Background: Short stature in adult life, a possible consequence of poor perinatal conditions, is associated with higher risk of mortality and social disabilities. We aimed to determine whether low-income, overweight/obese, short-stature (SS) women show alterations in body composition, self-body-image perception, and biochemical profile compared to their non-short (NS) counterparts. **Methods**: A cross-sectional study was conducted with women living in shantytowns and mother or relatives to undernourished children treated in a center for recuperation and nutritional education. Inclusion criteria were: (1) age, 19–45 years; (2) stature < 152.3 cm or >158.7 cm; and (3) body mass index > 25 kg/m². Socioeconomic, anthropometric, biochemical, and body image data were collected. We analyzed 56 SS and 57 NS women. **Results**: The SS group showed a higher waist-to-height ratio (mean: 0.63; standard deviation: 0.06 for SS and mean: 0.60; standard deviation: 0.07 for the NS group; p = 0.02), and, in the adjusted analysis, showed lower fat-free mass (Estimated Marginal Mean for the SS group: 45.7 kg 95%CI [45.2 – 46.2] and for the NS group: 46.9 kg 95%CI [46.4 – 47.4]; p < 0.01) and higher fat mass (Estimated Marginal Mean for the SS group: 32.5 95%CI [31.9 – 33.0] and for the NS group: 31.4 kg 95%CI [30.9 – 31.9]; p < 0.01). Body mass index was a better predictor of current self-body-image perception for NS women. The SS coefficient values were β = 0.141, *SE* = 0.059, and R²-Nagelkerke = 0.107, and the NS coefficients values were β = 0.307, *SE* = 0.058, and R²-Nagelkerke = 0.491 (*Z* = 2.006; p < 0.05). Considering the obese subgroup, 6 out of 32 (18.8%) SS women and 14 out of 33 (42.4%) NS women perceived themselves as obese (χ² = 4.27; p = 0.03). This difference remained significant even after adjustment by age, schooling, and number of children (p = 0.04). Only the total thyroxin showed significant differences between groups, lower in SS women (p = 0.04). **Discussion**: Overweight/obese, low-income SS women have more central adiposity and impaired self-body image perception, and the body mass index is a weaker predictor of it, compared to

NS women. Misperception about body size may be linked with an overestimation of health and underestimation of risk, which may lead to a lower utilization of the health care system and inadequate physician counseling. These features may account, at least partially, for the higher mortality risk seen in SS adults.

17 **Abstract**

18 **Background**: Short stature in adult life, a possible consequence of poor perinatal conditions, is

19 associated with higher risk of mortality and social disabilities. We aimed to determine whether

20 low-income, overweight/obese, short-stature (SS) women show alterations in body composition,

21 self-body-image perception, and biochemical profile compared to their non-short (NS)

22 counterparts.

23 **Methods**: A cross-sectional study was conducted with women living in shantytowns and mother

24 or relatives to undernourished children treated in a center for recuperation and nutritional

25 education. Inclusion criteria were: (1) age, 19–45 years; (2) stature < 152.3 cm or >158.7 cm;

26 and (3) body mass index > 25 kg/m². Socioeconomic, anthropometric, biochemical, and body

27 image data were collected. We analyzed 56 SS and 57 NS women.

28 **Results**: The SS group showed a higher waist-to-height ratio (mean: 0.63; standard deviation:

29 0.06 for SS and mean: 0.60; standard deviation: 0.07 for the NS group; p = 0.02), and, in the

30 adjusted analysis, showed lower fat-free mass (Estimated Marginal Mean for the SS group: 45.7

31 kg 95%CI [45.2 – 46.2] and for the NS group: 46.9 kg 95%CI [46.4 – 47.4]; p < 0.01) and

32 higher fat mass (Estimated Marginal Mean for the SS group: 32.5 95%CI [31.9 – 33.0] and for

33 the NS group: 31.4 kg 95%CI [30.9 – 31.9]; p < 0.01). Body mass index was a better predictor of

34 current self-body-image perception for NS women. The SS coefficient values were $\beta = 0.141$, *SE*

35 $= 0.059$, and R²-Nagelkerke $= 0.107$, and the NS coefficients values were $\beta = 0.307$, *SE* $= 0.058$,

36 and R²-Nagelkerke $= 0.491$ ($Z = 2.006$; $p < 0.05$). Considering the obese subgroup, 6 out of 32

37 (18.8%) SS women and 14 out of 33 (42.4%) NS women perceived themselves as obese ($\chi^2 =$

38 4.27; $p = 0.03$). This difference remained significant even after adjustment by age, schooling,

39   and number of children (p = 0.04). Only the total thyroxin showed significant differences

40   between groups, lower in SS women (p = 0.04).

41   **Discussion**: Overweight/obese, low-income SS women have more central adiposity and impaired

42   self-body image perception, and the body mass index is a weaker predictor of it, compared to NS

43   women. Misperception about body size may be linked with an overestimation of health and

44   underestimation of risk, which may lead to a lower utilization of the health care system and

45   inadequate physician counseling. These features may account, at least partially, for the higher

46   mortality risk seen in SS adults.

47   **Introduction**

48   Studies on the developmental origins of health and disease aim to understand how events

49   in early life shape the morbidity risk later in life (Gluckman, Hansona & Buklijasa, 2010). As

50   non-communicable chronic diseases are currently one of the major causes of morbidity and

51   mortality worldwide and their prevalence is currently increasing, the number of studies being

52   conducted on this topic has also been increasing. Poor health in the early stages of life may be

53   responsible for long-term social and metabolic/morphologic consequences (Victora et al., 2008)

54   and is responsible for the intergenerational transmission of inequality, where disadvantaged

55   parents give birth to disadvantaged children who will probably be disadvantaged parents in the

56   future (Aizer & Currie, 2014).

57   Adult short stature is a direct consequence of impaired early growth caused by poor

58   health, particularly inadequate nutrition and recurrent infections (Shrimpton et al., 2001). It is

59   possible to attenuate adult short stature with compensatory growth during childhood. However,

60   in low- and middle-income countries, people tend to remain in the setting in which they

61   developed childhood undernutrition, leading to poor compensation of growth failure and,

62   ultimately, the children grow into short adults (Martorell, Khan & Schroeder 1994). An analysis

63   of a Brazilian birth cohort showed that women who had a height-for-age Z score at 2 years lower

64   than -3, presented an attained height of approximately 146 cm in adulthood, in contrast with 163

65   cm presented by those who had a height-for-age Z score greater than -1 (Victora et al., 2008).

66   .Additionally, in the analysis of five birth cohorts in developing countries, stunted children were

67   more likely to have a reduced lean body mass, attain a lower education level, and have reduced

68   earnings in adulthood (Victora et al., 2008).

69   Short stature in adult life is associated with a higher mortality risk. A recent individual-

70   patient meta-analysis of more than 16.1 million person/year showed that the risk of all-cause

71   mortality is 3% lower per 6.5 cm height in adult life, although disaggregation by cause-specific

72   mortality revealed stronger and directionally opposing relationships with the risk of death from

73   different major causes of chronic disease. The study concluded that taller people have a lower

74   risk of death from coronary disease, stroke subtypes, heart failure, oral and gastric cancers,

75   chronic obstructive pulmonary disease, mental disorders, liver diseases, and external causes

76   (Emerging Risk Factor Collaboration et al., 2012).

77   An overweight/obese short-statured adult will be at a great risk of chronic disease,

78   especially cardiovascular diseases. Women in a low-income region from a developing country

79   that is facing a nutrition transition are especially at risk owing to persistent weight gain due to

80   low energy expenditure, working at home, and hyperenergetic diets (Kanter & Caballero, 2012).

81   This is a common situation in Brazilian northeast.

82   Mechanisms that justify the greater risk experienced by short-statured (SS) adults are not

83   fully understood, especially in the context of a low-income setting. Hence, the present study

84   aimed to determine whether overweight/obese SS women from Maceió, capital city of the state

85   of Alagoas, and one of the poorest capital city of Brazil, show any alterations in their body

86   composition, self-body-image perception, and blood biochemical profile as compared to their

87   non-short (NS) counterparts.

88

89   **Methods**

90   **Ethical Aspects**

91   Data were collected from all participants after they provided written informed consent.

92   The study was approved by the Ethical Research Committee of the Federal University of São

93   Paulo, number 275184.

94

95   **Study design and subjects**

96   This was a cross-sectional study of women living in a shantytown in Maceió-AL, Brazil.

97   The subjects were mothers and/or female relatives of undernourished children who attended the

98   Centre for Recuperation and Nutritional Education (CREN/Maceió), an extension of the Federal

99   University of Alagoas that treats undernourished children with a goal of improving their

100   nutritional status.

101   We investigated two different groups: SS women and NS women. Inclusion criteria were

102   as follows: (i) age, 19–45 years; (ii) stature $\leq$ 152.3 cm (5th percentile of the World Health

103   Organization growth curves) (SS group) or >158.7 cm (25th percentile) (NS group) (World

104   Health Organization, 2007); and (iii) a body mass index (BMI) > 25 kg/m². Pregnant and

105   lactating women and those taking chronic medication, insulin, and antiretrovirals) were not

106   included.

107   We used a non-probability convenience sampling approach, inviting all mothers and

108   relatives of the undernourished children treated at CREN to a screening at the center. All

109   included women were then invited to join a behavioral weight-loss program.

110

111   **Data collection**

112   Data were collected at CREN with a previously tested and structured protocol regarding

113   personal, socioeconomic, and demographic information such as age, years of schooling,

114   occupation, household conditions, and number of family members, wage, government benefits,

115   precedence (city or rural).

116   Anthropometric measurements (body weight, stature, and waist and hip circumferences)

117   were obtained from all participants while they were wearing light clothing without shoes. Body

118   weight was determined using electrical bioimpedance with Tanita Body Fat analyzer (model

119   TBF-300; Tanita Corporation of America, Inc., Arlington Heights, IL), which also measured fat

120   mass, fat-free mass, and body fat percentage and calculated the basal metabolic rate (BMR). To

121   measure the stature, the women were asked to stand in the full upright position using a portable

122   stadiometer, which was equipped with an inextensible metric tape marked by 0.1-cm

123   graduations. Waist circumference (WC) was measured during a normal expiration, using an

124   inextensible flexible metric tape at the umbilical point. Hip circumference was measured at the

125   point yielding the maximum circumference over the buttocks. The waist-to-hip ratio (WHR) and

126   waist-to-height ratio (WHtR) were also calculated by dividing the WC by the hip circumference,

127   and the WC for the height in centimeters, respectively. Body surface area was calculated

128   according to method used by Mosteller (1987). Blood pressure was measured on three

129   consecutive occasions using calibrated monitors against mercury manometers (Model HEM-421-

130   CO, Amsterdam, Netherlands) by the standard technique, with individuals being seated and

131   relaxed.

132   To measure body image, a scale consisting of 9 female figures, ranging from very thin to

133   very obese (figures 1–9), was used (Stunkard, 2000). Participants were asked to choose one

134   figure that, in their opinion, currently represented their body and one that represented their ideal

135   body. The discrepancy score was calculated by subtracting the ideal self-body image number

136   from the current self-body image number. These figures were classified into underweight

137   (figures 1 and 2), normal weight (figures 3 and 4), overweight (figures 5 through 7), and obese

138   (figures 8 and 9), according to the method of Lynch et al. (2009). This scale has already been

139   translated into Portuguese and tested with Brazilian women (Scagliusi et al., 2006).

140   Blood samples were collected at CREN facilities for biochemical profile studies. Women

141   were instructed to fast overnight before undergoing venous puncture. Tests for the following

142   parameters were performed: blood glucose and insulin, Homeostasis Model Assessment for

143   insulin resistance (HOMA-IR), β-cell function (HOMA-β), total cholesterol, high-density

144   lipoprotein, low-density lipoprotein, triacylglycerols, aspartate amino-transferase, alanine amino-

145   transferase, gamma-glutamyl transpeptidase, thyroid-stimulating hormone, triiodothyronine,

146   thyroxin, albuminuria, and cystatin-C.

147

148   **Statistical analysis**

149   Continuous and discrete data are presented as mean and standard deviation and

150   categorical data, as absolute and relative frequency. For all continuous variables, the normality

151   and variance's homogeneity assumptions were tested by the Lilliefors' and Levene's tests. When

152   the assumptions were met, Student t-tests were conducted; otherwise, Welch's t-tests were

153   conducted. Discrete variables were subjected to Mann-Whitney tests. Categorical variables were

154   compared using the χ^2 test or Fisher Exact test, when appropriate. Multivariate analysis with

155   dichotomous outcomes were performed by means of logistic regression.

156   Variables that could be influenced by body size (such as fat mass and lean mass) were

157   subjected to an analysis of covariance (ANCOVA) using body weight and age as covariates, and

158   the estimated marginal means (EMM) and 95% confidence intervals (CI) were calculated. An

159   ordinal regression was performed using current self-body-image perception as the dependent

160   variable and BMI as the independent variable for each subgroup (NS and SS). Further, regression

161   coefficients were compared by Fisher's Z-test. In addition, a full ordinal regression model

162   including confounders and an interaction term between height and BMI was designed. For all

163   analyses, a two-tailed approach was adopted, and alpha was set at 5%. For the statistical

164   analyses, SPSS v20.0 (IBM statistics, Chicago, IL) was used.

165

166   **Results**

167   At total, 262 women were invited to the screening, comprising all mothers and relatives

168   of the undernourished children treated at CREN. From these, 149 were not included in our

169   analysis: 116 did not meet inclusion criteria for age, height and/or body mass index; 15 were

170   pregnant or lactating; 5 were taking insulin; and 13 refused to participate. A total of 113 women

171   were finally included in the analyses. Of these, 57 were NS and 56 were SS women. Socio-

172   economic characteristics of the population are shown in Table 1. In general, the SS group

173   received less schooling, had more children, and were more likely to arise from rural areas. The

174   others variables did not show any significant differences.

175   Table 2 presents the women's anthropometric and self-body image assessments. The NS

176   group had significant higher values for body size variables, except WC, which did not show any

177   significance, and WHtR, which was higher in the SS group, indicating a central-obesity profile.

178   Table 3 shows the adjusted analysis for the between-group comparison for fat mass, lean

179   mass, body fat percentage and basal metabolic rate, including body weight as a covariate in the

180   model. In this case, the variables for body composition showed opposite results as those of the

181   unadjusted analysis, shown in Table 2, that is, according to the EMM of the adjusted analysis, SS

182   women showed lower lean mass, and higher fat mass. These differences between groups were

183   significant (Table 3). Results of the biochemical and blood pressure analyses are presented in

184   Table 4. Only a small difference in the total thyroxin level was noted, and the SS group showed

185   lower values than the NS group.

186   Although the self-body-image assessment did not show any significant differences

187   between groups, ordinal regression analysis showed that BMI is a significant better predictor of

188   current self-body-image perception for NS women than for SS women (Figure 1). The SS

189   coefficient values were $\beta = 0.141$, $SE = 0.059$, and R^2-Nagelkerke = 0.107, and the NS

190   coefficients values were $\beta = 0.307$, $SE = 0.058$, and R^2-Nagelkerke = 0.491 ($Z = 2.006$; $p < 0.05$).

191   In the full model, including age, schooling, and number of children, the interaction between BMI

192   and height category was also significant ($p = 0.018$), showing that height category acts as an

193   effect moderator variable.

194   When considering only the obese subgroup, 6 out of 32 (18.8%) SS women and 14 out of

195   33 (42.4%) NS women perceived themselves as obese based on the categorized score of the scale

196   (($\chi^2 = 4.27$; $p = 0.03$). This difference remained significant even after adjustment by age,

197   schooling, and number of children ($p = 0.04$).

198   Using WHtR as main variable, with an alpha-value of 5%, a mean standard deviation of

199   0,065 and the sample size and means reported in the study, the *post-hoc* power for the

200   comparisons between groups was 68%.

201

202   **Discussion**

203   As previously outlined, the mechanisms that lead to increased cardiovascular risks in SS

204   adults are not fully understood. Height is a biomarker that congregates the genetic endowment

205   and early-life experiences of the individuals (NCD Risk Factor Collaboration, 2016). Therefore,

206   the increased risk presented by short adults could be due to morphologic aspects, such as smaller

207   coronary vessels diameter and/or faster heart rate (Smulyan et al., 1998). Nevertheless, as short-

208   stature in adult life is believed to reflect, at least in part, poor nutrition and socioeconomic

209   aspects in early-life, the possibility of a "metabolic programming" is plausible and accepted

210   nowadays as the theory of "developmental origins of health and disease" (Heindel et al., 2015).

211   This theory states that adverse events in early-life (that would impair growth and possibly lead to

212   short-stature in adult life) could contribute to increased risk of cardiovascular disease in

213   adulthood. In our cross-sectional study, we found that overweight/obese SS women had

214   relatively more fat mass and less lean mass than their non-short counterparts. In addition, the

215   BMI of short-statured women had significantly less power to predict their actual body image. We

216   believe that these features may account, at least partially, for the higher mortality risk seen in SS

217   adults.

218   Our two study groups were socially very similar to each other, except for their schooling,

219   number of children and precedence. In populations originating from rural areas, where the health

220   conditions are worse, delivery at home is usually expected, and it is likely that the mothers came

221   to the capital city looking for better life conditions, which is a common phenomenon in this

222   population. As a whole, Alagoas is a very poor Brazilian state. A probabilistic survey conducted

223   in 1992 showed that stunting levels among children were 22.1% (Ferreira et al., 2013). These

224   levels were even higher in a survey with the rural population in 1995, reaching 39,8% (Ferreira

225   et al., 1997). Hence, it is likely that our sample, specially the SS group, went through hazardous

226   conditions during early life.

227   Undernutrition early in life has been consistently linked with a lower educational level

228   (Gratham-McGregor et al., 2007). Lower education, in turn, is linked with household crowding

229   (Melki et al., 2004), which we indirectly measured by the number of children in the household;

230   this is a known form of chronic stress that is detrimental to the psychological well-being (Fuller

231   et al., 1996). The increased adiposity noted in our study confirmed the trend reported by Lopez-

232   Alvarenga et al. (2003), although they had analyzed both men and women, and not all were

233   overweight/obese. Our finding is also in accordance with that of Martins et al. (2004) who

234   reported that stunted girls gained less lean mass and had a significantly higher fat mass at follow-

235   up than their baseline values. We analyzed body composition data by using an ANCOVA to

236   consider the differences in body size between groups, since NS women are significantly bigger

237   than SS women. We chose to use body weight as a covariate in the model because stature was

238   already considered as a fixed factor in the analysis (the subjects were grouped based on stature),

239   hence, using body surface area would use stature twice in the model.

240   Increased adiposity, which is associated with central obesity (Zhang et al., 2007), is a

241   well-known mortality risk for women and is of a greater risk to young women (Hu et al., 2004;

242   Lahmman et al., 2002). In our sample, we did not find any differences in the WHR between the

243   NS and SS groups, as was also reported by Florêncio et al. (2007). Nevertheless, we did find

244   differences in the WHtR, which is known to be as good as the other markers of central adiposity

245   that predicted cardiovascular events in women (Page et al., 2009) and a better marker than WHR

246   that predicted albuminuria in diabetic Chinese women (Tseng, 2005). Indeed, the utility of

247   WHR, although used widely, is questionable because individually, waist and hip circumferences

248   are known to have contrasting associations with mortality (Bigaard et al., 2004). In our sample,

249   although NS women had a significantly greater WC than SS women, when the WC values were

250   divided by stature, the NS women had a greater anthropometric advantage. Still regarding the

251   WC, as we measured it at the umbilical point, and not in the midpoint between iliac crest and

252   lower rib, it is possible that the value of WC for some women, especially those with higher

253   adiposity were overestimated.

254   Florêncio et al. (2007) reported that overweight/obese SS women had a greater

255   prevalence of insulin resistance and altered lipid profile as compared to women with average

256   stature. However, we were unable to confirm these findings. Nevertheless, they assessed women

257   in a poorer socioeconomic status, older and with lower stature than ours. Interestingly, although

258   the level of thyroxin was lower in the SS group, no effects were seen in the levels of thyroid-

259   stimulating hormone even after log-transformation and removal of outliers. This lower thyroxin

260   level could explain the lower basal metabolic rate found in the adjusted analysis. However, when

261   considering the absence of differences in thyroid-stimulating hormone between groups, and the

262   fact that 18 metabolic markers were compared in our analysis, it is likely that the difference

263   found in thyroxin levels between groups is spurious.

264   Regarding self-body image, it is reasonable to state that the BMI is the best determinant

265   of the current self-body image perception (Kaufer-Horwitz et al., 2006). In our sample, BMI was

266   a significantly weaker predictor of current self-body image assessment in SS women as

267   compared to NS women, and this relationship remained significant even after correction for

268   possible confounding social variables. In addition, obese SS women were less likely to perceive

269   themselves as obese as compared to NS women.

270   Holdsworth et al. (2004) found that Senegalese women believed that being overweight

271   was socially preferred, but being obese was associated with a greater risk of disease. In a

272   longitudinal investigation, Lynch et al. (2009) found that obese women who did not perceive

273   themselves as obese gained more weight over a course of 13 years. Powell et al. (2010) showed

274   that misperception about body size is prevalent among obese adults, particularly among ethnic

275 minorities. They emphasized that this phenomenon may be linked with an overestimation of

276 health and underestimation of risk, which may lead to a lower utilization of the health care

277 system and inadequate physician counseling. Taken together, all these issues could enhance the

278 risk of mortality among those with impaired self-body image in the long-term. It is possible that

279 SS women perceive themselves as small as compared to NS women. Since body weight is

280 possibly their parameter of choice to assess their body size, owing to its simplicity, they may not

281 perceive themselves as have "excess weight" when they weigh approximately 56 kg, which is the

282 average weight for a 149-cm tall woman to be considered overweight.

283   This study has some limitations. First, we used a non-probabilistic convenience sample,

284 which decreases our ability to extrapolate our findings. Second, we used bioimpedance analysis

285 to assess body composition, which is not a gold standard method, such as deuterium. Third, we

286 used a single scale to assess body image, which may weaken our findings regarding this

287 characteristic.

288

289 **Conclusions**

290   In conclusion, the present study showed that overweight/obese, shantytown-dwelling SS

291 women present with more central adiposity and impaired self-body image perception than NS

292 women, and BMI is a weaker predictor of current self-body-image perception. These findings

293 could partially explain the higher mortality rates found in SS adults. Further longitudinal

294 investigations, assessing these characteristics in mortality or cardiovascular events are needed.
