Introduction: There exist several barriers to maternal health service utilization in developing countries. Most of the previous studies conducted in India have focused on demand-side barriers, while only a few have touched upon supply-side barriers. None of the previous studies in India have investigated the factors that affect maternal health care utilization at health sub-centers (HSCs) in India, despite the fact that these institutions, which are the geographically closest available public health care facilities in rural areas, play a significant role in providing affordable maternal health care. Therefore, this study aims to examine the supply-side determinants of maternal service utilization at HSCs in rural India. **Data and Methods:** This study uses health facility data from the nationally representative District-Level Household Survey, which was administered in 2007–2008 to examine the effect of supply-side variables on the utilization of maternal health care services across HSCs in rural India. Since the dependent variables (the number of antenatal registrations, in-facility deliveries, and postnatal care services) are count variables and exhibit considerable variability, the data were analyzed using negative binomial regression instead of Poisson regression. Results: The results show that those HSCs run by a contractual auxiliary nurse midwife (ANM) are likely to offer a lower volume of services when compared to those run by a permanent ANM. The availability of obstetric drugs, weighing scales, and blood pressure equipment is associated with the increased utilization of antenatal and postnatal services. The unavailability of a labor/examination table and bed screen is associated with a reduction in the number of deliveries and postnatal services. The utilization of services is expected to increase if essential facilities, such as water, telephones, toilets, and electricity, are available at the HSCs. Monitoring of ANM's work by Village Health and Sanitation Committee (VHSC) and providing in-service training to ANM appear to have positive impacts on service utilization. The distance of ANM's actual residence from the sub-center village where she works is negatively associated with the utilization of delivery and postnatal services. These findings are robust to the inclusion of several demand-side factors.

Conclusion: To improve maternal health care utilization at HSCs, the government should ensure the availability of basic infrastructure, drugs, and equipment at all locations. Monitoring of the ANMs' work by VHSCs could play an important role in improving health care utilization at the HSCs; therefore, it is important to establish VHSCs in each sub-center village. The relatively low utilization of maternity services in those HSCs that are run solely by contractual ANMs requires further investigation.

Supply-side barriers to maternal health care utilization at health sub-centers in India

39

Introduction: There exist several barriers to maternal health service utilization in developing countries. Most of the previous studies conducted in India have focused on demand-side barriers, while only a few have touched upon supply-side barriers. None of the previous studies in India have investigated the factors that affect maternal health care utilization at health sub-centers (HSCs) in India, despite the fact that these institutions, which are the geographically closest available public health care facilities in rural areas, play a significant role in providing affordable maternal health care. Therefore, this study aims to examine the supply-side determinants of maternal service utilization at HSCs in rural India.

Data and Methods: This study uses health facility data from the nationally representative District-Level Household Survey, which was administered in 2007–2008 to examine the effect of supply-side variables on the utilization of maternal health care services across HSCs in rural India. Since the dependent variables (the number of antenatal registrations, in-facility deliveries, and postnatal care services) are count variables and exhibit considerable variability, the data were analyzed using negative binomial regression instead of Poisson regression.

Results: The results show that those HSCs run by a contractual auxiliary nurse midwife (ANM) are likely to offer a lower volume of services when compared to those run by a permanent ANM. The availability of obstetric drugs, weighing scales, and blood pressure equipment is associated with the increased utilization of antenatal and postnatal services. The unavailability of a labor/examination table and bed screen is associated with a reduction in the number of deliveries and postnatal services. The utilization of services is expected to increase if essential facilities, such as water, telephones, toilets, and electricity, are available at the HSCs. Monitoring of ANM's work by Village Health and Sanitation Committee (VHSC) and providing in-service training to ANM appear to have positive impacts on service utilization. The distance of ANM's actual residence from the sub-center village where she works is negatively associated with the utilization of delivery and postnatal services. These findings are robust to the inclusion of several demand-side factors.

Conclusion: To improve maternal health care utilization at HSCs, the government should ensure the availability of basic infrastructure, drugs, and equipment at all locations. Monitoring of the ANMs' work by VHSCs could play an important role in improving health care utilization at the HSCs; therefore, it is important to establish VHSCs in each sub-center village. The relatively low utilization of maternity services in those HSCs that are run solely by contractual ANMs requires further investigation.

Introduction

Although India appears to have missed its Millennium Development Goal (MDG)-5 target, which aimed

to reduce maternal mortality by two-thirds by the year 2015, the fact remains that it has witnessed a

considerable decline in maternal mortality over last 15 years or so (United Nations, 2016). This decline is

a result of concerted efforts made by the Government of India to improve financial and geographic access

to maternal health care services through the publicly-funded health system, especially in rural areas

(Kumar, 2010). Unfortunately, the utilization of maternal health care services is still low. For instance, the

proportions of Indian women who received full antenatal care, who had a successful delivery, and who

78   underwent a postnatal check-up were 18%, 51%, and 49%, respectively, in 2007–2008. The situation in

79   rural areas is even worse (International Institute for Population Sciences, 2010).

80   Health service utilization depends on a number of factors. These factors can be understood through the

81   demand–supply framework (Ensor & Cooper, 2004). In the demand–supply framework, demand-side

82   determinants are defined as individual, household, or community characteristics that influence the

83   demand for health services. These factors may operate at the individual, household, or community level.

84   In contrast, supply-side factors are those characteristics of the health system that exist beyond the control

85   of potential health service users, such as health facilities, drugs, equipment, finances, human resources,

86   geographic distance, and so on (Peters, Garg, Bloom, Walker, Brieger, & Rahman, 2008).

87   A number of previous studies have identified several demand-side factors as important obstacles to health

88   care utilization in developing countries (Ensor & Cooper, 2004; Kesterton, Cleland, Sloggett, &

89   Ronsmans, 2010; O'Donnell, 2007; Sarma, 2009). However, only a few have truly addressed supply-side

90   barriers (Metcalfe & Adegoke, 2013). Although many studies have documented the shortages of drugs,

91   equipment, physical infrastructure, finances, and human resources in the provision of health care (Bajpai,

92   Dholakia, & Sachs, 2008; Bajpai, 2014; Bhandari & Dutta, 2007; Hazarika, 2013; Raut-Marathe,

93   Sardeshpande, & Yakkundi, 2015; Varatharajan, Thankappan, & Jayapalan, 2004), the evidence on how

94   these supply-side factors affect service provision at publicly funded rural health facilities in India is still

95   very sparse (Kumar & Dansereau, 2014).

96   A health sub-center (HSC) serves as the first point of contact between the government-funded health

97   system and those individuals living in rural areas. HSCs play an important role in bringing about

98   behavioral changes through interpersonal communication, and they provide a wide range of services,

99   including maternal and child health (MCH) care, family planning, nutrition, and immunization services

100   (Bhandari & Dutta, 2007). The auxiliary nurse midwife (ANM), the sole female functionary at the HSC

101   level, is largely responsible for implementing maternal health programs in rural India (Malik, 2009;

102   Mavalankar & Vora, 2008). Unfortunately, the level maternal service utilization at HSCs in most states is

103   still very low (International Institute for Population Sciences, 2010). Therefore, it is imperative to

104   examine the factors responsible for the low utilization of maternal health care services at this delivery

105   point. In this regard, supply-side factors (health workers, drugs, equipment, infrastructure, and training)

106   are very important from a policy perspective, as managing these factors is far easier and more effective

107   than manipulating the factors that are known to improve the demand for health services. Hence, using

108   data from a large, nationally representative, cross-sectional household and health facility survey, this

109   study aims to examine the effect of supply-side factors on the utilization of maternal health services at the

110   HSC level.

111

112 **Data and Methods**

113 *What is a Health Sub-Center?*

114 The public health care system in rural areas is a three-tiered hierarchical system; HSCs are located at the

115 bottom tier, primary health centers (PHCs) are located at the middle tier, and community health centers

116 (CHCs) are featured at the top tier. CHCs are 30-bed rural hospitals that are equipped with specialists,

117 doctors, nurses, technicians, and other facilities to provide effective referral support to a population of

118 about 80,000 to 120,000 individuals. At the middle of the hierarchy is the PHC, which serves a population

119 of about 30,000 to 50,000 people. It is usually staffed with a qualified allopathic doctor, a pharmacist, and

120 a lab technician (Government of India, 2007).

121 HSCs are entrusted with a number of curative, preventive, and promotional health care-related tasks.

122 They are expected to bring about behavioral changes through interpersonal communication, and they

123 provide basic services related to MCH, family planning, nutrition, immunization, communicable diseases,

124 and so on (Government of India, 2007). Each HSC is staffed with a female health worker, officially

125 known as an ANM, and a male health worker (MHW), also known as a male multipurpose worker. In

126 some HSCs, two ANMs are posted. As per Indian Public Health Standards (IPHS), each HSC should have

127 at least four workers – two ANMs, one MHW, and a support worker (Pallikadavath, Singh, Ogollah,

128 Dean, & Stones, 2013).

129

130 *Data Source*

131 This study used data from the third round of the District Level Household and Facility Survey (DLHS-3),

132 a cross-sectional survey that was administered in 2007–2008. The survey was designed to collect data on

133 various aspects of MCH service utilization, and it aimed to assess the capacity and preparedness of

134 publicly funded health facilities in terms of their infrastructure, human resources, drugs, equipment, and

135 training. Data on the first aspect were collected through a household survey, while data on health facility

136 capacity and preparedness were collected through a facility survey. Apart from collecting information on

137 the resources available at these health facilities, the facility survey also gathered data on the utilization of

138 MCH services at the HSCs during the month preceding the survey.

139 The DLHS-3 used a multistage, stratified probability proportional to size (PPS) sampling design. In each

140 district, 50 primary sampling units (PSUs), or census villages, were selected during the first stage via

141 systematic PPS sampling. From each PSU, households were selected using circular systematic sampling.

142 The selection of rural health facilities for the Facility Survey was linked with the sampled rural PSUs. The

143   Facility Survey included only those PHCs and HSCs that were located in proximity to, and which were

144   expected to serve, the health care needs of the sampled rural PSUs. All CHCs and District Hospitals

145   (DHs) were included in the survey (International Institute for Population Sciences, 2010). The survey

146   collected data via face-to-face interviews. In the Facility Survey, some information was collected directly

147   from the official registers, which were maintained by the health facility itself. In all, the DHLS-3

148   household survey collected information from 720,320 households; there were 643,944 ever-married

149   women aged 15–49 years and 166,260 unmarried women aged 15–24 years. Conversely, the Facility

150   Survey from the DLHS-3 surveyed 18,068 HSCs, 8,619 PHCs, 4,162 CHCs, and 594 district hospitals.

151   The overall household response rate was around 94%. The overall response rates for ever-married women

152   and unmarried women were 89% and 85%, respectively. The survey oversampled households by 10%,

153   which would serve as a cushion to protect against the effects of non-responders. More information on the

154   sampling procedures, survey design implementation, and response rates for the DHLS-3 are found in the

155   DLHS-3 national report, which can be accessed from http://rchiips.org/pdf/INDIA_REPORT_DLHS-3.pdf.

156   This study used information on 18,068 HSCs to examine the association between a number of supply-side

157   factors (health personnel, infrastructure, medical equipment, drug availability, and so on) and the delivery

158   of maternal health care services. As per the DLHS-3 report, about 91% of HSCs had a permanent ANM in

159   place, while about 20% had a contractual ANM. The average population served by the sampled HSCs was

160   8,372 individuals (International Institute for Population Sciences, 2010).

161

162   ***Dependent Variables***

163   This study examined MCH service utilization at HSCs using three dependent variables – namely, the

164   number of antenatal care registrations (a proxy for antenatal care utilization), the number of deliveries

165   conducted, and the number of postnatal care services provided in each facility during the month preceding

166   the survey. Thus, the exposure period was the same for all health facilities. All of the aforementioned

167   variables were count variables. The proportion of HSCs with zero antenatal care registrations and

168   postnatal care services was about 3% and 9%, respectively. About 76% of facilities did not perform any

169   deliveries in the month preceding the survey. The average numbers of women who received antenatal

170   care, underwent deliveries, and provided with postnatal care were 15, 1, and 7, respectively.

171

172   ***Independent Variables***

173   The selection of independent variables in this study was guided by a demand–supply framework provided

174   by Ensor and Cooper (2004). The study included a number of supply- and demand-side variables that

175   were available in the DLHS-3 dataset. Most of these variables were found to be associated with health

176   care utilization in various settings around the world. For instance, the presence of an ANM was found to
177   be associated with an increase in maternal health care utilization by a study conducted in South India
178   (Navaneetham & Dharmalingam, 2002). Similarly, other supply-side factors such as drugs, physical
179   infrastructure, in-service training, equipment, and accessibility were also found to be influential in
180   shaping health care utilization patterns (Agrawal et al., 2012; Blankart, 2012; Kesterton et al., 2010;
181   Kumar & Dansereau, 2014; Kumar & Prakash, 2013; Peters, Garg, Bloom, Walker, Brieger, & Hafizur
182   Rahman, 2008; Shaikh & Hatcher, 2005; Valdivia, 2002; Yeager, 2012). These variables can be divided
183   into seven categories: a) health personnel, b) drugs, c) equipment, d) infrastructure, e) quality-related
184   variables, f) geographic variables, and g) socioeconomic and demographic variables. Detailed
185   descriptions of the variables included in the analysis are given in the following paragraphs.

186   An HSC is ideally supposed to have two ANMs (one permanent and another contractual) and an MHW.
187   The DLHS-3 featured a question that asked whether a position for a specific type of worker at a given
188   HSC was filled. Using this information (which involved combining permanent and contractual ANM
189   variables), a health worker variable with four categories – namely, HSC without an ANM, HSC with only
190   a permanent ANM (reference category), HSC with only a contractual ANM, and HSC with both ANMs –
191   was generated. The availability of drugs was captured using two binary variables – one for iron–folic acid
192   (IFA) tablets/syrup and another for paracetamol tablets. An index was created to capture the availability
193   of essential obstetric care drugs. The index featured scores that ranged from 0 to 5, with HSCs receiving
194   one point for having each of the following obstetric care drugs: gentamycin, magnesium sulfate,
195   ampicillin, metronidazole, and misoprostol. To measure the availability of medical equipment, the
196   following binary variables were used: blood pressure instrument, weighing scale for adults, and Sims
197   speculum. Three other categorical variables – the availability of a labor table, an examination table, and a
198   bed screen (using the following categories: available and functional [reference category], available but
199   unusable, and not available) – were also included in the analysis.

200   The following variables were included to capture the availability of basic amenities and infrastructure: a
201   categorical variable for the supply of electricity (using these categories: 'regular supply' (reference
202   category), 'irregular supply', and 'no electricity connection'), as well as three binary variables (water,
203   toilets, and telephone facilities). To capture the quality of a given health facility, and to check whether
204   high-quality facilities were likely to deliver a higher volume of services, three additional binary variables
205   were included. The first two of these binary variables captured the quality of an ANM by asking whether
206   the ANM received in-service 'integrated skills development training' and 'skilled birth attendance
207   training' at any time during the last five years preceding the survey. The third binary variable that
208   captured the quality of HSCs was whether the VHSC monitored the ANMs' work on a regular basis.

209   The main purpose of this study was to examine the effect of supply-side factors on the delivery of
210   maternal health care services at the HSC level. However, it also included a number of demand-side
211   variables that were previously found to affect the demand for health care services, such as socioeconomic,
212   demographic, and geographical factors (Metcalfe & Adegoke, 2013; Midhet, Becker, & Berendes, 1998;
213   Patel & Ladusingh, 2015; Singh, Kumar, & Pranjali, 2014; Singh, Rai, Alagarajan, & Singh, 2012; Sunil,
214   Rajaram, & Zottarelli, 2006; ten Hoope-Bender, Liljestrand, & MacDonagh, 2006). All of these variables
215   were calculated for the district as a whole. These variables included a log of the population living in the
216   facility's catchment area, a district-level fertility indicator (the total fertility rate was calculated using
217   birth-order information obtained from the DLHS-3 ever-married women dataset), the average number of
218   years of education among mothers, the percentage of households in the lowest economic quartile (as
219   defined by an asset score calculated from the DLHS-3 household file), and the percentage of Hindu
220   households in a given district. All of the aforementioned variables were continuous variables. The
221   analysis also included a categorical variable that captured the effect of the distance of the ANMs' actual
222   residence from the sub-center village where they work. The variable has four categories: 'within 4
223   kilometers' (reference category), '5–20 kilometers', '21–40 kilometers', and 'more than 40 kilometers'.

224   In this study, a 'region' represents a group of Indian states. The north region (1), which served as the
225   reference category for the 'region' variable, includes Jammu and Kashmir, Himachal Pradesh, Punjab,
226   Rajasthan, Haryana, Chandigarh (Union Territory – UT), and Delhi; the central region (2) includes the
227   states of Uttar Pradesh, Uttaranchal, Madhya Pradesh, and Chhattisgarh; the northeast region (3) includes
228   the states of Sikkim, Assam, Meghalaya, Manipur, Mizoram, Nagaland, Tripura, and Arunachal Pradesh;
229   the east region (4) includes the states of Bihar, Jharkhand, West Bengal, and Orissa; the west region (5)
230   includes the states of Gujarat, Maharashtra, Goa, and the UTs of Dadra and Nagar Haveli, and Daman and
231   Diu; and the south region (6) includes the states of Kerala, Karnataka, Andhra Pradesh, Tamil Nadu, and
232   the UTs of Andaman and Nicobar Islands, Pondicherry, and Lakshadweep.

233

234   ***Statistical Analysis***

235   The study used negative binomial regression to examine the association between the availability of
236   various resources at the HSCs and the volume of the maternal health care services provided during the
237   last month preceding the survey. Since the dependent variables consisted of non-negative count data, a
238   negative binomial regression technique was chosen for the analysis (Coxe, West, & Aiken, 2009). The
239   possibility of using a Poisson regression model was ruled out due to its strict assumption that the
240   conditional mean and variance of the dependent variable should be the same (Land, McCall, & Nagin,
241   1996). None of the dependent variables fulfilled this requirement; all of them exhibited clear over-

242 dispersion. For instance, the 'antenatal registration' variable had a mean of 14.7 and a variance of 364.5.

243 Similarly, delivery (with a mean of 1.1 and a variance of 10) and postnatal care (with a mean of 7.3 and a

244 variance of 56.4) also exhibited over-dispersion. In such cases, a Poisson regression model would usually

245 produce inefficient estimates. A negative binomial model does not require equality between the mean and

246 variance; thus, it also enabled us to take into account unmeasured characteristics that generated over-

247 dispersion in the count data (Gardner, Mulvey, & Shaw, 1995). Hence, a negative binomial model was

248 preferred over a Poisson model for the current analysis.

249 The generalized form of the negative binomial regression model used in this study can be written as
250 follows:

251

252 $$Y_{fd} = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_3 + \ldots + \beta_k X_k + (\sigma_d) + \varepsilon_{fd},$$

253

254 Where, Y is the outcome variable (the number of health services delivered during the last month

255 preceding the survey) at sub-center f in district d, X_n represents the facility and district-level demographic

256 factors affecting the outcome, and ε_{fd} is the error term and σ_d is the random effect that varies at the

257 district level. The random intercept σ_d captures the effect of unobserved district-specific characteristics

258 that cause some districts to have facilities that produce a greater volume of services than others, such as

259 the presence of fewer private health facilities or the socioeconomic and demographic characteristics of a

260 given population; these factors can potentially affect the demand for maternity services. The catchment

261 population of HSC served as an 'exposure variable' in all models. Initially, individual covariates were

262 tested separately for their association with the dependent variables; the results are given under the

263 'unadjusted' columns in Tables 2, 3, and 4. Following that, full regression models featuring all covariates

264 were run to obtain 'adjusted' coefficients.

265 After the regression, the residuals from each model were tested for the presence of heteroscedasticity

266 using Park's test. The test results of all three models confirmed the presence of heteroscedasticity (results

267 not shown; available on demand). In the presence of heteroscedasticity, although the estimated coefficient

268 remained unbiased and consistent, the estimated standard errors were not reliable. Hence, White's robust

269 procedure (using the 'robust' command in Stata) was applied to obtain robust standard errors.

270 Alpha, the over-dispersion parameter, is presented at the bottom of each model in Tables 2, 3, and 4. If

271 alpha is zero, then the data are not over-dispersed and a Poisson model is suitable. If alpha is greater than

272 zero, then the data are over-dispersed and the negative binomial distribution is able to model the data

273 more accurately than Poisson distribution. In order to test that the dispersion parameter, alpha, is equal to

274 zero, a likelihood ratio chi-square test was applied; the results are also presented in Tables 2, 3, and 4.

275 The presence of large test statistics with very small P-values suggests that the response variables were
276 over-dispersed and that they were better estimated using negative binomial regression than a Poisson
277 model.

278 All models were tested for any potential multicollinearity among the independent variables; the variance
279 inflation factor (VIF) was used as a post-estimation procedure. The overall VIFs for the models were very
280 small (see the footnotes in Tables 2, 3, and 4), and wherever there was any evidence of high
281 multicollinearity, the variables/categories responsible for causing this multicollinearity were dropped
282 from the analysis. Tables 1A, 1B, and 1C in the Appendix present detailed VIFs for each model. The
283 analysis was conducted using the Stata (version 12.0) statistical software (Stata Corp, 2012).

284

285 **Results**

286 In this study, the analytical samples did not include any missing or 'don't know' responses. Also, health
287 facilities with missing, zero, and 'don't know' responses were not included in the analytical sample. As a
288 result, the analytical sample was reduced to 17,537 HSCs for antenatal care, 16,030 HSCs for delivery
289 care, and 17,112 HSCs for postnatal care.

290 The summary statistics for the dependent and independent variables are given in Tables 1A and 1B.
291 Tables 2, 3, and 4 report the results from the negative binomial regression models for antenatal
292 registrations, deliveries, and postnatal services, respectively. The results are reported in the form of
293 unadjusted and adjusted incidence rate ratios (IRRs), along with their 95% confidence intervals (CIs). An
294 IRR greater than 1 implies that an increase in the dependent variable is associated with an increase in the
295 outcome variable, and vice versa. The independent variables used in this study have been grouped under
296 six previously described categories: health personnel, drug availability, equipment, infrastructure, facility
297 quality, and the population's socioeconomic and demographic characteristics.

298   [Tables 1A and 1B here]

299 The results of the analysis revealed that those HSCs run solely by a contractual ANM were associated
300 with a lower volume of maternal health care services when compared to those run solely by a permanent
301 ANM. The delivery of antenatal and postnatal services in those sub-centers that were solely run by a
302 contractual ANM was about 8%–9% less than at those sub-centers run solely by a permanent ANM. The
303 volume of deliveries in these HSCs decreased by about 30% [IRR=0.709, P=0.017]. The deployment of
304 two ANMs was associated with a slight increase in the volume of postnatal services [IRR=1.052,
305 P=0.014]. The HSCs without an ANM were expected to have a lower volume of antenatal registrations
306 [IRR=0.846, P=0.001], deliveries [IRR=0.579, P=0.000], and postnatal services [IRR=0.828, P=0.001].

307         [Table 2 here]

308  The availability of essential obstetric drugs was associated with increases in the volume of delivery

309  services provided [IRR=1.060, P=0.000]. In the case of antenatal registrations, the availability of IFA

310  tablets/syrup and paracetamol did not turn out to be statistically significant. The results also revealed that

311  the availability of a blood pressure instrument was expected to slightly increase the volume of antenatal

312  registrations [IRR=1.047, P=0.029] and postnatal care services [IRR=1.053, P=0.001]. The effect of the

313  availability of an examination table on the volume of health service delivery was also statistically

314  significant. In those HSCs where an examination table was not available, the volume of antenatal

315  registrations and postnatal services decreased by about 4%–6%. A similar finding emerged in the case of

316  labor table availability. The volume of deliveries that were conducted decreased significantly if a labor

317  table was 'available but not functional' [IRR=0.652, P=0.000] or not available at all [IRR=0.438,

318  P=0.000]. Another variable that turned out to be statistically significant in the analysis was the

319  unavailability of a bed screen. The unavailability of a bed screen decreased the volume of antenatal

320  registrations and postnatal services by about 4%–5%. The negative effect of the unavailability of a bed

321  screen was much stronger for delivery services [IRR=0.694, P=0.000].

322         [Table 3 here]

323  A number of variables under the infrastructure category were significantly associated with the volume of

324  maternal health services provided at the HSCs. Not having an electricity connection was associated with

325  an approximately 32% decrease in the volume of deliveries [IRR=0.678, P=0.000] and a nearly 9.5%

326  decrease in antenatal registrations [IRR=0.915, P=0.000]. The availability of water, telephones, and toilet

327  facilities was likely to increase the volume of deliveries at sub-centers by about 20%, 30%, and 44%,

328  respectively. The volume of postnatal services was also expected to increase in those HSCs that were

329  equipped with telephone and toilet facilities.

330         [Table 4 here]

331  In sub-centers where VHSCs monitored the ANMs' work, the volume of antenatal registrations and

332  postnatal services was expected to increase by about 5% and 8%, respectively. Although ISDT was not

333  associated with the volume of antenatal registrations, it was significantly associated with a slight increase

334  in the volume of postnatal services [IRR=1.030, P=0.028]. Similarly, skilled birth attendance training

335  (SBAT) was also associated with an increase in the volume of postnatal services [IRR=1.034, P=0.019]

336  and deliveries [IRR=1.285, P=0.000]. Maternal health service utilization at sub-centers was found to be

337  inversely associated with the distance of an ANM's actual residence from the sub-center village where

338  she works. This was particularly true for delivery and postnatal services. For instance, at HSCs where the

339   ANM lived 5–20 kilometers away from the sub-center village, the utilization of postnatal services

340   decreased by about 4%, and if the ANM lived more than 40 kilometers away, the utilization reduced by

341   about 9%.

342

343   **Discussion**

344   Using the most recent data available in the public domain, this study explored the association between

345   sub-center characteristics and the volume of maternal health services delivered by those HSCs. The

346   results suggest that the availability of essential obstetric drugs, blood pressure instruments,

347   labor/examination tables, bed screens, and basic amenities such as water, electricity, toilets, etc., are the

348   main supply-side factors that shape maternal health care utilization at sub-centers in India. The

349   monitoring of an ANM's work by the VHSC, the provision of an ANM's in-service training, and the

350   distance of the ANM's residence from the sub-center village also play important roles in maternal health

351   care utilization at the sub-centers.

352   One significant finding of this study is that those sub-centers that are run solely by a contractual ANM

353   delivered fewer services than those sub-centers run by a permanent ANM, despite controlling for other

354   relevant factors. This applies to all three maternal health services considered in this study. This finding is

355   particularly important because one of the key strategies of the National Rural Health Mission, which is an

356   immediate measure that has been implemented to increase the availability of health workers in publicly

357   funded rural public health facilities, is to deploy contractual ANMs instead of recruiting permanent

358   ANMs (Dhingra & Dutta, 2011). It is argued that recruiting contractual ANMs is both convenient and

359   economical for the government (Prinja et al., 2014). However, this study indicates that this measure,

360   despite its benefits to the government, does not seem to result in any substantial improvement in the

361   utilization of maternity services. The results of our study show that the utilization of maternal health care

362   services at HSCs run solely by a contractual ANM are not at par with those solely run by permanent

363   ANMs. The volume of service delivery does not rise substantially, even when both ANMs run a sub-

364   center. In other words, deploying a second ANM to sub-centers on a contractual basis is not likely to

365   improve maternal health service utilization.

366   There may be a number of factors that may lead to the anomalous performance of ANMs in these two

367   streams. Previous studies have recorded how low motivation is an important factor that underlies the poor

368   performance of contractual workers. Workers' low motivation is often the result of a number of factors

369   such as job insecurity, low salary, fewer privileges, discrimination between regular and contractual staff

370   by higher authorities, the lack of a career path, and so on (Kumar, Khan, Inder, & Anu, 2014; Kumar,

371   Khan, Inder, & Mehra, 2014; Kumar, Khan, Inder, & Sharma, 2013). With respect to workers' salary,

372   there is a significant difference in the pay offered to contractual and regular employees. Contractual

373   ANMs receive much less remuneration for the same amount of work and responsibilities as a permanent

374   ANM. For instance, a contractual ANM in the state of Bihar earns a meager ₹11,500 per month when

375   compared to a permanent ANM, who receives a salary of ₹25,000 per month (Government of Bihar,

376   2011, 2014). A similar difference is found in other states as well. Therefore, the government and

377   policymakers should look into this issue and develop a solution to ensure that the investment they are

378   making in deploying contractual ANMs is optimally utilized.

379   The provision of quality maternal care services not only depends on skilled health personnel, but it is also

380   reliant on the availability of essential drugs and supplies (Yeager, 2012). In line with previous studies,

381   this investigation finds that the availability of essential obstetric drugs is strongly associated with a higher

382   volume of delivery and postnatal care services at the HSCs (Mkoka, Goicolea, Kiwara, Mwangu, &

383   Hurtig, 2014). However, regrettably, about 42% of sub-centers are still devoid of all the essential obstetric

384   drugs recommended by the Indian Public Health Standards. A lack of essential obstetric drugs at the

385   facility may have huge implications for maternal mortality at the facility level. A recent study has

386   concluded that increased facility deliveries in India do not contribute to a reduction in maternal deaths

387   because these facilities often have a weak drug and medical supply system, which leads to poor obstetric

388   care quality (Randive, 2016). The lack of drugs has also been found to cause distrust between users and

389   health care providers; it creates a difficult working environment and decreases health workers' morale as

390   well (Mkoka et al., 2014). All of these factors, when combined, could result in the low utilization of

391   health care services.

392   The study also finds that the non-availability of a labor/examination table and bed screen significantly

393   reduced the volume of services delivered at the sub-centers. This finding is also in line with the findings

394   of a previous study (Kumar & Dansereau, 2014). Like labor or examination tables, bed screens are also

395   essential items; women do not feel comfortable during medical examinations when there are no bed

396   screens. It must be noted that the descriptive results indicate that about 60% of sub-centers do not have a

397   labor table and about 74% do not have a bed screen; furthermore, about 40% do not have an examination

398   table. It is clear that there is plenty of room for improvement in these areas. Therefore, efforts should be

399   made to equip sub-centers with these essential items.

400   In this study, the VHSC's ability to monitor the sub-center had a statistically significant effect on the

401   antenatal and postnatal care services provided. This finding was consistent with those of a recent study,

402   which concluded that the percentage of women seeking antenatal and postnatal care is higher in VHSC

403   villages than in non-VHSC villages (Sah et al., 2013; Srivastava et al., 2016). Unfortunately, about 28%

404   of all sub-centers do not have a VHSC constituted in their area. Furthermore, about 12% of all sub-centers

405 that do have VHSCs in their area are not monitored on a regular basis. Given the evidence that regular

406 monitoring of the ANMs' work by the VHSC is associated with an increase in the volume of health

407 services delivered, VHSCs should be in place for all sub-centers in the country; the VHSCs should also

408 regularly monitor the ANMs' work (Kumar & Prakash, 2013).

409 The quality of maternal health care services at sub-centers largely depends on the effectiveness with

410 which health workers discharge their responsibilities; this, in turn, would mainly depend on the workers'

411 training, particularly their in-service training (Giri et al., 2012). There are two types of in-service training

412 programs for ANMs that are relevant to the maternal health services provided at the sub-center level. The

413 first is known as integrated skills development training (ISDT), which is meant to upgrade the ANM's

414 clinical, managerial, and communication skills. The second type of training is referred to as SBAT, which

415 is intended to enable ANMs to successfully perform normal deliveries. The results of this study show that

416 both types of training are associated with a higher volume of maternal service utilization at the sub-center.

417 This finding is consistent with the results of two recent reports that investigated the utilization of MCH

418 services at publicly funded health facilities in India (Kumar & Dansereau, 2014; Sharma, Sharma, &

419 Livesley, 2014). Unfortunately, the descriptive results show that the ANMs in more than 51% of sub-

420 centers did not undergo IST even once in the last five years. The case is similar for SBAT, where the

421 figure is even higher (67% of sub-centers). Therefore, the government should take steps to implement

422 these trainings at regular intervals.

423 Another important variable that is significantly associated with the volume of maternal health services is

424 the distance of the ANM's actual residence from the sub-center village. The effect is particularly strong in

425 the case of delivery care. The descriptive statistics show that about 45% of ANMs live more than 5

426 kilometers away from their sub-center's village. Health workers living away from the health facility

427 where they work is associated with increased employee absenteeism and reduced hours of work which, in

428 turn, affect the quality and quantity of the health services provided (Mahapatra, Thota, George, & Reddy,

429 2012; Muralidharan, Chaudhury, Hammer, Kremer, & Halsey, 2011). Hence, it is not surprising that the

430 utilization of maternal health care services at those sub-centers with non-resident ANMs is lower than at

431 those sub-centers where the ANM lives within proximity of the sub-center's village.

432 This study has several strengths. First, it contributes to the scant literature that has investigated the effect

433 of facility characteristics (supply-side factors) on maternal health care utilization at public health facilities

434 in rural India. Since most of the basic MCH services are provided through HSCs, it is imperative to

435 understand the barriers that restrict a patient's utilization of maternal health services at this particular

436 level of the public health system in rural areas. Second, this study adopted a large-scale nationally

437 representative survey; hence, the results presented herein are fairly reliable and can be generalized to the

438   national level. Third, the application of a count model – i.e., a negative binomial model – provides us with

439   better estimates than other count models, particularly featuring variables like the ones used in this study;

440   here, a count model was the best model to use in this context.

441   This study has a few limitations as well. Firstly, the analysis does not include any indicators that represent

442   the availability of private sector health care services in the sub-center area. It is well known that a

443   considerable amount of the population in rural areas seeks health care services in private facilities,

444   arguably because of the poor quality of services in public health facilities. However, due to the lack of

445   variables in the dataset that pertained to private health facilities, the analysis could not control for private

446   health facilities in the analysis. For the same reason, the study was not able to incorporate any quality of

447   care-related variables (e.g., health workers' behavior toward patients). Secondly, all demand-side

448   variables were calculated at the district-level; therefore, they may not be truly representative of the

449   population's characteristics in the sub-centers' catchment areas. Thirdly, the variable 'number of antenatal

450   registrations' does not represent the actual number of antenatal care services provided at the health

451   facilities – a measure that is more important from a policy perspective. Fourthly, since the data used in the

452   study were collected using face-to-face interviews, it is also likely that the data suffer from response bias,

453   which arose from respondents' inability to accurately answer questions and their unwillingness to respond

454   honestly. Lastly, since the study is based on cross-sectional data, causality could not be inferred. One

455   needs to conduct a panel data study to address the issue of reverse causality or temporality.

456

457   **Conclusion**

458   Apart from highlighting the fact that a considerable number of HSCs are still understaffed and

459   inadequately equipped, this study found that essential obstetric drugs, blood pressure instruments,

460   labor/examination tables, bed screens, and basic amenities such as water, electricity, toilets, etc., are some

461   important supply-side factors that affect the utilization of health services at HSCs in rural India. Other

462   factors include the VHSC's ability to monitor the ANMs' work, the provision of in-service training for

463   ANMs, and distance of an ANM's residence from the sub-center's village. Unlike socioeconomic factors,

464   the supply-side factors mentioned above can be easily influenced by government interventions in a short

465   period of time. Hence, future government interventions to improve maternal health care utilization in rural

466   areas should consider these factors. Although this study has answered many questions, some unanswered

467   questions also remain. For instance, why is the volume of service utilization in those HSCs run solely by

468   contractual ANMs more likely to be lower than in those HSCs run solely by permanent ANMs? Future

469   studies can examine this anomaly in detail to determine why the presence of contractual ANMs is

470   associated with lower service utilization. Since the utilization of maternal health care services is shaped

471   by a complex web of supply and demand factors featuring a multitude of interactions, more research is

472   needed to tease out these complex relationships.

Other variables						
Region						
Central	1.517	0.000	1.330, 1.732	1.149	0.063	0.992, 1.330
Northeast	0.893	0.182	0.757, 1.054	1.029	0.705	0.887, 1.194
East	1.599	0.000	1.345, 1.901	1.222	0.025	1.026, 1.455
West	1.561	0.000	1.320, 1.845	1.268	0.003	1.084, 1.482
South	1.458	0.000	1.253, 1.698	1.191	0.017	1.031, 1.376
ANM's residence from SC (in km)						
5-20	0.941	0.000	0.914, 0.968	0.962	0.009	0.935, 0.991
21-40	0.901	0.000	0.868, 0.935	0.940	0.001	0.907, 0.976
>40	0.853	0.000	0.795, 0.915	0.918	0.015	0.856, 0.984
Log of catchment population	1.350	0.000	1.317, 1.384	1.318	0.000	1.286, 1.352
Socioeconomic variables						
% population in lowest wealth quintile	1.005	0.195	0.998, 1.012	1.007	0.024	1.001, 1.013
Total fertility rate	1.071	0.002	1.026, 1.117	1.011	0.675	0.960, 1.065
% Hindu population	1.008	0.000	1.006, 1.009	1.004	0.000	1.002, 1.006
Maternal education (in years)	0.949	0.000	0.933, 0.966	0.952	0.000	0.931, 0.973
Dispersion parameter (alpha)				0.419	0.000	0.407, 0.432
Likelihood-ratio test of alpha=0: Chi² Statistic = 1894.2 (*p* = 0.000)						

712 *Note: IRR- Incidence Rate Ratio, CI- Confidence Interval, ANM- Auxiliary Nurse Midwife, VHSC- Village Health and Sanitation*
713 *Committee, SC- Sub-Centre/Health Sub-Centre, ISDT- Integrated Skills Development Training, SBA – Skilled Birth Attendance.*
714 *Mean Variance Inflation Factor – 1.63 (for detailed VIF, see Appendix*
