

Evolutionary patterns of range size, abundance and species richness in Amazonian trees

Kyle Dexter, Jérôme Chave

Amazonian tree species vary enormously in their total abundance and range size, while Amazonian tree genera vary greatly in species richness. Here, we construct a phylogenetic hypothesis that represents half of Amazonian tree genera in order to analyse evolutionary patterns of range size, abundance, and species richness. We find several clear, broad-scale patterns. Firstly, there is significant phylogenetic signal for all three characteristics, i.e. closely related genera tend to have similar numbers of species and similar mean range size and abundance. Additionally, the species richness of genera shows a significant, negative relationship with the mean range size and abundance of their constituent species, while mean range size and abundance are significantly, positively correlated. These correlations are stronger in the raw data, but still significant when using phylogenetically independent contrasts. We suggest that tree stature and/or other phylogenetically related biological traits underlie these results. Lineages comprised of small-statured trees show greater species richness and smaller range sizes and abundances. Lastly, the phylogenetic signal that we evidence for range size suggests that should many small ranged species go extinct, greater phylogenetic diversity may be lost than expected if range size were distributed randomly across the phylogeny.

23 **Running Header:** Evolutionary Patterns of Amazonian Trees

24 **ABSTRACT**

25 Amazonian tree species vary enormously in their total abundance and range size, while
26 Amazonian tree genera vary greatly in species richness. Here, we construct a phylogenetic
27 hypothesis that represents half of Amazonian tree genera in order to analyse evolutionary
28 patterns of range size, abundance, and species richness. We find several clear, broad-scale
29 patterns. Firstly, there is significant phylogenetic signal for all three characteristics, i.e. closely
30 related genera tend to have similar numbers of species and similar mean range size and
31 abundance. Additionally, the species richness of genera shows a significant, negative relationship
32 with the mean range size and abundance of their constituent species, while mean range size and
33 abundance are significantly, positively correlated. These correlations are stronger in the raw data,
34 but still significant when using phylogenetically independent contrasts. We suggest that tree
35 stature and/or other phylogenetically related biological traits underlie these results. Lineages
36 comprised of small-statured trees show greater species richness and smaller range sizes and
37 abundances. Lastly, the phylogenetic signal that we evidence for range size suggests that should
38 many small ranged species go extinct, greater phylogenetic diversity may be lost than expected if
39 range size were distributed randomly across the phylogeny.

46

47 **Introduction**

48 Some Amazonian tree species attain incredibly high abundance (tens to hundreds of millions of
49 mature individuals), while most have small populations sizes, numbering in the thousands to tens
50 of thousands (ter Steege *et al.* 2013). Similarly, the range of some Amazonian tree species
51 extends across the entire Amazon basin, while most are restricted to much smaller areas
52 (Kristiansen *et al.* 2009). A similar imbalance is observed in species to genus ratios. Over half of
53 all Amazonian tree species belong to genera with 100 or more species, while the majority of
54 genera (52%) have ten or fewer species (Gentry 1993). Recent studies have begun to document
55 variation in the range size (Feeley & Silman 2009) and abundance (ter Steege *et al.* 2013) of
56 Amazonian tree species and in the species richness of Amazonian tree genera (Baker *et al.*
57 2014), but these studies have largely failed to find causal factors to explain the variation
58 (although see Baker *et al.* 2014). Here, we explore broad-scale evolutionary patterns for these
59 characteristics for the first time using a newly derived, genus-level phylogeny that covers half of
60 all Amazonian tree genera.

61

62 **Methods**

63 We intersected a list of all Neotropical tree genera (from
64 ctfs.arnarb.harvard.edu/webatlas/neotropicaltree) with a list of Amazonian plant species (Feeley
65 & Silman 2009) in order to generate a list of Amazonian tree species. The Feeley and Silman
66 (2009) dataset additionally includes estimates of range size for all species. We obtained estimates
67 for the total abundance of Amazonian tree species from ter Steege *et al.* (2013).

68

69 We obtained sequences of the *rbcL* plastid gene for 631 Amazonian angiosperm tree genera
70 (Table S1), with 568 sequences coming from Genbank (www.ncbi.nlm.nih.gov/genbank/) and an
71 additional 64 genera being newly sequenced following protocols outlined in Baraloto *et al.*
72 (2012). We obtained sequences of the *matK* plastid gene from Genbank for 452 of the 631
73 genera with *rbcL* data (Table S1). Sequences were aligned using the MAFFT software (Katoh &
74 Standley 2013) and then manually checked and edited. Preliminary phylogenetic analyses
75 allowed us to exclude sequences from GenBank that likely represent taxonomic
76 misidentifications.

77

78 We estimated an initial phylogeny using maximum likelihood analysis in RAxML v8.0.0
79 (Stamatakis, Hoover & Rougemont 2008), on the CIPRES web server (www.phylo.org). We
80 included sequences of *Amborella trichopoda* (Amborellaceae) and *Nymphaea alba*
81 (Nymphaeaceae) as outgroups. This initial tree was used as a starting point for simultaneous
82 topology and divergence time estimation in the software BEAST v1.82 (Drummond & Rambaut
83 2007). We implemented fossil-based age constraints for 25 nodes distributed across the
84 phylogeny (see Table S2).

85

86 For each genus in the phylogeny, we calculated the mean range size and abundance for all
87 constituent species in the Feeley and Silman (2009) and ter Steege *et al.* (2013) datasets. Of the
88 631 genera in the phylogeny, 493 had an abundance estimate for at least one species in ter Steege
89 *et al.* (2013). We considered the number of species for each genus in the Feeley and Silman
90 (2009) dataset as an estimate of the species richness of that genus in the Amazon. As an
91 alternative estimate, we used the Neotropical species richness estimates for genera in Gentry

92 (1993). We assessed correlations amongst these genus-level characteristics, both in the raw data
93 and using phylogenetically independent contrasts.

94

95 We tested for phylogenetic signal for each of these genus-level characteristics using Pagel's λ
96 (Freckleton, Harvey & Pagel 2002). Under Brownian motion evolution, where trait values drift
97 randomly over evolutionary time and where the phylogenetic relationships of taxa perfectly
98 predict the covariance among taxa for trait values, the expected value of λ is one. When the
99 phylogenetic relationships of taxa do not predict the covariance at all, the expected value of λ is
100 zero. We compared the fit of different values for λ (one, zero and the maximum likelihood
101 estimate) using the Akaike information criterion (AIC).

102

103 In order to determine which lineages may be responsible for significant phylogenetic signal for a
104 given characteristic (e.g. mean range size of genera), we used the following approach. We first
105 estimated the ancestral value at each node in the phylogeny using maximum likelihood ancestral
106 state reconstruction (Schluter *et al.* 1997). We then randomised the tips of the phylogeny 1000
107 times, reconstructed ancestral values at nodes each time, and compared the observed
108 reconstructed value to that across the randomisations. If the observed value for a node was
109 greater than that in 97.5% of the randomisations, we considered the lineage descending from that
110 node to show significantly high values for the trait, while if the observed value was lower than
111 2.5% of the randomisations, we considered the lineage to show significantly low values.

112

113 **Results**

114 The phylogeny derived from these sequences spans from the Magnoliids to the Asterids, thus
115 encompassing all major lineages of angiosperms (Fig. 1). Most orders and families were
116 monophyletic in the phylogeny with the notable (previously known) exceptions of Olacaceae and
117 Icacinaceae, while the large-scale phylogenetic relationships are largely in agreement with those
118 from recent, angiosperm-wide phylogenetic analyses (*e.g.* Magallón *et al.* 2015).

119
120 The species richness of genera is negatively correlated with mean range size ($r = -0.40$, $p <$
121 0.001) and mean abundance ($r = -0.38$, $p < 0.001$). These relationships are weaker, but still
122 significant, when using phylogenetically independent contrasts (PICs), indicating that
123 phylogenetically related traits partially underlie the correlations (mean range size PICs: $r = -0.28$,
124 $p < 0.001$; mean abundance PICs: $r = -0.24$, $p < 0.001$; Fig. 2). Meanwhile, mean range size and
125 abundance of genera are strongly positively correlated, using both the raw data and PICs ($r =$
126 0.44 , $p < 0.001$; PICs: $r = 0.43$, $p < 0.001$). All of the genus-level characteristics show significant
127 phylogenetic signal, but less than what would be expected under a Brownian motion model of
128 evolution (Table 1).

129
130 Significant phylogenetic signal for these characteristics is driven by significantly high or low
131 values in many lineages (Fig. 1, Table S3). Diverse lineages in the Magnoliids and the Asterids
132 show high species richness and low mean range size and abundance, including the Lamiales and
133 multiple lineages in the Rubiaceae and Solanales. One marked exception to the general pattern in
134 the Asterids is Lecythidaceae, which shows low species richness and high abundance.
135 Meanwhile, diverse lineages in the Rosids show low species richness and high mean range size
136 and abundance, including Euphorbiaceae, Salicaceae and Moraceae. Within the Rosids, the

137 exception to this pattern is found in multiple lineages in the Myrtales, including the
138 Melastomataceae, which show a pattern similar to most lineages in the Asterids. The
139 Leguminosae (Fabaceae), the most genus-rich family in our dataset, does not show any
140 significant departures from null expectations, although individual lineages therein show low
141 species richness and high mean range size. Within the monocots, the Arecaceae show
142 significantly low mean range size, while one lineage (*Iriartea* with *Socratea*) shows significantly
143 high abundance.

144

145 All results concerning species richness were highly similar when analyses alternatively used
146 species richness estimates from Gentry (1993).

147

148 **Discussion**

149 Our analyses have revealed that fundamental characteristics of Amazonian tree genera, such as
150 their species richness and mean range size, show strong relationships with phylogeny (Fig. 1)
151 and with each other (Fig. 2). Closely related genera have similar numbers of species and are
152 comprised of species with similar range sizes and abundances, while the species richness of
153 genera shows a significant negative correlation with mean range size and abundance. This
154 negative relationship is pervasive across multiple phylogenetic scales. At a broad scale, we found
155 that various lineages in the Rosids are comprised of genera that show low species richness and
156 high mean range size and abundance, while lineages in the Magnoliids and Asterids show the
157 opposite pattern.

158

159 Many of the lineages in our study that show high species richness and small geographic ranges
160 (e.g. Myrtaceae, Melastomataceae, Rubiaceae, Asterales, Solanales, and Lamiales) tend to be
161 small in stature. Previous studies have shown a positive relationship between the height of
162 Amazonian trees and their range size (Kristiansen *et al.* 2009, Ruokolainen *et al.* 2002). Such a
163 relationship may be due to larger-statured trees being able to disperse their seeds greater
164 distances, likely through greater fecundity, which would increase the chances that at least some
165 seeds make it a long distance and would, for animal-dispersed species, potentially attract more
166 dispersers. Increased dispersal ability would also increase gene flow among distant populations,
167 which, in turn, could reduce opportunities for allopatric isolation and contribute to reduced
168 diversification. Smaller statured trees may also have shorter generation times, which could
169 contribute to increased diversification (Baker *et al.* 2014). Thus, small-stature may be a
170 biological trait that spurs diversification and may also underlie the negative correlation between
171 mean range size and species richness of genera.

172

173 Small-statured lineages also show lower abundances, although this is partly, if not entirely,
174 explained by the abundance estimates being derived from tree plots that survey individuals >10
175 cm diameter at breast height (ter Steege *et al.* 2013). In any case, we are keen to emphasise that
176 the genus-level characteristics that we studied here do not represent biological traits *per se*, but
177 rather reflect underlying biological traits that are driving the observed phylogenetic signal and
178 correlations. Traits other than tree stature (e.g. dispersal syndrome) may also show phylogenetic
179 signal and be responsible for the observed correlations; large-scale compilations of trait data for
180 Amazonian trees are clearly needed to advance our understanding of these patterns.

181

182 The mean range size of genera shows higher phylogenetic signal than mean abundance or species
183 richness, and it is the characteristic most relevant for conservation. Should many small-ranged
184 species go extinct, more phylogenetic diversity may be lost than if range size were distributed
185 randomly across the phylogeny as deeper phylogenetic branches would be more likely to be lost
186 (Purvis *et al.* 2000).
