic

18   group of test-strains were tolerant of copper at wastewater-relevant concentrations. Overall, more

19   than half of the isolated strains, particularly those from stormwater ponds, show promise as

20   candidates for biofuel feedstock.

21

22

23   **Introduction**

24   As the earth's human population increases, world energy demands and reliance upon

25   fossil fuels has continued to rise. Consequently, global carbon emissions, including green-house

26   gases, have increased and contributed to global climate warming. The need to move to fossil-fuel

27   alternatives is not only necessary for addressing anthropogenic climate change, but also

28   depleting world energy-stores (Hook et al. 2013). Algal biofuels in particular have been

29   identified as an exceptional source of carbon neutral, renewable energy (Sharif Hossain et al.

30   2008, Schenk et al. 2008, Clarens 2010). Their high photosynthetic efficiency, biomass

31   production, and ability to accumulate relatively large amounts of triacylglycerides (TAG) for

32   conversion to fatty acid methyl esters (FAME) have made them a desirable alternative to land-

33   plant biofuel crops. Unlike first and many second-generation biofuel feedstocks, microalgae can

34   be cultivated using saline, brackish or wastewater streams on non-arable land. Additionally, algal

35   feedstock can be harvested batch-wise throughout the year from industrial-scale

36   photobioreactors, reducing land, nutrient, and fresh water requirements (Guischina et al. 2006,

37   Graef et al. 2009). The success and economic viability of an microalgae-based biofuel industry

38   will depend on several factors, including the selection of robust strains that exhibit exceptional

39   growth rates, suitable biofuel lipid profiles, resistance to disease and predation, and tolerance to a

40   wide range of environmental parameters (Griffiths and Harrison 2009). Tolerance to

41   environmental conditions is an important, but often over looked characteristic when

42   bioprospecting for biofuels, and offers several benefits such as ease of cultivation and resiliency.

43   Griffiths and Harrison (2009) outlined a framework in the selection of appropriate algal

44   strains. It identified the selection of fast-growing strains optimized for local climatic conditions

45   as a fundamentally important quality. They also argued that lipid content as a key characteristic

46   may not be as critical as previously thought, because fast growth encourages high biomass

47   productivity, and high biomass density can increase yield-per-harvest volume. Research to

48   increase growth rates and lipid production has identified optimal temperatures, pH, photoperiods

49   and nutrients for several species (Lv et al. 2010, Sforza et al. 2012, Adams et al. 2013). These

50   parameters, however, are dissimilar among strains and require individual optimization.

51   Moving forward, it is recognized that bioprospecting for biofuel microalgae will require

52   assessments of individual and mixed-cultures of strains (Zhou et al. 2011). Additionally, ideal

53   candidate strains may need an inherent tolerance to sub-optimal growth conditions, since

54   wastewater from a variety of sources may be the most economically and environmentally

55   feasible growth medium. As a first step in assessing temperate-climate microalgae for their

56   potential as biofuel feedstock, we aimed to isolate and culture strains from several engineered

57   wastewater systems that included urban stormwater ponds and a municipal wastewater system.

58   These environments were targeted because they are known to support algal communities, but

59   also experience fluctuating conditions that include variation in contaminant loads and residence-

60   time.

61   For example, we know that stormwater ponds typically have elevated metal

62   concentrations (Campbell 1994; Marsalek and Marsalek 1997; Karlsson et al. 2010), including

63   the ponds in our study (Vincent and Kirkwood 2014). It also has been well documented that

64   municipal wastewaters have elevated levels of metals and other contaminants (Chambers et al.

65   1997; Gagnon and Saulnier 2003; Wang et al. 2005; Principi et al. 2006). Hence, these

66   engineered environments were considered promising source habitats for microalgae with

67   inherent tolerance to fluctuating conditions and contaminant loads, including metals. Overall, the

68   primary goal of this study was to elucidate if certain algal taxa from these wastewater source-

69   locations possessed growth, fatty acid, and metal-tolerance traits suitable for biofuel-feedstock

70   production.

71

72   **Materials and Methods**

73   *Sample Collection and Strain Isolation*

74   Three 1-L water samples were collected from nine urban stormwater ponds and two

75   natural reference ponds across Durham Region, Ontario, Canada between June and August,

76   2011. All of these ponds have been previously described using a similar numbering scheme in

77   Vincent and Kirkwood (2014). In June, 2011, 3-L of municipal wastewater was collected from

78   each of three locations along the secondary treatment system of the Corbett Creek activated

79   sludge Water Pollution Control Plant in Whitby, Ontario, Canada. Additionally, several litres of

80   water were collected from Lake Ontario at a single nearshore location in Whitby, Ontario to

81   expand the isolations from natural, local habitats.

82   Sub-samples of all collected water were transferred to sterile 250-mL Erlenmyer flasks

83   stoppered with cotton bunts on a light bank table (12:12 dark/light cycle) in triplicate. Upon

84   confirmation of algal growth by visual inspection, 10-mL sample aliquots were transferred to

85   250-mL Erlenmyer flasks and enriched with 90-mL of two defined media recipes: BG11 (Rippka

86   et al. 1979) modified by reducing $NaNO_3$ by one-tenth stock concentration; and CHU10 (Stein et

87   al. 1973). Two media types were employed to broaden isolation success for a diversity of strains,

88   and both had nitrogen and phosphorus concentrations on par with ranges typically found in the

89   municipal-wastewater system of our study (unpublished data) and stormwater ponds (Vincent

90   and Kirkwood 2014). F2 vitamin mixture (Guillard 1973) was added by syringe filter (Progene)

91   to both media types after autoclaving. Isolation of unialgal strains was accomplished by methods

92   outlined by Andersen and Kawachi (2005). In brief, mixed-culture samples were serially diluted,

93   1 in 10 with sterile millipore water and spread plated on to 1.5% agar plates. Visible and distinct

94   colonies were pegged with sterile loop and re-cultured in BG11 or CHU 10 media and examined

95   microscopically to verify they were a single strain throughout the study period,with re-culturing

96   every three weeks. Isolated strains were observed using an EVOS xl core inverted microscope at

97   400X to ensure unialgal status, and subsequent sequencing of strains confirmed this. Tentative

98   taxonomic strain identification was assigned based upon morphological descriptions in Sheath

99   and Wehr (2003).

100

101 *Growth Assays*

102   Growth assays were conducted under standardized conditions to determine growth rate

103 and generation time for all isolates. A 10-mL inoculum of exponentially-growing stock-culture

104 was aseptically introduced to 90-mL of sterile isolation media and grown in cotton-stoppered

105 flasks on a cool-white fluorescent plate-glass light table (20-22 ˚C, 12:12 dark/light cycle) and

106 shaken by hand once a day. Algal cell concentration was determined by microscopic

107 enumeration using a Brightline haemocytometer on a VistaVision compound light microscope at

108 100X magnification. The optical density of 1-mL samples was measured at 550nm every 24-hrs

109 for a seven-day period using the Genesys 10S UV/VIS Spectrometer. These data were used to

110 construct growth curves for each algal strain. Specific growth rate (μ), and generation time (T_h)

111 were calculated as per Guillard (1973) over a period of exponential growth.

112

113 *Antibiotic Treatment of Algal Isolates*

114   Great care was taken to attain axenic cultures to remove the influence of bacteria on

115   FAME profiles (Stemmler et al. 2016) using a modified antibiotic treatment method adapted

116   from Jones et al. (1973). Isolated strains were first treated with a serial dilution of antibiotics (a

117   combination of Penicillin G sodium salt and Streptomycin sulfate) (Bioshop Canada) for an

118   exposure period of 24 hours. Algal colonies were selected from the lowest antibiotic

119   concentration that had no bacterial growth. Aliquots of the exposed strains were transferred to

120   fresh media, with no antibiotics, after 24 hours, followed by pour plate preparation, 1% peptone

121   and 1.5% agar, to evaluate bacterial contamination in addition to microscopic observation.

122   Strains deemed to be axenic were monitored by this method once a month to ensure axenic status

123   was sustained. Strains that were found to be non-axenic were re-treated, but a few non-axenic

124   strains were classified as such if bacterial contamination could not be removed. Only axenic

125   strains were assessed for fatty acid analyses.

126

127   *DNA Extraction, Amplification, and Sequencing*

128   Genomic DNA of isolated strains was extracted using the commercial kit UltraClean

129   Plant DNA Isolation kit (MoBIO, USA). Cell lysis was achieved by chemical, SDS and

130   mechanical means using a Vortex Genie with horizontal microtube attachment (Scientific

131   Industries, USA). Bead tubes provided by the extraction kit were subjected to three, 5-minute

132   bead beating sessions at 3200 rpm. Samples rested in the tubes on ice for 5 minutes between

133   bead beating sessions. Upon completion of cell disruption, 20 µL of RNase A (Geno

134   Technology, USA) was added and vortexed gently for 10 minutes. Extracted DNA was

135   quantified at 260/280nm by UV-Spectrophotometry (Gensys 10S UV/VIS) and frozen at -20°C

136   or kept at 4°C until PCR amplification.

137   The 18S rRNA forward primer NS1 (White et al. 1990) and reverse primer ITS2 (White

138   et al. 1990) were used to prime PCR at a concentration of 1.0 µmol. Reactions were carried out

139   using Illustra Ready-To-Go PCR beads (GE Healthcare, USA) in a final volume of 25 µL. The

140   PCR reaction was performed using the T100 Thermal cycler (BIORAD, Canada) with the

141   following cycle parameters: initial denaturation 96°C for 3 min, annealing at 51°C /1 min, and

142   extension at 72°C for 1.30 min. This was followed by 29 cycles of denaturation at 93°C /1.30

143   min, annealing at 51°C for 1.30 and extension at 72°C for 1.30 min, followed by a final

144   extension step at 72°C for 5 min. Strains that would not amplify by this method were amplified

145   using the forward NS1 primer and reverse 18L primer (Hamby and Zimmer 1991), along with a

146   touchdown PCR cycle with annealing beginning at 61°C and reducing by 2°C every 2 cycles

147   until 51°C was reached. Gel purification of PCR bands was carried out using the Wizard SV Gel

148   and PCR Clean-Up System (Promega, USA). Modifications were made to the general protocol

149   with the addition of an extra rinse of the column with membrane wash-solution as well as an

150   additional 1-minute spin at 16000 x g with the lid off to aid in evaporation of wash solution.

151   Extracted bands were sent to the Génome Québec Innovation Centre, McGill University, Canada

152   for Sanger sequencing.

153   Sequencing results were locally aligned using the NCBI Nucleotide BLAST and closest

154   matches assigned based on sequences from the NCBI database. BLAST matches that aligned

155   closely, between 90-99% with culture strains, were selected and added to sequence comparisons

156   in addition to more distantly related species within each family. Only NS1 region sequences

157   greater than 400 base pairs (bp) were included in further phylogenetic analyses. These sequences

158   were deposited into the NCBI database and accession numbers for each sequence were acquired.

159   Phylogenetic tree reconstruction was performed on the Phylogeny.fr platform (Dereeper

160   et al. 2008; Dereeper et al. 2010), which comprised a series of steps in the analysis. Sequences

161   were aligned and configured with the highest accuracy using MUSCLE (v 3.8.31) (Edgar 2004).

162   After alignment, ambiguous regions containing gaps or poorly aligned regions were removed

163   with Gblocks (v0.91b) using the following parameters: minimum length of a block after gap

164   cleaning=10; no gap positions were allowed; all segments with contiguous non-conserved

165   positions bigger than 8 were rejected; and minimum number of sequences for flank position was

166   85% (Castresana 2000). The phylogenetic tree was reconstructed using the neighbour-joining

167   method (Saitou and Nei 1987, Gascuel 1997) implemented in the BioNJ program with 1000

168   bootstrap replicates (Felsenstein 1985; Elias and Lagergren 2007). The analysis involved 45

169   nucleotide sequences with an average sequence length of 735 bp. Graphical representation and

170   editing of the phylogenetic tree was performed with TreeDyn (v198.3) (Chevenet et al. 2006).

171

172   *Fatty Acid Methyl Esters (FAME) Analysis*

173   To avoid possible confounding effects of bacteria, only axenic isolates (thirty-four in

174   total) were subjected to fatty acid analysis. Isolated strains were grown to stationary phase under

175   previously described growth conditions and 10-mL subsamples were transferred to 14-mL glass

176   tubes with lids and centrifuged at 16000 rpm (Sorval ST16, Thermo Scientific, USA) for five

177   minutes. Pelleted biomass was frozen at -20°C for 48 hours followed by 24-48 hrs of

178   lyopholization with a modulyoD freeze dryer (Thermo Scientific, USA). A direct method of

179   transesterfication of algal fatty acids was performed as per O'fallon et al. (2007). A 100 ppm

180   nonadecanoic acid methyl ester C19:0 (Sigma Aldrich, Canada) internal standard was added to

181   each sample followed by analysis by Gas Chromatography/Mass Spectrometry (GC/MS).

182   Methylated fatty acids in hexanes were analyzed on a Varian 450 gas chromatographer

183   with HP-5ms Ultra Inert GC Column, 30 m x 0.25 mm x 0.25 μm, (Agilent J&W). A split ratio

184   of 10:1 was used for 3.5 min with a flow rate of 1.0 mL/min, helium carrier gas. The oven

185   temperature was held at 135 °C for 4 minutes and increased by 4 °C/min until 250 °C, where it

186   was held for 10 minutes until run-end. A Varian 240 Ion Trap Mass Spectrometer detector was

187   used and fame peaks were identified based upon spectral comparison and retention times to

188   FAME standards: BAME and Supleco C8:0-C24:0 (Sigma Aldrich, Canada). A negative control

189   was included in the FAME process as a quality measure and analyzed under identical sample

190   conditions to ensure peaks obtained were attributable to microalgae samples.

191   To assess the biofuel potential of the lipid content measured for each isolate, several

192   measures of biodiesel quality were determined using the methodologies and equations outlined in

193   Ramos et al. (2009) and Nascimento et al. (2013). ASTM Standard D675 for biodiesel quality

194   requires a minimum Cetane Number (CN) of 47 and a maximum Iodine Value (IV) of 120.

195

196   *Copper Toxicity Bioassays*

197   Five isolates representing diverse taxonomic genera were further characterized to assess

198   their inherent tolerance to copper, a particularly toxic metal to microalgae and a metal that is

199   commonly found in industrial and municipal wastewaters. Genera selected include:

200   *Scenedesmus, Monoraphidium, Chlorella, Selenastrum* and *Microcystis*. The Canadian

201   Phycological Culture Collection strain *Chlorella kesslerii* CPCC266 was also tested as it is a

202   commonly used bioassay reference-strain. A standard 72-hour static growth response bioassay

203   was used to assess inherent tolerance to copper. The assay methodology was based on the

204   protocol established by Environment Canada (2007). Prior to commencing the bioassays, all

205   glassware, tips, and applicable materials were acid-washed in a 10% HCL solution for a period

206   of 24 hours followed by triplicate rinse with Milli-Q™ filtered water. A stock Copper (II) Sulfate

207   Pentahydrate (32 mg L^{-1} Cu) solution was prepared with a solution of CHU 10 media and

208   sterilized by autoclave. The stock solution was used to aseptically prepare copper concentrations

209   of 0.01, 0.1, 0.32, 1.0 and 3.2 parts per million (ppm) Cu, diluted with sterile CHU 10 media. All

210   concentrations and control cultures were prepared in triplicate to a final volume of 25-mL in 50-

211   mL Erlenmyer flasks. Innocula (1-mL) from exponential phase cultures were added to three

212   replicate flasks with each test concentration and maintained under the same growth conditions in

213   a controlled environment incubater with shaker table (Algaetron AG130-ECO) at 22°C $^{+/-\ 2°C}$

214   under 12h light/dark cycles at 150 mmol photons m^{-2} s^{-1} and 200 rpm. The pH of each replicate

215   was monitored daily using an Oakton pH/Ion 510 bench meter. Fluorescence measurements of

216   chlorophyll *a* were taken at 24-hr intervals using an Aquafluor Hand Held fluorometer, whereby

217   the chlorophyll *a* solid secondary standard (Turner Designs, USA) was used as a qualitative

218   calibration tool for chlorophyll *a* measurement. The growth rate was calculated as previously

219   described and data were normalized to percent-control. Growth-rate data were also used to

220   calculate percent inhibition:

$$\% \, I = \frac{C - X}{C} \times 100$$

221

222   Where C = average control growth-rate, X = average test-concentration growth-rate.

223

224   **Results**

225   In total, forty-three algal strains were isolated from all habitat types. Tentative taxonomic

226   assignments were given to all isolates and, with the exception of one cyanobacterial strain

227   (*Microcystis* sp. Sp21.01), NCBI BLAST searches of partial 18S rRNA sequences were

228   performed (Table 1). All eukaryotic isolates are members of the algal division Chlorophyta,

229   which is a diverse group of green microalgae. Taxonomic assignment and BLAST matches were

230   fairly congruent, but there were several exceptions. All isolates were initially characterized for

231   growth-rate under standardized conditions (Table 1), and for all strains, exponential growth was

232   most commonly observed to last up to three days. Fastest growing strains came from stormwater

233   ponds and included *Scenedesmus sp* Sp19.011 and *Desmodesmus* sp. Sp19.15, which doubled

234   their biomass in just over 13 hours. In contrast, the slowest growing strains *Scenedesmus* sp.

235   Sp21.12 and *Chlorella* sp. Sp21.20 had generation times between 40-42 hours. Over 60 % of the

236   strains were found to have a generation time less than 24 hours (Table 1).

237   A subset of twenty-seven isolates with NS1sequences greater than 400 bp were used with

238   eighteen NCBI database-taxa to reconstruct an unrooted neighbour-joining phylogenetic tree

239   (Fig. 1). All strains included in the tree belong to the Chlorophyceae and Trebouxiophyceae

240   classes. Tree topology distinctly groups isolates into families and genera. In total, the tree

241   demarcates study-isolates into seventeen unique phylotypes based on branch lengths ≤ 0.001

242   base-pair substitutions per site. Most isolates had sequence matches with taxa from the BLAST

243   database, with the exception of only a few including: *Monoraphidium sp*. Sp19.015,

244   *Scenedesmus sp*. Sp19.011, *Desmodesmus sp*. Sp19.15 and *Chlamydomonas sp*. SpU9.

245   FAME results for thirty-four axenic isolates identified seven different fatty acids,

246   including saturated (lauric acid (C12:0) and palmitic acid (C16:0)), monounsaturated (oleic acid

247   (C18:1)) and polyunsaturated (linoleic acid (C18:2), hexadecatetraenoate (C16:4(n-3) and

248   eicsoatetraenoic acid (C20:4)) forms. Palmitic and oleic fatty acids were the predominant lipid

249   components found in all strains. Several strains including *Chlamydomonas* sp. SpU9,

250   *Chlamydomonas* sp. Sp19.40, *Ankistrodesmus* sp. LO47 and *Chlorella* sp. LO51 had a large

251   percentage (70-90%) of their total FAME lipid as palmitic acid. *Desmodesmus* sp. WW39 and

252   *Scenedesmus* sp. Sp16.34 had oleic acid greater than 80% of their total FAME lipid profile.

253   *Chlorococcum* sp. Sp17.022 was the only strain observed to have oleic acid C18:1 present in

254   both cis- and trans- forms. One of the most unique profiles belongs to *Chlorella sp*. Sp21.02,

255   which was found to have 53% of its lipids in polyunsaturated forms (Fig. 2). There was no

256   apparent distinction of FAME profiles among strains isolated from different source-locations

257   (see supplemental information).

258   To determine if there was any congruence among strains with respect to lipid

259   composition and phylogenetic relatedness, the FAME profiles of strains sharing a phylotype with

260   at least one other strain were compared using hierarchical cluster analysis (Fig. 3). The Bray-

261   Curtis similarity dendrogram grouped strains of the same phylotype as being most similar based

262   on their FAME profile. The cophenetic correlation coefficient of 0.87 indicates that the

263   dendrogram adequately preserved the pairwise distances among strains. Bootstrap scores were

264   mixed, but were moderate to strong for most nodes in the dendrogram. Strains *Scenedesmus sp*.

265   Sp12.36 and *Scenedesmus sp*. LO48 are the same phylotype and had the most similar FAME

266   profiles (>95% similarity). In contrast, *Ankistrodesmus sp*. LO47 and *Ankistrodesmus* sp. Sp1.50,

267   which are the same phylotype, were only about 55% similar based on their FAME profiles. Even

268   so, they were grouped as most similar among isolates in the cluster dendrogram (Fig. 3).

269   With respect to biodiesel quality, twenty-eight isolates had a CN greater than 47, and

270   thirty isolates did not exceed an IV of 120 (Table 2). In combination, twenty-eight isolates had

271   acceptable CN and IV values according to the ASTM standard. The degree of unsaturation

272   among isolates was quite varied, ranging from very low (10.6) for *Chlorella sp*. Sp23.13 to very

273   high (120) for *Ankistrodesmus sp*. Sp1.50. Long-chain saturation factor also varied among

274   isolates, where isolate *Scenedesmus* sp. Sp16.34 had the lowest value (0.55) by an order of

275   magnitude, and *Chlorella* sp. Sp23.13 had the highest value (8.94). The Saponification Value

276   was less varied among strains, where most had values varying from 200-210. Strain

277   *Chlamydomonas sp*. SpU9 had a notably high SV of 241. The majority of isolates had negative-

278   integer values for Cold Filter Plugging Point. *Scenedesmus sp*. Sp16.34 in particular, had a CFPP

279   as low as -15 °C. In contrast, Sp23.13 had a relatively high CFPP at 12 °C.

280   To assess the inherent tolerance of algal isolates to the common wastewater contaminant

281   copper, five representative-strains from a variety of taxonomic groups were subjected to static

282   growth-response bioassays. The cyanobacterial strain *Microcystis* sp. Sp21.01 was the least

283   tolerant to copper, having complete growth inhibition at 0.32 mg·L^{-1} or higher. The two

284   stormwater pond isolates *Monoraphidium* sp. Sp17.38 and *Selenastrum* sp. Sp14.35 had

285   significantly higher (Student's t-test $p<0.05$) tolerance to 0.32 mg·L^{-1} copper than the reference

286   strain *Chlorella kesslerii* CPCC26. The most tolerant strain was *Selenastrum sp*. Sp14.35, which

287   had the highest growth rate at 1 mg·L^{-1} copper. No strains could grow at the highest test

288   concentration 3.2 mg·L^{-1}. At municipal-wastewater relevant concentrations of copper, all test

289   strains, with the exception of *Microcystis* sp. Sp21.01, had minimal to no growth inhibition at the

290   highest copper concentration 0.1 mg·L^{-1} (Table 3).

291

292   **Discussion**

293   *Diversity of algal isolates*

294   All isolated algal strains (with the exception of one cyanobacterial isolate) belong to the

295   Chlorophyta, a class of algae that includes taxa commonly used in algal biofuel research and

296   application (Mata et al. 2010). In particular, *Chlorella sp*. and *Scenedesmus sp*. are the most

297   commonly used for biofuel feedstock, and our study isolated several strains from each of these

298   genera. Chlorophyte taxa such as the strains from our study are easy to culture, which in part, is

299   likely why they are common in biofuel studies. Yet, these taxa have also been shown to be

300   relatively good lipid producers (Mata et al. 2010), which increases their utility as feedstock in

301   biodiesel production. As such, all source locations in this study, and in particular stormwater

302   ponds and the municipal wastewater treatment plant, were fruitful habitats for isolation of lipid-

303   rich strains suitable for biodiesel production.

304   Several discrepancies between taxonomic assignment and BLAST match (Table 1) was

305   not entirely unexpected as this can be a common scenario. Though many chlorophyte species

306   exhibit type-features, such as spine and coenobium formation, culture condition will often affect

307   these characteristics used in identification. Morphological heterogeneity also makes algal

308   identification challenging, so it is possible that some strains were misidentified. In contrast, 18S

309   rRNA sequencing can be useful in distinguishing phylotypes of morphologically similar strains

310   (Friedl, 1995, Lewis and McCourt, 2004). This was evident in the phylogenetic tree

311   reconstruction, which provided a clear resolution to generic assignment for isolates in the tree. In

312   most instances, morphological similarities of clade members were supported by genetic

313   homology presented in the tree organization. BLAST sequence searches for some of the more

314   closely related *Scenedesmus, Desmodesmus* and *Coleastrum* taxa often returned similar local

315   alignment matches for query cover and percent identity, making them difficult to confirm solely

316   based on closest-match results. Again, the phylogenetic tree topology provided useful

317   clarification of misidentifications found in the BLAST database. Sequence databases are known

318   to have a small percentage (~20%) of their sequence collection to be mislabelled or misidentified

319   (Bridge et al, 2003, Vilgalys, 2003), and algal systematics is currently in flux. As such, definitive

320   taxonomic and phylogenetic assignment for strains in this study will likely require further

321   classification in the future.

Algal growth and fatty acid production

323   Rapid growth rates are an important characteristic of biofuel feedstock, since fast-

324   growing strains would have increased yields in a shorter time-frame. According to Griffiths and

325   Harrison (2009), the average doubling time for green microalgae is 24 h, which corresponds to a

326   growth-rate (μ) = 0.69 d^{-1}. Of the forty-three isolates evaluated, the majority of strains were able

327   to double their biomass in 24-hours or less (Table 1). Twelve isolates from our study could grow

328   ≥ 1.0 d^{-1} (Table 1), which is considered to be a relatively fast growth-rate for microalgae in

329   general, and thus a desirable trait for biofuel-feedstock. Many of the fastest growing taxa were

330   from stormwater ponds and included closely related genera such as *Scenedesmus*, *Desmodesmus*,

331   and *Ankistrodesmus* (Fig. 1). If these phylogenetically related taxa were to be targeted for

332   isolation from other systems, our results from a subset of strains would suggest that they may

333   have similar fatty acid profiles (Fig. 2), even for those of the same phylotype (Fig. 3). However,

334   calculations presented in Table 2 show phylogenetically similar strains (e.g., Sp12.07 and

335   Sp12.21) have differing biodiesel qualities. This finding concurs with the Culture Collection of

336   Algae at Goettingen University (SAG) study that found similarities among fatty acid distribution

337   patterns were only found at phyla and class levels (Lang et al. 2011). When accounting for all

338   strains that were assessed for their fatty acid profiles (Fig. 2, Table 2), it is apparent that the

339   diverse array of taxa, even from the same class, exhibited a broad range of variation in fatty acid

340   composition. The observed variation in growth rate and fatty acid profile among strains in our

341   collection supports the continued need to characterize microalgae at the strain-level, rather than

342   targeting a certain family or genera, when bioprospecting for biofuel candidates.

343   Common fatty-acid esters found in manufactured biodiesel include: palmitic C16:0

344   (hexadecanoic) acid, stearic C18:0 (octadecanoic) acid, oleic C18:1 (9(Z)-octadecenoic) acid,

345   linoleic C18:2 (9(Z),12(Z)-octadecadienoic) acid, and linolenic C18:3 (9(Z),12(Z),15(Z)-

346   octadecatrienoic) acid (Knothe 2008). The dominant saturated fatty-acid in most strains from this

347   study was C16:0 palmitic acid, and in many cases, represented approximately 50% of the total

348   fatty-acid profile. The dominant unsaturated fatty acid in most strains was C18:1 oleic acid, and

349   it too represented about 50% of the total fatty acid profile among several strains. Biofuels with

350   high oleic acid content have been reported to have reasonable ignition quality, combustion heat,

351   cold filter plugging point (CFPP), oxidative stability, viscosity, and lubricity (Chen 2012). Hu et

352   al. (2008) confirm that fatty acids with carbon chain lengths from 16 to 18 units are ideal

353   precursors for biodiesel production. Not only does carbon chain length provide a basis for

354   deriving biodiesel, but specifically, the saturation versus unsaturation garners characteristics that

355   make the fuel more versatile.

356   *Potential for biodiesel production*

357   Biodiesel derived from microalgae with more saturation provide a higher cetane number,

358   would have lower NOx emissions, and have shorter ignition delay time (Cherisilp and Torpee

359   2012). Nevertheless, this can come at a cost since lower temperatures would cause saturated

360   fatty- acids to solidify due to their high melting point (Doğan and Temur 2013). Unsaturated

361   fatty-acids require less heating and are often liquids at room temperature, however, the higher the

362   number of double-bonds, the more prone the fuel is to producing NOx emissions (Gopinath et al.

363   2010). Gopinath et al. (2010) claim that having a 50/50 blend of saturated and unsaturated fatty

364   acids produces better thermal efficiency and reduces NOx emissions. Based on this biodiesel

365   characteristic, many of the strains isolated in this study have desirable fatty-acid profiles

366   reflecting a ~50/50 saturated/unsaturated blend.

367   TAG commonly accumulate in many algal species as a storage product. As culture

368   resources are depleted and algal growth slows, so does the production of new membrane

369   compounds such as phosphoglycerides, glycosylglycerides and sterols. Under these conditions,

370   fatty-acid production is diverted to TAG synthesis (Guschina and Harwood 2006). This

371   metabolic shift results in a trade-off impacting biomass production. Griffiths and Harrison (2009)

372   reported that cultivation conditions focusing on biomass productivity instead of lipid production

373   per cell may ultimately be more beneficial and more efficient in increasing total lipid

374   productivity. Several fast growing isolates from this study (including *Scenedesmus* sp. Sp1.41,

375   *Scenedesmus* sp. Sp19.011, and *Desmodesmus sp*. Sp19.15) have ideal biodiesel properties based

376   on their Cetane Number, Iodine Values and Degree of Unsaturation (Table 2). Hence, these

377   strains may represent the best candidates for optimal lipid yields based on growth-rate alone.

378   *Algal copper tolerance*

379   Although a select, but diverse group, of isolates were tested for copper tolerance, all

380   chlorophyte strains exhibited high tolerance at wastewater-relevant concentrations (Table 3).

381   Thus it is plausible that many chlorophyte isolates in our collection would likely have some

382   inherent tolerance to copper if one extrapolates from the copper bioassay results. Others have

383   also recognized the higher tolerance thresholds of chlorophyte microalgae to wastewater

384   conditions, focusing primarily on *Chlorella* and *Scenedesmus* strains (Lau et al. 1995; Bhatnagar

385   et al. 2010; Ruiz-Marin et al. 2010). Interestingly, the only non-chlorophyte strain in our study

386   (*Microcystis*) was uniquely less tolerant to copper than the chlorophyte strains, even though it

387   was also isolated from a stormwater pond. It is also interesting that two of the stormwater pond

388   isolates *Monoraphidium* sp. Sp17.38 and *Selenastrum* sp. Sp14.35 were notably tolerant to

389   copper at concentrations orders of magnitude higher than their source stormwater ponds (Table

390   3). Therefore, these strains in particular may be ideal candidates for industrial-wastewater

391   feedstock since they are relatively fast growers (Table 1), have ideal fatty-acid profiles (Fig. 2

392   and Table 2), and have inherent tolerance to the algicidal-metal copper (Table 3).

393   *Conclusions*

394   Bioprospecting of algal strains for use in biofuel production is a relatively new trend.

395   Though our study is the first to target biofuel bioprospecting efforts in stormwater ponds and a

396   municipal wastewater system, the dominant taxa isolated, including *Chlorella, Scenedesmus, and*

397   *Desmodesmus,* are cosmopolitan in freshwater environments. Strains identified as the species

398   *Scenedesmus obliquuss* and *Chlorella leuteoiviridis* in blast matches were prevalent in both

399   stormwater ponds and the wastewater treatment facility, and they typically out-competed other

400   species during cultivation. Zhou et al. (2011) found similar results in isolations of microalgae

401   from wastewater sites in the United States, isolating several species of *Chlorella*. Past efforts to

402   isolate microalgae from various habitats including wastewater systems was mainly for

403   wastewater remediation. *Chlorella* and *Scenedesmus* are common taxa isolated for this purpose,

404   especially for nutrient removal (Tam and Wong 1989; Tam and Wong; 1990, Gonzalez et al.

405   1997; Woertz et al. 2009; Chinnasamy et al. 2010). Nutrient removal by microalgae cultivated in

406   wastewater would provide a value-added benefit during biofuel-feedstock production.

407   While the results presented here are only a first step in assessing algal strains from

408   wastewater habitats as biofuel-feedstock candidates, the ultimate goal is to establish and select

409   strains most tolerant to municipal and/or industrial wastewater conditions. The use of wastewater

410   to support algal biomass production is not a new approach, but it is for biofuel feedstock

411   production. Several studies have all concluded that there is great potential for algal biofuel

412   production using wastewater (Pittman et al. 2011; Bhatnagar et al. 2011; Christenson and Sims

413   2011). Yang et al. (2011) looked at the total water and nutrient requirements of microalgae-based

414   biofuels and found that biofuels sourced from wastewater decreased total water requirements by

415   90% in comparison to freshwater sourcing without recycling. What has not been investigated

416   explicitly is the viability of using wastewater on a continuous basis in a pond or photobioreactor

417   system growing single or mixed strains of microalgae. Broad variations can occur in wastewater

418   quality, in addition to fluctuations in toxic-metal constituents (Cole et al. 1989; Ahuwalia et al.

419   2007). In the case of municipal wastewater, the nutrient and contaminant content can vary daily

420   depending on the source-population. As such, future studies of biofuel microalgae, including

421   promising isolates from this study, would need to be assessed for their tolerance and resilience to

422   fluctuating wastewater conditions while maintaining an acceptable growth rate and lipid yield.

Table 1(on next page)

Summary list of isolated strains.

Summary list of isolated strains and their associated isolation medium, source location, tentative taxonomic assignment and 18S rRNA sequence similarity with BLAST taxa. Growth rate and generation time under standardized growth conditions over 7-days are also included. With the exception of one cyanobacterial strain (*Microcystis* sp.) which has been listed because of its inclusion in the bioassay results, all eukaryotic strains were subjected to 18S rRNA sequencing using NS1 and ITS2/18L primers. NS = Strain not successfully sequenced, WWTP = Wastewater Treatment Plant, SWP = Stormwater Pond, RP = Reference Pond, Lake ON = Lake Ontario. See Vincent and Kirkwood (2014) for more information on stormwater and reference pond characteristics.

Table 2(on next page)

Biodiesel properties of algal isolates.

Biodiesel properties of algal isolates based on their fatty acid profiles. The ASTM Biodiesel Standard D675 requirement for Cetane Number is a minimum value = 47 and Iodine Value maximum = 120. Degree of Unsaturation is a weighted sum of the masses of monounsaturated and polyunsaturated fatty acids, and Long-Chain Saturation Factor is a weighted sum of long-chain fatty acids (C16, C18, C20, C22 and C24). Saponification value is equivalent to milligrams of potassium hydroxide required to saponify 1 g of oil.

1 Table 2. Biodiesel properties of algal isolates based on their fatty acid profiles. The ASTM Biodiesel Standard D675 requirement

2 for Cetane Number is a minimum value = 47 and Iodine Value maximum = 120. Degree of Unsaturation is a weighted sum

3 of the masses of monounsaturated and polyunsaturated fatty acids, and Long-Chain Saturation Factor is a weighted sum of

4 long-chain fatty acids (C16, C18, C20, C22 and C24). Saponification value is equivalent to milligrams of potassium

5 hydroxide required to saponify 1 g of oil.

Table 3(on next page)

Comparison of algal tolerance to copper.

Comparison of algal tolerance to the range of copper concentrations typically found in municipal-wastewater systems (Environment Canada 2001). Copper concentrations previously measured for source stormwater-ponds are also included (Vincent and Kirkwood 2014). Average percent-inhibition is reported for each test concentration: N/A = information not available.
