Altruism toward strangers is considered a defining feature of humans. However, manifestation of this behaviour is contingent on the costliness of the selfless act. The extent of altruistic tendencies also varies cross-culturally, being more common in societies with higher levels of market integration. However, the existence of local variation in selfless behaviour within populations has received relatively little empirical attention. Using a 'lost letter' design, we dropped 300 letters (half of them stamped, half of them unstamped) in 15 residential suburbs of the greater Perth area that differ markedly in socioeconomic status. The number of returned letters was used as evidence of altruistic behaviour. Costliness was assessed by comparing return rates for stamped vs unstamped letters. We predicted that there is a positive association between suburb socioeconomic status and number of letters returned and that altruistic acts decrease in frequency when costs increase, even minimally. Both predictions were solidly supported and demonstrate that socioeconomic deprivation and elevated performance costs independently impinge on the universality of altruistic behaviour in humans.

20 **Abstract**

21 Altruism toward strangers is considered a defining feature of humans. However,
22 manifestation of this behaviour is contingent on the costliness of the selfless act. Evidence
23 shows that the extent of altruistic tendencies also varies cross-culturally, being more
24 common in societies with higher levels of market integration. However, the existence of
25 local variation in selfless behaviour *within* populations has received relatively little
26 empirical attention. Using a 'lost letter' design, we dropped 300 letters (half of them
27 stamped, half of them unstamped) in 15 residential suburbs of the greater Perth area that
28 differ markedly in socioeconomic status. The number of returned letters was used as
29 evidence of altruistic behaviour. Costliness was assessed by comparing return rates for
30 stamped vs unstamped letters. We predicted that there is a positive association between
31 suburb socioeconomic status and number of letters returned and that altruistic acts
32 decrease in frequency when costs increase, even minimally. Both predictions were solidly
33 supported and demonstrate that socioeconomic deprivation and elevated performance
34 costs independently impinge on the universality of altruistic behaviour in humans.

41 **1. Introduction**

42 Prosocial sentiments, i.e. caring about the welfare of others, have emerged as hallmarks of
43 humans (Gintis 2003; Henrich *et al.* 2004; Hill *et al.* 2009; Alvard 2012); but see (Burton-
44 Chellew & West 2013). Altruism represents a special case of prosociality in which an actor
45 helps others at a personal cost. Altruism can become fixed in stable groups of humans and
46 other animals through kin selection, a process whereby individuals accrue indirect benefits
47 through the successful reproduction of relatives (Hamilton 1964). Explaining altruism
48 directed at unrelated individuals requires the framework of direct reciprocity (Trivers
49 1971) or indirect reciprocity (Alexander 1987). In direct reciprocity, the temporary costs
50 individuals incur by performing an 'altruistic' act will be recouped by subsequent
51 generosity on the part of the recipient. In indirect reciprocity, lending a helping hand can
52 enhance the reputation of individuals and increase the likelihood of others cooperating
53 with them in the future.

54 However, when altruism surfaces in large anonymous groups of unrelated individuals
55 canonical evolutionary approaches based on nepotistic biases, direct reciprocity and
56 indirect reciprocity can largely be ruled out as explanations. It has been argued that large-
57 scale cooperation can be maintained when behaviourally rather homogenous groups of
58 prosocial individuals gain a competitive edge against groups of less prosocially cohesive
59 individuals (cultural groups selection) (Henrich 2004; Richerson *et al.* 2016; but see
60 Yamagishi and Mifune 2015).

61

62

63 Despite its ubiquity in human societies, the propensity for altruism varies and is expected
64 to be superseded by selfish motives when acts of altruism are more costly, that is when
65 they entail larger sacrifices to one's own payoff (Fehr & Fischbacher 2003). This argument
66 has been substantiated through economic games such as the dictator game, e.g. when the
67 cost of relinquishing one monetary unit to the recipient increases, the dictator donates less
68 (Andreoni & Miller 2002). In a study using children it was shown that in a costly sharing
69 game (when delivering rewards to a recipient required personal sacrifice) the likelihood of
70 prosocial behaviour was lower than in a prosocial game (in which offering a reward to a
71 recipient had no inherent costs) (House et al. 2013). Further evidence for cost-dependent
72 variation in altruism is presented by Stewart-Williams (2007) who used questionnaires
73 about help exchanged with individuals of different relatedness classes and found that with
74 increasing costs of help, nonkin received a smaller share of the help given than kin.

75

76 Prosocial inclinations are also contingent on the social and ecological environment (Lamba
77 & Mace 2011). House et al. (2013) demonstrated the emergence of population-specific
78 variation in costly prosociality during middle childhood. A cross-cultural study of
79 behaviour in ultimatum games showed that levels of prosociality increased with market
80 integration and the reliance on cooperative partners from outside the immediate family
81 (Henrich *et al.* 2005; Henrich *et al.* 2010). However, the existence of local variation in
82 prosocial behaviour *within* such industrialized populations has received relatively little
83 empirical attention (but see Wilson et al. 2009; Nettle et al. 2011; Holland et al. 2012; Silva
84 & Mace 2014, 2015).

85 A simple but powerful way to quantify pure altruism toward strangers in a naturalistic
86 setting (urban context) is through the lost letter experiment. This experiment involves
87 dropping letters on the sidewalk and counting the number of letters that are picked up by
88 passers-by and mailed to the addressee (Milgram *et al.* 1965). Previous applications of this
89 methodology have found that letter return rates were correlated with perceived
90 neighbourhood quality (Wilson *et al.* 2009) and objective neighbourhood wealth and
91 socioeconomic status (Nettle *et al.* 2011; Holland *et al.* 2012; Silva & Mace 2014).

92 In the present study we aim to apply the lost letter technique to simultaneously disentangle
93 the effects of both socioeconomic status and the inherent costs of executing a task on the
94 prevalence of altruistic behaviour in an urban setting. We first predicted that spontaneous
95 prosociality would be less prevalent in areas of low socioeconomic status because poorer
96 neighborhoods are characterized by low neighbourhood quality (Wilson *et al.* 2009), high
97 crime rates (Sampson *et al.* 1997; Nettle *et al.* 2011), low social capital and trust (Sampson
98 *et al.* 1997; Li *et al.* 2005; Nettle *et al.* 2011), and low rates of civic engagement (Li *et al.*
99 2005). Hence letters dropped in socioeconomically poorer areas should have a lower
100 likelihood of being returned. We also predicted that increased costs of returning the letter
101 would decrease altruism (Fessler 2009). That is, among the returned letters there would be
102 fewer unstamped letters; due to the additional financial expense required to post an
103 unstamped letter, it can be implied that returning unstamped letters imposes a larger cost
104 to the actor.

105

106 **2. Methods**

107 2.1 Data collection

108 We (the authors) dropped a total of 300 letters (150 stamped and 150 unstamped) were
109 dropped in 15 residential suburbs in the Perth Metropolitan area that differed in levels of
110 socioeconomic deprivation/affluence. We distributed twenty letters, ten stamped and ten
111 unstamped, face up on sidewalks of each suburb. We addressed envelopes to one of the
112 author's home address; we did not drop any letters in the suburb that the letters were
113 addressed to. We chose the addressee's name to be 'S. Roberts', as we considered it to be a
114 gender-neutral name. We chose a 'Western' name to remove any potential ethnic biases
115 (Ahmed 2010). There was no 'return to sender' address. We addressed all the letters in the
116 same handwriting in the same standard white envelope. Since the letter was handwritten,
117 it can be deduced that the letter did not contain official documents, utility bills or company
118 letters. The content of the letter was a folded piece of A4 paper containing the name of the
119 suburb the letter was dropped in and a note on whether it was stamped or unstamped. The
120 content of the letter was indistinguishable from the outside.

121 We dropped all 300 letters in their respective suburbs on the same evening between 17:00
122 and 19:00. We dropped the letters on a Saturday evening to ensure no postmen would pick
123 up the letters, as they do not work until Monday morning. We dropped the letters
124 strategically dropped on a weekend that had no rain forecasted to avoid damage to the
125 letters. We dropped the letters approximately 5 meters from a house driveway or front
126 gate on the pedestrian walkway to ensure visibility. We did not drop any letters in front of
127 any of the small businesses that exist in the residential suburbs, and also avoided
128 construction sites. This increased the likelihood of the letters being returned by actual
129 members of the area rather than short-term visitors. We did not drop any letters in sight of
130 a post box or post office so as to make it more likely that the effort the finder would have to

131 go to was roughly consistent across suburbs. There was only a maximum of one letter in
132 each street to maximize the spread of the letters within the suburb, which reduced the
133 likelihood of a participant coming across more than one letter and potentially alerting them
134 to the nature of the experiment.

135 Ethics approval for the above project was granted in accordance with the requirements of
136 the National Statement on Ethical Conduct in Human Research and the policies and
137 procedures of The University of Western Australia (RA/4/1/7801).

138

139 2.2 Data analysis

140 Suburbs were classified according their economic status. The Socio-economic Indexes for
141 Areas (SEIFA) was used to determine the socioeconomic status of the different suburbs in
142 which the letters were distributed. Specifically, the Index of Relative Socioeconomic
143 Disadvantage (IRSD) was used which ranks areas on a scale from most disadvantaged to
144 least disadvantaged. The index takes into account 16 different variables from the 2011
145 census data, with each variable receiving a different weighting. Some of the more heavily
146 weighted variables included the percentages of low-income houses, jobless parents,
147 individuals living without internet and other variables including education level,
148 occupation and average rent (Australian Bureau of Statistics 2009, 2014). These variables
149 are combined to produce a decile ranking of deprivation for specific areas, on a scale of 1 to
150 10 (henceforth termed *socioeconomic index*). A score of 1 for an area shows that the
151 residents in that area are in the most disadvantaged 10% in the nation. Some suburbs are
152 composed of smaller statistical areas; for these suburbs the median rating of deprivation
153 was taken (Supplemental File 1). Suburbs characterized by large socioeconomic variation

154 (difference between maximum and minimum IRSD for statistical areas >300) were not
155 included in the experiment.

156 We first ran a Generalized Linear Mixed Model with binomial error structure and logit link
157 function using the glmer function from the lme4 package (Bates *et al.* 2015) in R (R
158 Development Core Team 2014) version 3.1.0. The response variable – letter returned vs.
159 not returned – was binary. Fixed effects were socioeconomic status, and whether or not a
160 letter was stamped or unstamped. We also included number of postboxes in a suburb as a
161 control variable. Suburb was classified as a random effect and included in the statistical
162 model. Next, using a likelihood ratio test, we compared a saturated model containing all
163 fixed effects with a null model containing none of the fixed effects but the same random
164 effect as the saturated model (Forstmeier & Schielzeth 2011). The interaction between
165 stamped/unstamped and socioeconomic status was not significant and was therefore not
166 retained in the final model. P-values for individual predictors were calculated based on
167 Satterthwate's approximations using the lmerTest package (Kuznetsova *et al.* 2014).

168

169 **3. Results**

170 A total of 92 stamped and 46 unstamped letters were returned (Supplemental Files 1, 2). A
171 comparison of the full model to the null model showed that the set of predictors had a
172 strong effect on whether a letter would be returned or not ($\chi^2 = 45.373$, $p < 0.001$). An
173 analysis of the individual predictors in the model showed that unstamped letters had a
174 significantly lower chance of being returned (estimate = -0.320, SE = 0.054, $p < 0.001$) (Fig.
175 1). Socioeconomic index also had a significant effect on whether or not a letter was

176 returned (estimate = 0.035, SE = 0.011, $p = 0.00167$) (Fig. 2). A confounding effect of
177 density of postboxes could be ruled out (estimate = -0.002, SE = 0.012, $p = 0.919$).

178

179 **4. Discussion**

180 A steady stream of recent research has undermined the original characterization of
181 humans as *Homines economici* by uncovering substantial levels of prosocial behaviour
182 (Gintis 2003; Henrich *et al.* 2004; Hill *et al.* 2009; Alvard 2012). The present field
183 experiment using lost letters demonstrating people's willingness to engage in truly
184 altruistic acts conforms with this paradigm. However, our experimental approach has
185 revealed that these altruistic tendencies vary strongly with both levels of neighborhood
186 socioeconomic status and the costs involved in performing the altruistic act. Cost of the act
187 has rarely been investigated within this experimental paradigm. When there was the likely
188 added cost of going to a post office and purchasing a stamp, a letter was roughly half as
189 likely to be returned. This is in line with results from economic games (Isaac & Walker
190 1988; Andreoni & Miller 2002), questionnaire-based studies on helping behaviour
191 (Stewart-Williams 2007) and two earlier implementations of the lost letter experiment
192 (one of which was not couched in an evolutionary framework) (Simon 1971; Fessler 2009).
193 The negative effect of low socioeconomic status on letter return rates is in agreement with
194 most studies that utilized the lost letter technique to measure altruism.

195 The lower level of altruistic behaviour evident in poorer suburbs has been suggested to be
196 a consequence of individual or neighborhood characteristics associated with
197 socioeconomic deprivation (Holland *et al.* 2012). Individuals facing financial hardship, poor

198 health and general life instability are likely to be preoccupied with achieving immediate
199 needs, leaving less time and effort available to spend on benefiting a stranger (Lynam *et al.*
200 2000; Holland *et al.* 2012). In contrast, resource-rich individuals are not likely to be
201 affected by such time and financial constraints. Individuals residing in poorer
202 neighborhoods are also less likely to be embedded in a socially cohesive and supportive
203 network and are exposed to higher levels of crime, conditions that discourage the
204 development of trust required for civic efforts and prosociality (Holland *et al.* 2012).
205 Wilson *et al.* (2009) found a good match between individual prosociality and the quality of
206 the neighborhood (or more specifically the prosociality of the individuals' social
207 environment) and reasoned that "this empirical result explains why it is possible for
208 prosociality to succeed as a behavioural strategy in contemporary human life. Very simply,
209 those who give to others also get from others." (p. 198).

210

211 One mechanism by which altruistic behaviour to unrelated individuals can be explained is
212 reputation enhancement (Nowak & Sigmund 2005). In our study, a number of the returned
213 envelopes were annotated, detailing that the person had found and returned the letter on
214 their own goodwill. In one instance, the mobile phone number of the finder was written on
215 the envelope. In addition, one letter was hand delivered to the addressee's house. These
216 actions suggest that the actors desired recognition of their good deed, supporting the
217 theory of reputation enhancement.

218 Overall, our findings show that the willingness of individuals within a community to be
219 altruistic decreases with increasing costs and social disadvantage. More broadly, this

220 research shows that ecological variation within a given population can evoke divergent
221 patterns of helping behaviour. In the context of business and industry, these results can aid
222 charities and other crowd-funded organizations in directing their efforts to where they will
223 likely receive the greatest return. Data such as the ones collected in this study provide a
224 reflection of community attitudes and may therefore prove relevant to municipal
225 government for policy development and intervention.
