The greater horseshoe bat, *Rhinolophus ferrumequinum*, is an important model organism for studies on chiropteran phylogeographic patterns. Previous studies revealed the population history of *R. ferrumequinum* from Europe and most Asian regions, but there have still been arguments about their evolutionary process in Northeast Asia. In this study, we obtained mitochondrial DNA *cyt b* and D-loop data of *R. ferrumequinum* from Northeast China, South Korea and Japan, to clarify their phylogenetic relationships and evolutionary process. Our results indicated a highly supported monophyletic group of Northeast Asian greater horseshoe bats, in which Japanese populations formed a single clade, and clustered into the mixed branches of South Korean and Northeast Chinese populations. We inferred that *R. ferrumequinum* in Northeast Asia could be originated in Northeast China and South Korea during a cold glacial period, then some ancestors might arrive in Japan by flying or land bridge and subsequently adapt to local environment. During the warm Eemian interglaciation, the Korea Strait became a barrier to Japanese populations and inland populations, while Changbai Mountains didn't play the role as geographical barriers between populations from South Korea and Northeast China.

9 **Abstract** The greater horseshoe bat, *Rhinolophus ferrumequinum*, is an important  
10 model organism for studies on chiropteran phylogeographic patterns. Previous  
11 studies revealed the population history of *R. ferrumequinum* from Europe and most  
12 Asian regions, but there have still been arguments about their evolutionary process  
13 in Northeast Asia. In this study, we obtained mitochondrial DNA *cyt b* and D-loop  
14 data of *R. ferrumequinum* from Northeast China, South Korea and Japan, to clarify  
15 their phylogenetic relationships and evolutionary process. Our results indicated a  
16 highly supported monophyletic group of Northeast Asian greater horseshoe bats, in  
17 which Japanese populations formed a single clade, and clustered into the mixed  
18 branches of South Korean and Northeast Chinese populations. We inferred that *R.*  
19 *ferrumequinum* in Northeast Asia could be originated in Northeast China and South  
20 Korea during a cold glacial period, then some ancestors might arrive in Japan by  
21 flying or land bridge and subsequently adapt to local environment. During the  
22 warm Eemian interglaciation, the Korea Strait became a barrier to Japanese

23 populations and inland populations, while Changbai Mountains didn't play the role  
24 as geographical barriers between populations from South Korea and Northeast  
25 China.

## 26 **Introduction**

27 During the past 2.5 million years, earth has been in Quaternary glacial and  
28 interglacial periods (Capinera, 2011). Climatic change and the existence of refugia  
29 have influenced effective population size and demographic history of organisms,  
30 and left genetic signatures in current populations (Awise, 2000; Hewitt, 2000; Qu et  
31 al., 2014). The effective population size of organisms may decrease during the  
32 glacial period or remain stable or grow due to intermittent gene flow between  
33 refugia during warming periods (Li et al., 2009; Qu et al., 2014). The large volume  
34 of accumulated ice during Quaternary glaciation period caused a worldwide sea  
35 level drop by 120-140 m below the present sea level (Lambeck et al., 2002). Land  
36 bridges appeared in several parts of the world, inevitably led to range changes for  
37 most living organisms (Hewitt, 2000). Then, organisms adapted to different  
38 environments and new neighbors, which would cause their genetic variation, both  
39 through selection and drift, and ultimately led to speciation (Harrison, 1993;  
40 Hewitt, 2000).

41 The greater horseshoe bat, *Rhinolophus ferrumequinum* (Rhinolophidae,  
42 *Rhinolophus*), is widely distributed in northern Africa, southern Europe, and Asia

43 (Csorba et al., 2003). In China, it ranges from northeastern to southwestern regions  
44 (Wang, 2003). Previous studies (Rossiter et al., 2000; Rossiter et al., 2007; Bilgin et  
45 al., 2009; Flanders et al., 2009; Flanders et al., 2011) have revealed the impact of  
46 glaciations on their geographic patterns in Europe and most Asian regions, but little  
47 is known about this species from Northeast Asia. Flanders et al. (2009, 2011)  
48 showed that *R. ferrumequinum* from Jilin Province was affiliated with those from  
49 Japan unexpectedly based on mtDNA *ND2* gene, which suggested the greater  
50 horseshoe bats might move between east China and Japan by using South Korea as  
51 a stepping-stone (Flanders et al., 2009), or by Korean Peninsula-Japanese land  
52 bridge during glacial period (Flanders et al., 2011). However, no Korean sample  
53 and only one sample from Jilin Province were analyzed in Flanders et al. (2009,  
54 2011). Their results indicated that Jilin's sample was located in East clade of China,  
55 whereas Sun et al. (2013) showed that all samples from Jilin Province were divided  
56 into another Northeast clade based on mtDNA D-loop region. Therefore, it's very  
57 necessary to combine more samples from Northeast China, South Korea and Japan,  
58 to investigate the population evolutionary process of *R. ferrumequinum* in  
59 Northeast Asia.

60 Natural landscape features, such as mountains and rivers, can function as genetic  
61 boundaries and shape the population structure of animals because they can hinder  
62 dispersal and gene flow (Funk et al., 2008; Bilgin et al., 2009; Fünfstück et al.,  
63 2014). For *R. ferrumequinum* in Northeast Asia, Yalu River and Changbai

64 Mountains separated the populations from Northeast China and Korean Peninsula.  
65 The Korea Strait separated the populations in Korea from those in Japan. Koh et al.  
66 (2014) considered that the Yalu River and Changbai Mountains did not play the  
67 role as physical barriers for Korean populations and adjacent Northeast Chinese  
68 populations in *R. ferrumequinum* based on mtDNA *cyt b* gene. However, only one  
69 sample from Northeast China was included in their analyses.  
70 In this study, we collected and sequenced mtDNA *cyt b* and D-loop sequences of  
71 more *R. ferrumequinum* samples from Northeast China and South Korea, and  
72 analyzed them with all of the previously published mtDNA sequences from China,  
73 Japan and South Korea. Our aims are (i) to clarify the phylogenetic relationships of  
74 *R. ferrumequinum* in Northeast Asia, (ii) to infer their evolutionary process in  
75 Northeast Asia, and (iii) to detect whether the Changbai Mountains and Korea  
76 Strait act as geographical barriers for *R. ferrumequinum*.

## 77 **Materials and methods**

78 Twenty-two and 49 individuals of *R. ferrumequinum* from Northeast China and  
79 South Korea were sampled and used to sequence mtDNA *cyt b* and D-loop region,  
80 respectively. Total 76 sequences (63 *cyt b* sequences and 13 D-loop sequences) of  
81 *R. ferrumequinum* were collected from Japan, South Korea and China (Fig.1; Table  
82 S1, supporting information). For the D-loop region, our study did not include the  
83 sequences from Japan because no D-loop sequence of Japanese *R. ferrumequinum*

84 was deposited in GenBank. All field studies were approved by National Animal  
85 Research Authority in Northeast Normal University, China (approval number:  
86 NENU-20080416).

87 Previous studies and this study both showed South Korean, Japanese and Northeast  
88 Chinese *R. ferrumequinum* have very low genetic divergence (Sakai et al., 2003;  
89 Koh et al., 2014). Therefore, we regarded the bats from South Korea, Japan or  
90 Northeast China as a single geographic population.

### 91 **DNA extraction and amplification**

92 Bats' wing membrane tissues were taken and stored at 95% ethanol solution until  
93 genome extraction by the UNIQ-10 Column Animal Genomic DNA Isolation Kit  
94 (SK1205) (Sangon, China). Mitochondrial DNA *cyt b* and D-loop region were  
95 amplified by polymerase chain reaction (PCR) using universal primers L14724 and  
96 H15915 (Irwin et al., 1991) and P and E (Wilkinson & Chapman, 1991),  
97 respectively. Amplified products were purified and sequenced by Shanghai Sangon  
98 Biotechnology Co., Ltd. Sequences were edited and aligned using Geneious v8.0.2  
99 (Kearse et al., 2012), and then were assembled by eye. Sequence data were  
100 deposited in GenBank (accession number: KX237527-KX237538 and KX237546).

### 101 **Genetic diversity**

102 Haplotype diversity, nucleotide diversity and polymorphic sites of each population  
103 were calculated based on *cyt b* and D-loop sequences, respectively. The gene flow  
104 was calculated using *cyt b* gene sequences based on an equation:  $F_{st} = 1 / (1 +$

105 4Nm). All calculations were carried out using DnaSP v4.0 (Rozas et al., 2003).  
106 Pairwise distances between populations were obtained using Kimura-2-Parameter  
107 (K2P) distance model (Kimura, 1980), with 1,000 bootstrap replications, using  
108 MEGA v5.0 (Tamura et al., 2013).

### 109 **Phylogenetic analysis**

110 Phylogenetic trees of *cyt b* and D-loop were reconstructed using maximum  
111 likelihood (ML) methods in PhyML v3.1 (Guindon et al., 2010) and Bayesian  
112 Inference (BI) in MrBayes v3.2.2 (Ronquist & Huelsenbeck, 2001; Ronquist &  
113 Huelsenbeck, 2003). PhyML starts with a BioNJ tree by default (Gascuel, 1997),  
114 and statistical support for branching patterns was estimated by bootstrap with 1,000  
115 replicates. BI was run with four Markov Chains Monte Carlo (MCMC), each of  
116  $1 \times 10^7$  generations, sampled every 100 generations. Two congeneric species from  
117 the Afro-Palaearctic clade, *Rhinolophus euryale* (GenBank nos. EU436671 and  
118 KF031268) and *R. fumigatus* (GenBank nos. EU436678 and KU531336) were used  
119 as outgroups.

120 ML and BI methods are sensitive to nucleotide substitution models, which can be  
121 estimated by jModelTest v0.1 (Posada, 2008). According to the Akaike information  
122 criterion (AIC) (Posada & Buckley, 2004), the HKY + G (transition/transversion =  
123 12.9820; gamma shape = 0.1510) and HKY + G (transition/transversion = 4.5832;  
124 gamma shape = 0.1840) were selected for *cyt b* and D-loop, respectively.

125 The program NETWORK v4.6 (Bandelt et al., 1999) was used to build a maximum

126 parsimony network using median-joining method which simplified same-possible  
127 trees and removed redundant nodes and connections (Puizina et al., 2013). This  
128 method has advantage in representing the intraspecific genetic variation (Posada &  
129 Crandall, 2001).

130 In order to estimate divergent time, the time to the most recent common ancestor  
131 (TMRCA) was estimated using BEAST v1.6 (Drummond & Rambaut, 2007) under  
132 a strict clock and a constant-size tree prior. The chain was run for  $1 \times 10^7$   
133 generations, with the ESS values  $>200$  taken as evidence for convergence. Cyt *b*  
134 gene was chosen to calculate TMRCA because of its moderate evolutionary rate. A  
135 mean substitution rate of 1.3% per million years (Nabholz et al., 2008) used in  
136 *Hipposideros turpis* complex (Thong et al., 2012), *Hipposideros commersoni*  
137 (Rakotoarivelo et al., 2015) and *Myotis nattereri* complex (Puechmaille et al.,  
138 2012) was used in this analysis.

### 139 **Demographic analysis**

140 The demographic expansion of Northeast Asian *R. ferrumequinum* was examined in  
141 Arlequin v3.1 (Schneider et al., 2000). Tajima's *D* test (Tajima, 1989) and Fu's *F<sub>s</sub>*  
142 test (Fu, 1997) were employed to confirm neutral expectation based on 1,000  
143 coalescent simulations. Significant negative Tajima's *D* and Fu's *F<sub>s</sub>* values indicate  
144 a sudden expansion, whereas significant positive values indicate processes such as  
145 population subdivision or recent bottlenecks. When the values nearly zero, they  
146 represent population of constant size (Liao et al., 2010). Then the raggedness index

147 (Hri; Harpending, 1994) and sum of squared deviations (SSD; Schneider &  
148 Excoffier, 1999) were generated with 10,000 replicates parametric bootstrapping.  
149 Hri was calculated to describe the smoothness of observed mismatch distribution.  
150 The small value means a population which has experienced sudden expansion  
151 event, and the higher value indicates a stationary or bottlenecked population  
152 (Harpending, 1994; Liao et al., 2010). SSD value was used to describe the  
153 goodness-of-fit of observed mismatch distribution to that expected under the spatial  
154 expansion model. A non-significant SSD value ( $P_{SSD} > 0.05$ ) suggests a good fitness  
155 (Excoffier et al., 2005). The mismatch distribution graphs were drawn in DnaSP  
156 v4.0. A smooth or unimodal mismatch distribution indicates an expanded  
157 population, while a ragged or multimodal distribution indicates a more stable  
158 population (Rogers & Harpending, 1992; Flanders et al., 2011).  
159 If the expansion was detected, the time of expansion in generations ( $t$ ) can be  
160 estimated by an equation,  $\tau = 2ut$ , where  $\tau$  (tau) means the time to expansion in  
161 mutational units and  $u$  is the mutation rate per generation for the DNA sequence  
162 being studied. Cyt  $b$  mutation rate is 1.3% per million years (Nabholz et al., 2008).  
163 The generation time is 2 years (Ransome, 1995).

## 164 **Results**

### 165 **Genetic diversity and divergence**

166 A total of 85 sequences based on cyt  $b$  gene (1140 bp) and 62 sequences based on

167 D-loop region (465 bp) were obtained and analyzed (Table S1, supporting  
168 information). For *cyt b* gene, 15 different haplotypes were identified from 79  
169 sequences of Northeast Asian *R. ferrumequinum*. Japanese population had 7 unique  
170 haplotypes, while Chinese and South Korean populations shared haplotype H15,  
171 which was the most shared haplotype. For D-loop region, 10 unique haplotypes  
172 were identified from 51 sequences of *R. ferrumequinum* in Northeast Asia. H9 was  
173 shared by individuals from Ji'an and Benxi in Northeast China; whereas H10 was  
174 shared by most individuals and populations (including individuals in all four  
175 localities of China and some individuals in South Korea) (Table S2, supporting  
176 information).

177 Within *cyt b* and D-loop haplotypes, there were 15 (1.3%) and 9 (2.0%)  
178 polymorphic sites and 10 (0.87%) and 5 (1.1%) parsimonious informative sites,  
179 respectively. Genetic diversity of South Korean population was highest, while that  
180 of the Northeast Chinese population was lowest (Table 1).

181 The *cyt b* divergence of Northeast Asian *R. ferrumequinum* was lower than 1%.  
182 The average K2P distances between populations from Northeast China and South  
183 Korea (0.07%) were lower than those between Japanese and other Northeast Asian  
184 populations (0.21%-0.26%). Furthermore, the gene flow between South Korea and  
185 Northeast China ( $N_m \geq 3$ ) were highest, which was enough to prevent genetic  
186 divergence caused by genetic drift (Slatkin, 1987; Yang et al., 2011). However, the  
187 gene flow levels between Japanese and the other Northeast Asian populations were

188 low (Table 2).

### 189 **Phylogenetic relationships and TMRCA**

190 The ML and BI tree topologies based on *cyt b* gene produced highly concordant  
191 phylogenetic relationships. All samples from Northeast Asia formed a highly  
192 supported monophyletic clade (Fig. 2). In the tree, the relationship between  
193 Northeast Chinese and South Korean haplotypes was much less resolved, probably  
194 because of only a few mutations. Japanese haplotypes formed their own clade, but  
195 with relatively low bootstrap values (62/79% in ML/BI, respectively) (Fig. 2A).  
196 The Japanese clade clustered into the mixed branches of South Korean and  
197 Northeast Chinese haplotypes. The haplotypes of Northeast Asia were sister to  
198 those of the Central-East China (Fig. 2A). The haplotype network showed similar  
199 relationships with the phylogenetic trees, but showing relationship between the  
200 haplotypes more clearly (Fig. 2B).

201 The noncoding D-loop region generally provides sufficient variation for studies at  
202 intraspecific level (Qu et al., 2009). However, in the phylogenetic tree and  
203 haplotype network based on D-loop region, the Northeast Chinese haplotypes were  
204 still hardly separated from South Korean haplotypes (Fig. 3).

205 The TMRCA of all examined *R. ferrumequinum* individuals could be dated to 1.87  
206 Ma (95% CI 1.39-2.35 Ma). The TMRCA estimates obtained for Clade CE  
207 China/Northeast Asia were 0.87 Ma (95% CI 0.60-1.16 Ma). For East Asian *R.*  
208 *ferrumequinum*, the TMRCA was 0.22 Ma (95% CI 0.12-0.34 Ma), which could be

209 traced back to late Pleistocene.

### 210 **Historical demography**

211 Mismatch distribution analysis based on *cyt b* revealed different historical  
212 demography. Japanese and South Korean populations failed to reject the model of  
213 population expansion based on Hri, SSD ( $P_{SSD} > 0.05$ ,  $P_{Hri} > 0.05$ ) (Table 3), and  
214 their smooth or unimodal mismatch distributions (Fig. S1, supporting information).  
215 The significant negative Fu's  $F_s$  value also indicated a sudden expansion. The most  
216 recent expansion times were estimated to be 0.15 Ma (95% CI 0.05-0.27 Ma) and  
217 0.12 Ma (95% CI 0.03-0.20 Ma) for Japanese and South Korean populations,  
218 respectively. However, the high Hri, non-significant positive Fu's  $F_s$  value and  
219 multiple mismatch distribution of Northeast Chinese population suggested a stable  
220 population history or population bottlenecks (Liao et al., 2010) (Table 3, Fig S1,  
221 supporting information).

### 222 **Discussion**

223 *Rhinolophus ferrumequinum* from Northeast Asia diverged from other populations  
224 during 0.87-0.22 Ma, corresponding to Quaternary Pleistocene (Ehlers et al., 2011).  
225 Climate fluctuations of this epoch are supposed to have played important roles in  
226 shaping the geographical distribution, historical demography and genetic  
227 diversification of many organisms in the Palaeartic region (Qu et al., 2009).  
228 In this study, the TMRCA of the greater horseshoe bats from Northeast Asia could

229 date back to 0.22 Ma (95% CI 0.12-0.34 Ma), a time at the Saale glaciation (0.13-  
230 0.30 Ma) (Lisiecki & Raymo, 2005). Accompanied with temperature dropping in  
231 this period, the sea level declined gradually, and reached the lowest (about 130 m  
232 lower than it is today) at 0.14 Ma (Rohling et al., 1998; Molodkov &  
233 Bolikhovskaya, 2002), which could be beneficial for bats to go through the sea.  
234 Flanders et al. (2011) supposed that the greater horseshoe bats are most likely to  
235 have originated in Shandong Province of China. Therefore, we inferred that *R.*  
236 *ferrumequinum* might disperse to Northeast China and South Korea from Shandong  
237 Province by the Bohai Sea, because this is the shortest way and the Bohai Sea  
238 would have disappeared if the sea level dropped 120 m (Ray & Adams, 2001).  
239 Furthermore, haplotype network seemed to support this scenario, where H15 is a  
240 most likely ancestor haplotype occupying the center of network with lots of  
241 connects (Fig. 2B).

242 In Northeast China, the population might have undergone a founder effect or a  
243 bottleneck event due to its low genetic diversity. However, a specific haplotype  
244 H14 was detected in Northeast China, which may be not congruent with founder  
245 effect. Combining the high  $H_{ri}$  and non-significant positive Fu's  $F_s$  value, we  
246 inferred a bottlenecked event may have occurred in Northeast China (Liao et al.,  
247 2010). However, compared with previous studies on *R. ferrumequinum* (Flanders et  
248 al., 2011; Sun et al., 2013), an expanding event was firstly detected at 0.12 Ma  
249 (95% CI 0.03-0.20 Ma) in the South Korean population, which corresponds to the

250 relatively warm Eemian interglaciation (0.12-0.13 Ma) in Pleistocene.

251 The Changbai Mountains are the boundary of Northeast China and Korean  
252 Peninsula. Extremely low genetic divergence and high gene flow level between  
253 populations from Northeast China and South Korea suggested that the Changbai  
254 Mountains haven't acted as geographic barriers. In previous studies, Sun et al.  
255 (2013) and Flanders et al. (2011) found the Qinling Mountains have played an  
256 important role in forming different lineages of *R. ferrumequinum* bats; however,  
257 Rossiter et al. (2007) considered the Pyrenees (above 2,000 meters) haven't  
258 hindered gene flow of *R. ferrumequinum* and Bilgin et al. (2009) showed the  
259 Taurus Mountains and eastern Anatolian Diagonal Mountain Chain haven't limited  
260 western clade of *R. ferrumequinum* bats' distribution. Therefore, the isolation effect  
261 of different mountains is variable. Moreover, we can't rule out other reasons, such  
262 as incomplete lineage sorting and ancestral polymorphism, which can also cause  
263 low divergence between populations from Northeast China and South Korea  
264 (Flanders et al., 2009).

265 In our study, Japanese population formed a single sub-clade and diverged more  
266 recently than the populations from Northeast China and South Korea (Fig. 2A),  
267 which is contrast with that inferred by Flanders et al. (2009, 2011). Flanders et al.  
268 (2009) considered that *R. ferrumequinum* might colonize from Japan to East China.  
269 However, our results showed that Japanese population colonized most recently  
270 from Eurasian continent. It was known that the Korea Strait is about 130 m deep, so

271 the land bridge can only be formed during main glacial period (McKay, 2012).  
272 Ohshima (1990) mentioned that the Korean Peninsula-Japanese land bridge was  
273 estimated to be remained in place until 0.15 Ma (also see Watanobe, Ishiguro &  
274 Nakano, 2003). Thus, we inferred that the emergence of land bridge favored some  
275 *R. ferrumequinum* bats colonize in Japan from northeast China and South Korea.  
276 Other mammals, such as Japanese wild boar (*Sus scrofa leucomystax*) (Watanobe et  
277 al., 2003), sika deer (*Cervus nippon*) (Nagata et al., 1999) and Asian black bear  
278 (*Ursus thibetanus*) (Ohnishi et al., 2009) were also found to colonize in Japan from  
279 Eurasian continent via Korean Peninsula-Japanese land bridge (Flanders et al.,  
280 2011).

281 However, some studies showed that Japan was not connected to Eurasian continent  
282 during this period. There was a narrow seaway (about 20 km wide) in Korea Strait  
283 connecting the East China Sea and the East Japan Sea (Park et al., 2000). Bats of *R.*  
284 *ferrumequinum* are able to fly, typically travelling up to 30 km between the winter  
285 and summer roosts, with the longest recorded movement being 180 km (Paz et al.,  
286 1986). And Bilgin et al. (2009) found the Marmara Sea (70 km) does not seem to  
287 limit the dispersal in *R. ferrumequinum*. Although narrow seaway would have been  
288 present, *R. ferrumequinum* from Eurasian continent could go through the Korea  
289 Strait and enter Japan during the glacial period. *Rhinolophus ferrumequinum* in  
290 Japan might have expanded at 0.15 Ma (95% CI 0.05-0.27 Ma), which is consistent  
291 with the expansion time (0.13-0.19 Ma) calculated by Flanders et al. (2011). This

292 expansion time is in the Saale glaciation, which suggested that Japan might act as a  
293 refuge for mammals in Northeast Asia during glacial periods.  
294 With the arrival of Eemian interglaciation (0.12-0.13 Ma), the temperature was  
295 higher gradually, resulting in rising of sea level. Korea Strait became a natural  
296 barrier which isolated Japanese *R. ferrumequinum* from other Eurasian continental  
297 populations. Some other studies on bats also showed that gene flow can be  
298 hindered by water bodies, such as the Taiwan Strait (131 km) and English Channel  
299 (100 km) (Chen et al., 2006; Rossiter et al., 2007). The wider Korea Strait (180 km)  
300 was inferred to play an important role in acting as a barrier to hinder the gene flow  
301 between Japanese and Eurasian continental populations.

### 302 **Acknowledgements**

303 We would like to thank Tinglei Jiang and Guanjun Lu who worked hard with us in  
304 the field to collect the samples used in this study. We also thank Ying Tang for the  
305 lab work.

**Figure 1**(on next page)

Sampling localities of *Rhinolophus ferrumequinum* in this study.

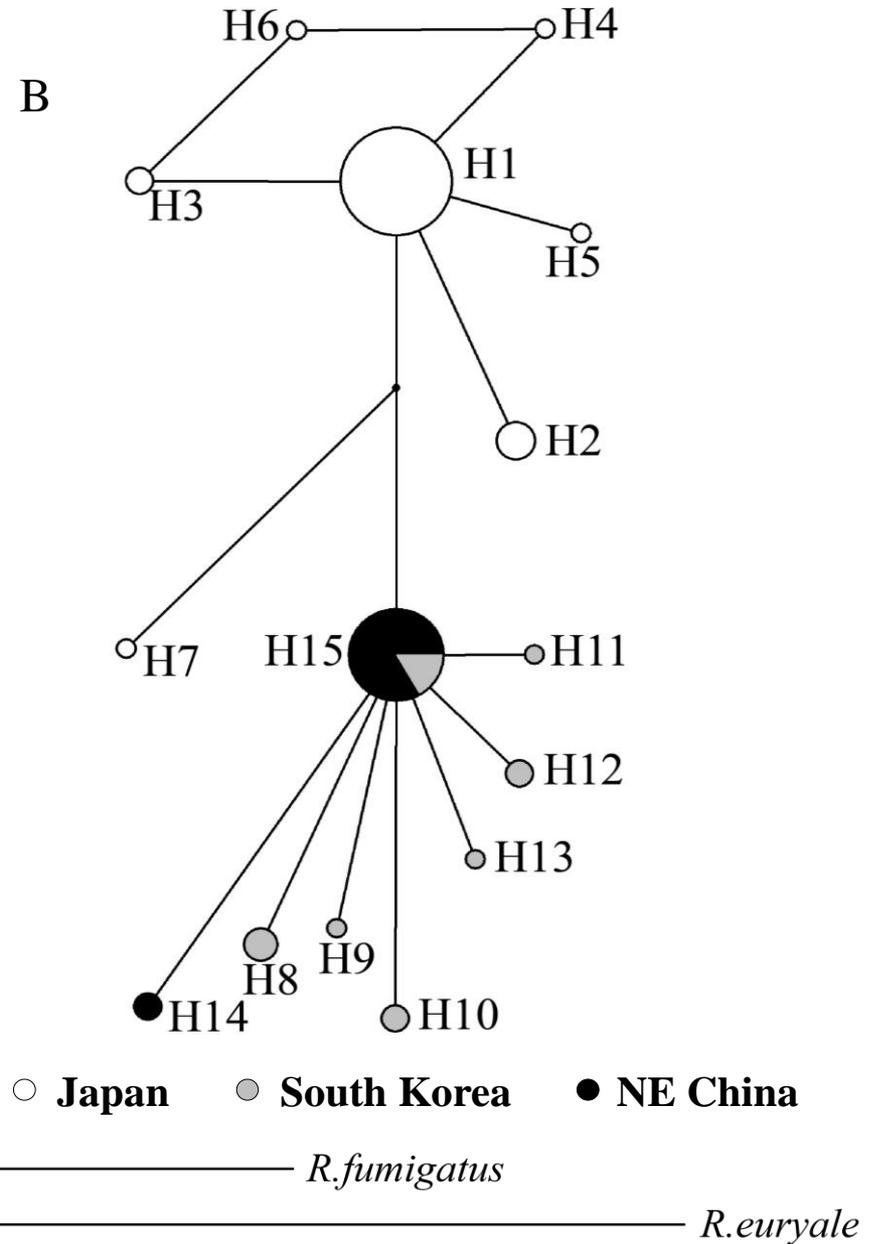

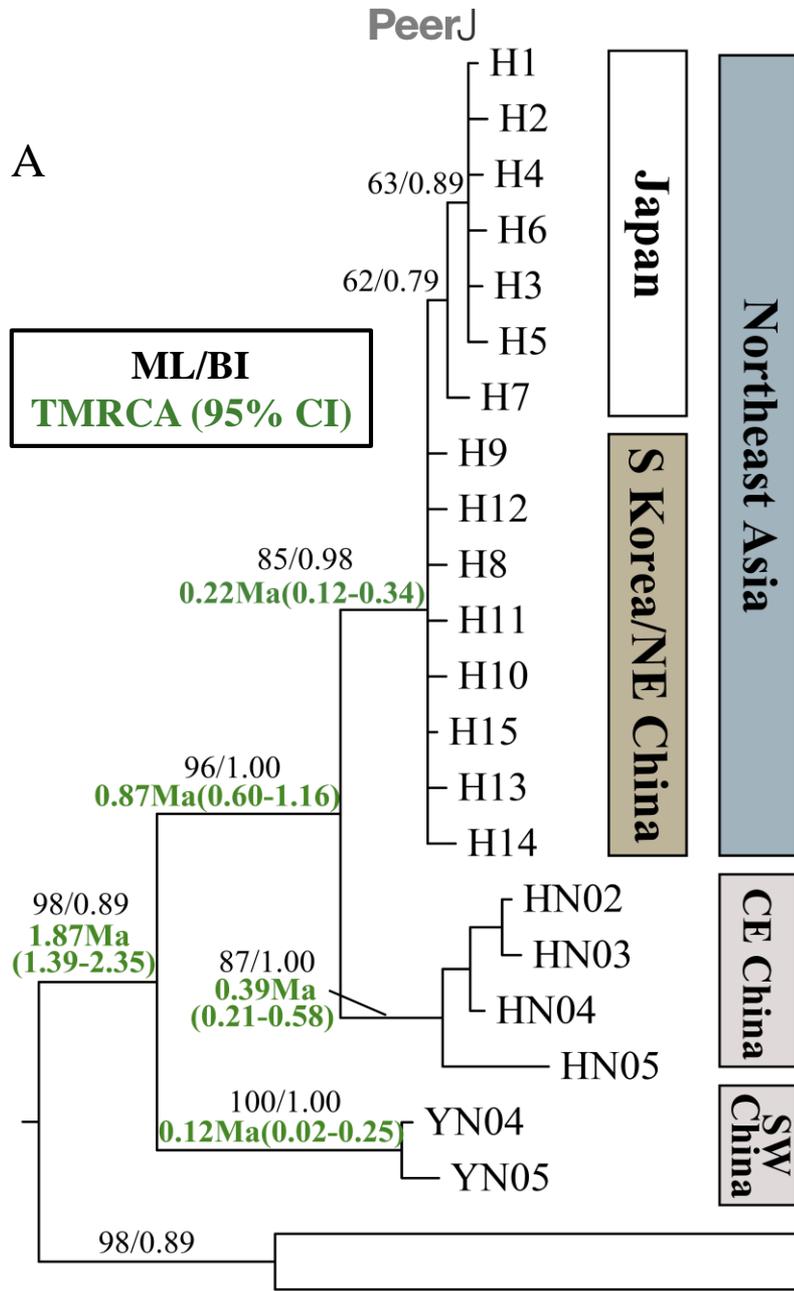

The colors of sampling points fit with clades identified in Fig. 2. Locality codes are identical to those in Table S1 (Supporting information). The map was freely reused and modified under the terms of the GNU Free Documentation License , Version 1.2.

**Figure 2**(on next page)

Phylogenetic trees and network for *Rhinolophus ferrumequinum* populations based on *cyt b* haplotypes.

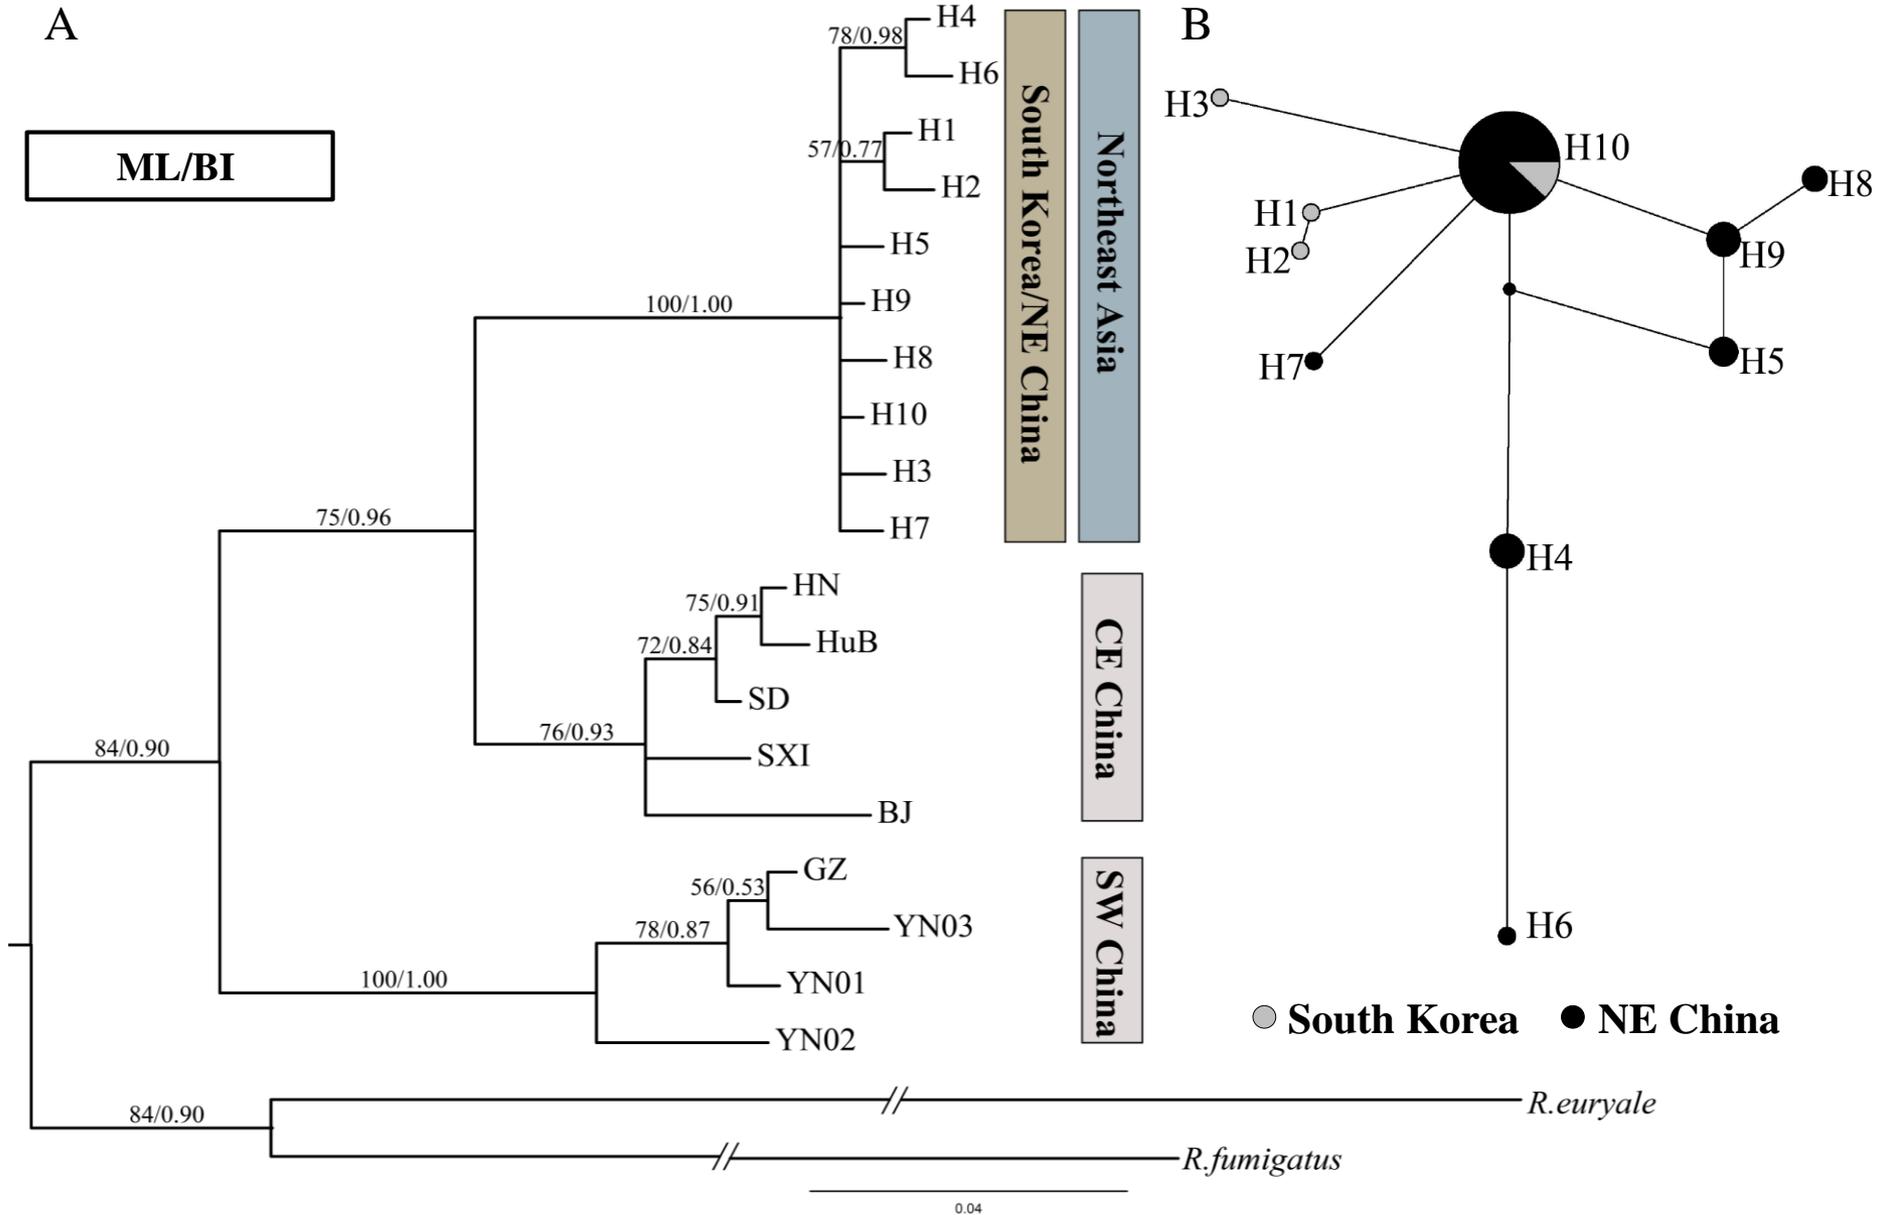

(A) Phylogenetic trees constructed by ML and BI methods. (B) Median-joining network for the East Asian *R. ferrumequinum* haplotypes. The circle size is proportional to the frequency of that haplotype. Small black dots represent missing haplotypes. Locality codes and haplotype are described in Table S1 and Table S2 (Supporting information), respectively.

**Figure 3**(on next page)

Phylogenetic trees and network for *Rhinolophus ferrumequinum* populations based on D-loop haplotypes.

(A) Phylogenetic trees constructed by ML and BI methods. The D-loop data of Japanese population was unavailable. (B) Median-joining network for the South Korean and Northeast Chinese *R. ferrumequinum* haplotypes. The circle size is proportional to the frequency of that haplotype. Small black dots represent missing haplotypes. Locality codes and haplotype are described in Table S1 and Table S2 (Supporting information), respectively.

**Table 1** (on next page)

Genetic diversity of *Rhinolophus ferrumequinum* in Northeast Asia.

1 **Table 1** Genetic diversity of *Rhinolophus ferrumequinum* in Northeast Asia.

	$N_s$	$N_h$	$N_{ss}$	$h$ (cyt <i>b/D</i> -loop)	$\pi$ (cyt <i>b/D</i> -loop)
