

A global meta-analytic contrast of cushion-plant effects on plants and on arthropods.

Nurse plant facilitation is a commonly reported plant-plant interaction and is an important factor influencing community structure in stressful environments. Cushion plants are an example of alpine nurse plants that modify microclimatic conditions within their canopies to create favourable environments for other plants. In this meta-analysis, the facilitative effects of cushion plants was expanded from previous syntheses of the topic and the relative strength of facilitation for other plants and for arthropods were compared globally. The abundance, diversity, and species presence/absence effect size estimates were tested as plant responses to nurse plants and a composite measure was tested for arthropods. The strength of facilitation was on average three times greater for arthropods relative to all plant responses to cushions. Plant species presence, i.e. frequency of occurrence, was not enhanced by nurse-plants. Cushion plants nonetheless acted as nurse plants for both plants and arthropods in most alpine contexts globally, and although responses by other plant species currently dominate the facilitation literature, preliminary synthesis of the evidence suggests that the potential impacts of nurses may be even greater for other trophic levels.

Introduction

Facilitation is a positive, non-trophic interaction that benefits at least one species (Callaway, 1995; Bruno et al., 2003). This interaction tends to occur in high-stress environments such as deserts (Holzapfel & Mahall 1999) or arctic and alpine ecosystems (Antonsson et al., 2009). The importance of facilitation tends to increase with environmental stress (Choler et al., 2001; Brooker et al., 2008; le Roux & McGeoch, 2010). A commonly used tool to examine plant facilitation in stressful environments is the use of nurse plants. Nurse plants modify microclimatic conditions of stressful environments within their canopies and thus may increase species richness (Nunez et al., 1999; Arroyo et al., 2003; Badano & Marquet, 2009), abundance (Cavieres et al., 2002; Badano et al., 2007; Sklenar 2009), diversity (Badano & Marquet, 2009; Butterfield et al., 2013), and species survival (Cavieres et al., 2007; Badano et al., 2007; Cavieres et al., 2008). Less commonly, nurse plants can also increase seedling tolerance to herbivory (Acuna-Rodriguez et al., 2006). Cushion plants are nurse plants that grow in alpine, subalpine, arctic, and subarctic ecosystems. The physiology of cushion plants, including their low height and compact form, makes them well adapted to stressful alpine environments. It also allows them to alter microclimatic conditions within their canopies (Cavieres et al., 2006). The canopy traps heat providing a warmer microclimate for other plants to grow in (Arroyo et al., 2003; Molenda et al., 2012), increases soil water content by retaining moisture (Cavieres et al., 2007; Schoeb et al., 2012; Anthelme et al., 2012), reduces wind (Cavieres et al., 2007; le Roux and McGeoch, 2010), and increases litter accumulation which contributes to increased soil nutrients (Cavieres et al., 2008; Schoeb et al., 2012; Anthelme et al., 2012). Consequently, cushion plants are an excellent set of species to explore positive interactions in the alpine, particularly for impacts on other plant species.

Most cushion plant facilitation studies have focused on the facilitation of other plants with few examples of effects on arthropods (but see Molina-Montenegro et al., 2006; Sieber et al., 2011; Lortie & Reid, 2012; Molenda et al., 2012). Accordingly, reviews of cushion plant facilitation have also focused on plants (Arredondo-Nunez et al., 2009; Anthelme & Dangles 2012; Reid et al., 2010). For instance, Anthelme and Dangles (2012) examined plant-plant interactions in tropical alpine environments and compared them to other alpine environments. They found that cushions have a similar facilitative effect in tropical alpine environments to other alpine environments in that cushions modified microclimatic conditions within their canopies and similarly facilitated other plant species. A review by Reid et al. (2010) compared publications on nurse-plant shrubs to cushion plants and found that although there are fewer studies using cushion plants, these nurses have many of the same effects as shrubs in terms of modifying microclimatic conditions and enhancing plant species diversity. Cushions are thus an ideal model in many respects to study the effects of facilitation on diversity in alpine or arctic ecosystems. However, these two reviews summarized cushion plant effects on understory species across studies, and did not quantitatively assess these effects in terms of richness, abundance, survival etc.

A pioneering meta-analysis by Arredondo-Nunez et al. (2009) quantitatively examined the effect of cushion plants on plant species presence at high and low stress and concluded that facilitation increased with environmental stress. This meta-analysis was very successful in quantitatively demonstrating the facilitative effects of cushions on other plant species. However, the literature available for synthesis at that time only examined plant-plant interactions in the Southern Andes, and only tested plant species presence/absences a response variable in sufficient numbers (a total of 9 studies). Hence, there is need for a quantitative synthesis update for these specific forms of nurse plants.

75

76 In this meta-analysis, the effect of cushion plants will first be extended to assess effects on other
77 plant species globally by comparing the following three potential plant responses to nurses:
78 abundance, diversity, and presence/absence. The synthesis of facilitation literature will be further
79 extended by contrasting the responses of other plant species to nurses with the responses of
80 arthropods to nurses. These are critical extensions to the facilitation literature in general because
81 nurse plants may be foundation species for many trophic levels – not just other plants, and
82 identifying the appropriate responses to nurse plants may have important implications for
83 population and community dynamics of alpine plant populations. The following questions will be
84 addressed in this meta-analysis. (1) Is there significant evidence that cushion plants facilitate
85 plant abundance, diversity, and presence/absence globally? (2) Is there significant evidence that
86 cushion plants also facilitate arthropods? (3) Does the strength of evidence associated with
87 facilitation of plants and arthropods by cushion plants differ? Plants and arthropod responses to
88 cushions can be contrasted herein because the same effect size estimate is calculated and both
89 involve the same field of methodologies, i.e. contrasts of measures associated with cushion and
90 open microsites. This satisfies the best practices recommended for such meta-analytical contrasts
91 (Moayyadi, 20004; Borenstein et al., 2009; Jennions et al., 2013; Koricheva & Gurevitch, 2013)
92 when the efficacy of treatment is evaluated at larger scales.

93

94 **Methods**

95 *Study selection process*

96 A search was conducted using ISI Web of Knowledge for articles associated with cushion plant
97 facilitation. Three separate searches were performed in July 2013 on this topic and resulted in

613 articles (Table 1, search terms listed). These searches were refined in three stages with increasing specificity in the inclusion criteria applied. The first stage limited articles to English language publications and to the following Web of Knowledge search categories: plant science, ecology, environmental sciences, geography physical, environmental studies, biodiversity conservation, evolutionary biology, horticulture, entomology, biology, and mycology (Table 1, 432 articles remained). In the second stage of refinement, duplicate articles were removed, and all publications were screened to determine if the study examined facilitation (retention of 52 articles). Only two taxa were reported in this set of publications, plants, and arthropods. The third stage in the workflow inspected all studies for useable/extractable data and then sorted these publications by response variables, i.e. abundance, diversity, and presence, and by plant or arthropod species. This final refinement generated 16 studies for a total of 673 unique experimental contrasts of nurse-plant cushion effects in the field (Table 2, $N_{\text{study}} = 13$ plants responses, $N_{\text{study}} = 2$ arthropods, and $N_{\text{study}} = 1$ examined both taxa). A PRISMA flow diagram was generated (Moher et al., 2009) outlining the publication selection process (Fig 1).

Data Collection and Analyses

Data for abundance, diversity and/or presence of plant and/or arthropod species were extracted from tables, figures, or by contacting authors directly when not reported. All studies excepting one included in the meta-analysis were observational (table 2). To compare results across studies, the Relative Interaction Index (RII) effect size estimate was calculated as $RII = (B_w - B_o) / (B_w + B_o)$ where B_w is the value of species within the cushion, and B_o is the value of species without the cushion (Armas et al., 2004). RII ranges from +1 to -1 with positive values indicating facilitation, negative values indicating competition, and values not significantly different from zero indicating neutral/no effects (Armas et al., 2004). Sets of meta-analytic contrasts were used to compare the

122 nurse effect of cushions on plants and to arthropods. The effect of cushions was determined by
 123 comparing plant and arthropod responses within the cushion canopy to adjacent open areas
 124 identical to the field methodology used to assess plant-plant interaction in most facilitation
 125 studies (Brooker et al., 2008). These nurse plant-open pairs were extracted from each study and
 126 used for each meta-analytic contrast resulting in 662 pairs for plants and 11 for arthropods.).
 127 Pairs were first coded as a unique replicate/instance based on study number, cushion species,
 128 elevation, and response variable reported within the study (i.e. abundance, diversity, or species
 129 presence). However, to be very conservative, we chose not to model each field instance as fully
 130 independent in our analyses. The mean RII values were calculated within each publication for
 131 independent tests only, i.e. tested a different cushion species or a different elevation, for a total of
 132 63 unique study cases for plants and 5 tests for arthropods. We first tested whether abundance,
 133 diversity, and presence differed between plants on average. Next, we compared the composite
 134 measure of all responses between plants and arthropods. Diversity data included raw species
 135 richness and Shannon-Weiner diversity indices. Both meta-analyses were modeled as categorical
 136 random effects. Heterogeneity tests (Q) were conducted to determine if the effect sizes calculated
 137 in each meta-analysis were significantly different (Rosenberg et al., 2000). To determine if the
 138 effect size was significantly different from zero and therefore significantly different from a
 139 neutral effect, bias corrected confidence intervals were calculated. An effect size was
 140 significantly different from zero if the confidence interval does not overlap zero (Cote &
 141 Jennions, 2013). In order to explore bias, Rosenthal's fail-safe analyses were conducted for each
 142 meta-analysis. To determine if the Rosenthal value for each meta-analysis is within the acceptable
 143 range, we applied the bias rule of $X=5k+10$ where X = the Rosenthal value and k is the number
 144 of studies (Moller & Jennions, 2001). An acceptable Rosenthal value for plants would be greater
 145 than 80 whilst for arthropods it would be greater than 25. If the Rosenthal value of the meta-
 146 analysis is greater than these values, then the results are generally considered robust (Moller &

Jennions, 2001). All univariate meta-analyses were conducted using Metawin 2.1 (Rosenberg et al., 2000).

Results

Plant abundance was the most strongly facilitated response variable enhanced by cushions, and it was significantly different from the other responses (Fig 2, different from 0 and non-overlapping confidence intervals with either alternative response mean $\text{RII}_{\text{abundance}} = 0.434 \pm 0.144$, mean $\text{RII}_{\text{diversity}} = 0.130 \pm 0.081$, mean $\text{RII}_{\text{presence}} = 0.095 \pm 0.166$). Plant species diversity was also enhanced by cushions whilst the presence plant response variable was not significantly different from zero (Fig 2). Heterogeneity between groups was significantly different ($Q_{\text{between}} = 11.7$, $df = 2$, $p = 0.01$) with presence plant response having the highest levels of within group variation (presence $\text{variance}_{\text{pooled within group}} = 0.13$). The Rosenthal value for this meta-analytic comparison is 381 indicating robust results.

Cushion plants facilitated both plants and arthropods (Fig 3, i.e. grand mean significantly different from zero and positive grand mean $= 0.278 \pm 0.082$). The facilitative effect of cushion plants was significantly greater for arthropods compared to plants with arthropods having a RII value more than 3.5 times greater than plants (Fig 2 mean $\text{RII}_{\text{plants}} = 0.226 \pm 0.079$, mean $\text{RII}_{\text{arthropods}} = 0.830 \pm 0.041$). Heterogeneity between groups was not significantly different ($Q_{\text{between}} = 3.3$, $df = 1$, $p = 0.08$) in spite of unequal sample sizes. The Rosenthal value was 461.8, and this is 5 times greater than the threshold of 80 suggesting robust results.

169 Discussion

170 There is significant evidence that nurse-plant species function as foundation species in relatively
171 stressful ecosystems (Cavieres & Badano, 2009; Butterfield, 2009). Particularly in arid systems,
172 shrub nurse plants have been shown to positively influence many aspects of plant community
173 structure (Maestre et al., 2005), and this has been linked to restoration via synthesis, i.e. meta-
174 analysis (Gomez-Aparicio, 2009). However, in the alpine, the research is not as extensive but also
175 suggests that cushion plants can serve as foundation species with strong effects in driving the
176 frequency of occurrence of plant species within these communities (Arredondo-Nunez et al.,
177 2009). To update and extend this previous synthesis, we conducted a meta-analysis on the current
178 research examining cushions to include other plant responses, other alpine regions globally, and
179 to compare to effects on arthropods. Similar to the previous syntheses of nurse plants in general,
180 cushion plants facilitate other plant species and arthropods and are thus likely a foundational
181 species. Consequently, we propose that these species are an excellent model organism available
182 to ecologists to explore community dynamics and change in many alpine ecosystems.

183

184 There were several novel and sometimes contradictory findings in this synthesis effort relative to
185 previous reviews. In this meta-analysis, the abundance and diversity of plant species was
186 facilitated by cushion plants. This is a novel extension to the previous synthesis by Arredondo-
187 Nunez et al. (2009) wherein only frequency of occurrence, or as we termed here presence, was
188 examined. Increases in diversity and total abundance of plant species within the cushion
189 understory is not a surprising result given the above described mechanisms of abiotic stress
190 amelioration. Shelter in the alpine is a commonly assumed mechanism of facilitation for plants
191 (Carlsson, 1991; Cavieres et al., 2002; Cavieres & Sierra-Almeida, 2012). There is accumulating
192 support that cushions can enhance species richness in the alpine through higher rates of

193 addition/retention of species at the community level (Cavieres & Badano, 2009). This retention
 194 by cushion plants has been shown to extend to reduced loss of phylogenetic diversity compared
 195 to adjacent open areas in the alpine globally (Butterfield et al., 2013). Even more broadly,
 196 facilitation can enhance diversity in many other ecosystems (Badano & Marquet, 2009;
 197 Butterfield et al., 2013; McIntire & Fajardo, 2013). However, all species may not equally benefit
 198 from nurse plants in alpine systems, and there are also instances of negative association of other
 199 species with cushions (Fajardo et al., 2008) or different sets of species differentially associating
 200 with cushions (Cavieres & Badano, 2009; Arredondo-Nunez et al., 2009). This synthesis thus
 201 contradicted the previous synthesis of this topic (Arredondo-Nunez et al., 2009) in that the
 202 presence, or frequency of occurrence, was not facilitated as was formerly detected. This
 203 difference is likely due to several factors ranging from ecological to statistical. The current meta-
 204 analysis included studies from a variety of alpine ecosystems because the cushion plant literature
 205 has expanded in number and geographic scope since the former synthesis. This necessarily
 206 introduces greater heterogeneity in the potential responses of plant communities to cushions
 207 because very different alpine communities were sampled that likely differ in stability (Butterfield,
 208 2009), net interactions (Callaway et al., 2002), and climate (Kikvidze et al., 2011) to name a few
 209 important ecological considerations. Importantly, significant statistical heterogeneity was
 210 detected for the presence plant response variable unlike the other responses tested suggesting
 211 that this measure of community structure may be more sensitive the local ecological context
 212 versus regional drivers of change (Ricklefs, 2008). The inconsistency between this study and the
 213 meta-analysis conducted by Arredondo-Nunez et al. (2009) is also due to purely statistical
 214 reasons because the scope of inference differed. Herein, we fit random-effects statistical models
 215 as we sought to describe global patterns whilst the former meta-analysis, quite appropriately, used
 216 a fixed-effects model because they were describing a set of studies all from within the same
 217 region, the Southern Andes. Random effects models estimate variance less conservatively

(Jennions et al., 2013), and we would thus expect that heterogeneity would be greater in some instances. In summary, cushion plants have the capacity to shape many aspects of plant community structure in the alpine, but research gaps associated with species specificity, scale, and the sensitivity of different community-level responses to nurses can be further developed.

Although the facilitation of arthropods is an emerging field of research, arthropods were facilitated by cushion nurse plants in the alpine in this limited set of studies conducted to date. Interestingly, the strength of facilitation was significantly greater for arthropods relative to the benefits accrued by other plant species. There are several explanations for this general finding. Microclimatic modifications made by cushion plants may benefit arthropods even more extensively than plants given their mobility and foraging behaviour. The canopy of cushions provides a warmer and more stable microclimate (Cavieres et al., 2002; Arroyo et al., 2003; Molenda et al., 2012). This may allow more arthropods to function and thermoregulate relative to colder conditions outside cushions (Molina-Montenegro et al., 2006). If sets of arthropods seek refuge within cushions, then the availability of prey may also be greater within cushions thereby concentrating resources for other species (Lortie et al., 2012). Cushion plants also increase plant abundance and diversity when compared to open areas in many instances (finding in this synthesis and broadly reviewed in McIntire & Fajardo (2013)). This can provide arthropods with a more diverse range of resources and niches in general (Molenda et al., 2012) particularly for life-stages associated with colonization (Mysterud et al., 2010). Finally, pollinators have been shown to benefit from cushions as they provide an increased availability of flowers (Reid & Lortie, 2012). Hence, cushion plants likely have direct and indirect effects on arthropod community dynamics related to both microclimate and to the other plant and arthropod species present. The evidence to date strongly suggests that cushion nurse plant research should now

242 include and address multi-trophic perspectives (McIntire & Eliot, 2013; Van DerPutten, 2009;
 243 Ferenc et al., 2009). In addition, decoupling direct and indirect interactions of cushion plants and
 244 understory plant species is another important area of research. Biodiversity changes in the alpine
 245 will be unavoidable given a changing climate and will not be restricted to plant species.
 246 Therefore, understanding interactions that structure the greater community will be important in
 247 determining the consequences of a rapidly changing climate in the alpine.

Search terms used to select studies

Table 1. The search terms used in defining the scope of studies used in this meta-analyses of nurse-plant cushions on other plant species and arthropods. Web of Knowledge was the tool used to secure the population of studies. Each workflow step of literature screening is described in details in the methods, but in short, step 1 – all studies, step 2 –duplicates removed and reported facilitation, and step 3 –useable data reported and sorted by response and taxa.

Le Roux and McGeoch, 2010	46°54'S, 37°45'E	89, 97, 102	<i>Azorella selago</i>	Plants	Abundance
Molenda et al., 2012	50°15'N, 122°16'W	2160	<i>Silene acaulis</i>	Plants and arthropods	Abundance, diversity
Molina-Montenegro et al., 2006	33°20'S, 70°16'W	3200	<i>Laretia acaulis</i> , <i>Azorella monantha</i>	Arthropods	Abundance
Quiroz et al., 2009	33°20'S, 70°16'W	3200, 3580	<i>Azorella madreporica</i>	Plants	Abundance, diversity, presence
Schoeb et al., 2012	37°05'N, 03°23'W	3240	<i>Arenaria tetraquetra</i>	Plants	Abundance, diversity
Sieber et al., 2011	46°31'N, 09°43'W	3000	<i>Eritrichium nanum</i>	Arthropods	Presence
Yang et al., 2010	28°20'N, 99°05'E	4500, 4700	<i>Arenaria polytrichoides</i>	Plants	Presence

Figure 1

PRISMA diagram describing the search protocol used for the meta-analysis

Figure 1: PRISMA flow diagram depicting the search protocol and workflow in determining the effective population of studies for meta-analysis.

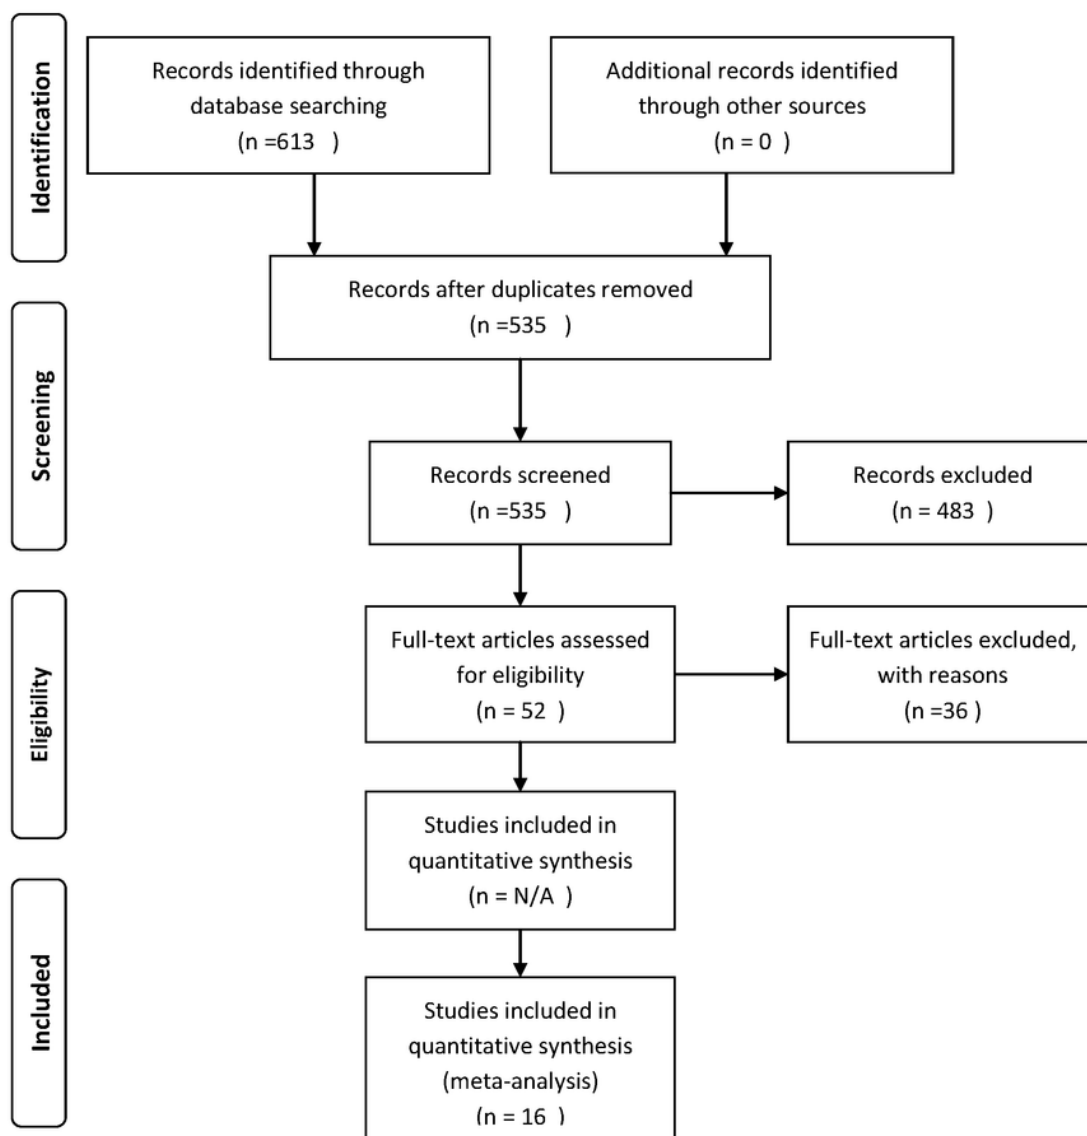

Figure 2

Mean RII values for the effect of cushion plants on the abundance, diversity, and presence of other plant species

Figure 2: The mean RII values for the effect of alpine cushion plants on the abundance, diversity, and species presence for other plants. Presence refers to presence/absence responses via associational pattern analyses in this literature. The bias-corrected 95% confidence intervals are shown.

Figure 3

Composite mean RII values for plants, arthropods and the overall grand mean

Figure 3: A contrast of the composite mean RII values for plants and arthropods. The overall or grand mean is the mean RII value for both plants and arthropods. The bias-corrected 95% confidence intervals are shown.
