

# Germination of *Acacia harpophylla* (Brigalow) seeds in relation to soil water potential: Implications for rehabilitation of a threatened ecosystem

Initial soil water conditions play a critical role when seeding is the primary approach to revegetate post-mining areas. In some semi-arid climates, such as the Brigalow Belt Bioregion in eastern Australia, extensive areas are affected by open-cut mining. Together with erratic rainfall patterns and clayey soils, the Brigalow Belt denotes a unique biome which is representative of other water-limited ecosystems worldwide. Apart from other environmental stressors, germination is governed by the water potential of the surrounding soil material. While previous studies have confirmed the high tolerance of Brigalow (*Acacia harpophylla*) seeds to a broad range of temperature and salinity, the question of how soil water potential triggers seed germination remains. In this study, we used three replicates of 50 seeds of Brigalow to investigate germination in relation to water potential as an environmental stressor. Solutions of Polyethylene Glycol (PEG 6000) were applied to expose seeds to nine osmotic water potentials ranging from soil water saturation (0 MPa) and field capacity (-0.01 to -0.03 MPa) to the permanent wilting point (-1.5 MPa). We measured germinability (number of germinated seeds relative to total number of seeds per lot) and mean germination time (mean time required for maximum germination of a seed lot) to quantify germination. Based on the empirical data of the germination we estimated the parameters of the hydrotime model which simulates timing and success of seed emergence. Our findings indicate that Brigalow seeds are remarkably tolerant to water stress, with germination being observed at a water potential as low as -1.5 MPa. Likewise, the average base water potential of a seed population (hydrotime model) was very low and ranged between -1.533 MPa and -1.451 MPa. In general, Brigalow seeds germinate opportunistically over a broad range of abiotic conditions related to temperature, salinity, and water availability. Direct seeding and germination of native plants on post-mining land may be an effective and economically viable solution in order to re-establish plant communities.

However, due to their capacity to reproduce asexually, alternative rehabilitation approaches such as transplantation of whole soil-root compartments may become attractive for restoration ecologists to achieve safe, stable, and non-polluting ecosystems.

## 4 1 Introduction

5 The Brigalow Belt is an extensive bioregion located between the subtropical coastline and semi-arid  
6 interior of eastern Australia ([Arnold et al. 2013](#)). Climatically and pedologically the bioregion is distinct  
7 from surrounding areas ([Isbell 2002](#); [Lloyd 1984](#)), and as a consequence, its ecological and biodiversity  
8 attributes are unique worldwide ([Johnson 1980](#)). Rainfall events occur erratically, both between years and  
9 intra-seasonally, and the clayey soils have high fertility and good water holding capacities ([Gunn 1984](#)).  
10 Of the few plant species able to survive under these water-limited constraints ([Connor & Tunstall 1968](#)),  
11 *A. harpophylla* (Brigalow) is the predominant one, from which the bioregion derives its name.

12 Since the 1950s, the delicate balance between soils and the native plant communities has been  
13 disrupted ([Eyre et al. 2009](#)) through clearance of Brigalow woodland for agricultural land use (cropping,  
14 grazing), which reduced the original extension of the bioregion dramatically ([Arnold et al. 2013](#)).  
15 Consequently, *A. harpophylla* dominant ecosystems have been listed as endangered under both state  
16 (*Vegetation Management Act 1999*) and national legislation (*Environment Protection and Biodiversity*  
17 *Conservation Act 1999*: EPBC Act) ([DEWHA 2010](#)). More recently, areas in the Bowen Basin (largest  
18 coal reserve in Australia) have been concurrently affected by surface mine developments. The legislative  
19 requirement to reclaim post-mining land to provide safe, stable, and non-polluting environments  
20 ([Australian Government 2006](#)) provides the opportunity to re-establish native Brigalow plant  
21 communities.

22 Re-vegetation typically comprises either passive regeneration or proactive management such as  
23 transplanting seedlings and mature stands ([Musselman et al. 2012](#)), tube stocking, or direct seeding. The  
24 latter may be an effective and economically viable solution in order to re-establish Brigalow plant  
25 communities ([Engel & Parrotta 2001](#); [Lamb et al. 2005](#); [Reichman et al. 2006](#)). In this regard, seed  
26 germination is an important indicator of re-vegetation success as it represents the first stage of plant  
27 physiological response and development to environmental conditions. Seed germination can be controlled  
28 by a range of abiotic stressors of which temperature and salinity have only limited impact on *A.*  
29 *harpophylla* seeds within the ranges of 15 to 38°C and 0 to 20 dS/m, respectively ([Reichman et al. 2006](#)).  
30 However, given the unique pedological and climatic conditions of the Brigalow Belt, the question remains  
31 how Brigalow seeds respond to changes in water availability from soil. This quantitative information is  
32 crucial for simulating timing and success of seed emergence, for example when applying the hydrotime  
33 model ([Bradford 1990](#); [Gummerson 1986](#)).

34 Although being the major environmental stressor in the Brigalow Belt Bioregion, less information  
35 exists on the direct effect of soil water potential on germination of *A. harpophylla* seeds. Therefore, the  
36 primary aim of this study is to determine their germination response in relation to soil water potential. In  
37 this regard, we investigate whether reduced germination at high values of soil salinity is due to toxic rather  
38 than osmotic effects ([Reichman et al. 2006](#)). As a secondary goal and based on the empirical data of the  
39 germination trials we estimate the parameters of the hydrotime model for *A. harpophylla*. Finally, we  
40 discuss our findings in the context of previous seed germination trials and alternative opportunities to re-  
41 establish plants on post-mining areas under water limited conditions.

## 42 2 Materials and Methods

### 43 2.1 Experimental design

44 We used seeds<sup>1</sup> of *A. harpophylla* to investigate germination in relation to water potential as  
 45 environmental factor. Three replicates of 50 seeds per treatment (i.e., water potential) were placed at equal  
 46 distance on an absorbent substrate (Wettex®). Materials (e.g., tweezers, Wettex®, glassware) were  
 47 autoclaved for 20 minutes at 121°C and preparation of treatments as well as any monitoring took place in  
 48 a laminar flow cabinet. All treatments and replicates were then placed randomly within a germination  
 49 cabinet under constant temperature (25°C) and a 12 hour day and night cycle. Seeds were removed from  
 50 petri dishes once a perceptible radicle emerged. The experiment ceased after five days with no further  
 51 germination. No pre-treatment of seeds was required for the selected species to break dormancy ([Schmidt](#)  
 52 [2000](#); [Turnbull & Martensz 1982](#)).

53 For controlled experiments on seed-soil relations the osmotic water potential can be used to represent soil  
 54 matric potential ([Carpita et al. 1979](#); [Gray et al. 1990](#); [McWilliam & Phillips 1971](#)). We used solutions of  
 55 polyethylene glycol (PEG 6000) to expose seeds to nine osmotic water potentials: 0, -.01, -.03, -.1, -.25,  
 56 -.5, -.75, -1, and -1.5 MPa. These values capture soil water conditions ranging from water saturation (0  
 57 kPa) and field capacity (-.01 to -.03 MPa) to the permanent wilting point (-1.5 MPa). The empirical  
 58 equation derived by [Michel & Kaufmann \(1973\)](#) and revised by ([Wood et al. 1993](#)) was used to set up the  
 59 required water potential ( $\psi$  in kPa):

$$60 \quad \psi = (6.3 \cdot 10^{-5} T - 0.02196) O^{2.2357}, \quad (1)$$

61 where  $T$  is the temperature in K (here 298.15 K), and  $O$  denotes the osmolality in g 1,000 g<sup>-1</sup> of  
 62 water. Solutions measuring 15 ml of PEG 6000 were added to the seeds on the Wettex® substrate within a  
 63 90 mm petri dish and wrapped with Parafilm® to prevent evaporation. The dishes were opened each day  
 64 to provide aeration and to count and remove germinated seeds.

### 65 2.2 Germinability and mean germination time

66 We used germinability  $G$  (%) and mean germination time  $\bar{t}$  (days) as measurements to quantify  
 67 germination ([Ranal & Santana 2006](#)). While  $G$  simply represents the number of germinated seeds ( $g$ )  
 68 relative to the total number of seeds per replicate ( $n$ ):

$$69 \quad G = (g/n) 100, \quad (2)$$

70  $\bar{t}$  denotes the mean length of time required for maximum germination of a seed lot ([Czabator 1962](#)):

$$71 \quad \bar{t} = \frac{\sum_{i=1}^k g_i t_i}{\sum_{i=1}^k g_i}, \quad (3)$$

72 where  $t_i$  is the time elapsed from initiation of the experiment to the  $i^{\text{th}}$  observation day until germination  
 73 ceases on the  $k^{\text{th}}$  day.

1 1 Seeds were collected in November 2012 from the native Brigalow catchment at the Brigalow Research  
 2 Station (Cowie et al., 2007).

We applied a generalised logistic regression model (GLM) on a logit scale and simple linear regression for  $G$  and  $t$ , respectively, to test the significance of the relationship between germination percentage or time required for maximum germination and decreasing water potential. Assumptions were tested via diagnostic plots, which showed no violation of homogeneity of variance and normal distribution for the residuals. Separate GLM models were adopted for each species as this provided the best fit for the data. We also employed other models (linear regression and logistic regression with a probit scale) and various transformations (arcsine, square root transformations) but they either did not fit the data, or when they did, failed homogeneity of variance and normal distribution of error ( $p > 0.05$ ).

We compared the results for  $G$  with those published by [Reichman et al. \(2006\)](#) for salinity. Therefore, we estimated the osmotic pressure  $\psi_o$  (MPa) based on the value range of electrical conductivity used in Reichman 2006:

$$\psi_o = MRT \quad (4)$$

where  $M$  is the molarity ( $\text{mol L}^{-1}$ ) of the sodium chloride solution,  $T$  is the temperature in K (here 298.15 K), and  $R$  is the gas constant ( $\text{J mol}^{-1} \text{K}^{-1}$ ). The corresponding values of  $\psi_o$  are presented in Table 1.

### 2.3 Estimating parameters of the hydrotime model

The hydrotime model was proposed by ([Bradford 1990](#); [Gummerson 1986](#)) to “simultaneously account for both the timing and the extent of germination of a given seed population in relation to its  $\psi$  environment” ([Bradford 2002](#)). It is defined as:

$$\theta_H = (\psi - \psi_b(P)) t_P \quad (5a)$$

where  $\theta_H$  is the hydrotime constant (MPa hr),  $t_P$  (hr) is the time to germination of percentage  $P$  of the seed population, and  $\psi_b(P)$  (MPa) is the base or threshold water potential above which  $P$  can still complete germination. Among the seed population,  $\psi_b$  is variable and can be described by a range of frequency distributions ([Mesgaran et al. 2013](#)) of which the normal frequency distribution is the most commonly used one, defined by its mean  $\psi_b(P_{50})$  and standard deviation  $\sigma_{\psi_b}$  ([Gummerson 1986](#)). Together, these parameters enable prediction of the germination time courses, i.e. both rate and extent of germination of the seed population, at any  $\psi$  at a constant temperature ([Bradford 2002](#)):

$$t_P = \theta_H / (\psi - \psi_b(P_{50})) \quad (5b)$$

In this regard,  $\theta_H$  “quantifies the inherent speed of germination, which can vary among species and physiological states” ([Bradford 2002](#)), whereas  $\psi_b(P_{50})$  indicates the average stress tolerance of a seed population, and  $\sigma_{\psi_b}$  describes the synchrony in germination timing among seeds in a population. We estimated these parameters based on the observed values of  $t_P$  for each  $\psi$ , i.e. we plotted the germination rates ( $1/t_P$  in  $\text{hr}^{-1}$ ) as a function of  $\psi$  and fitted regressions to the observed data (Fig. 4). This resulted in straight lines with slopes of  $\theta_H^{-1}$  and intercepts on the  $\psi$ -axis corresponding with  $\psi_b(P)$ . The values of  $\psi_b(P)$  were then fitted to a normal and log-logistic frequency distribution, respectively, and their distribution parameters were estimated accordingly.

### 109 3 Results

110 Spearman's correlation coefficient of -0.96 indicated a significant ( $p = 10^{-4}$ ) negative correlation  
 111 between mean time required for maximum germination and germinability (Fig. 1). Above -.75 MPa  
 112 germinability was remarkably large and mean germination time small. The mean time required for  
 113 maximum germination ranged between three and five days at water potentials higher than -.75 MPa and  
 114 increased to over seven days at water potentials lower than -1 MPa (Fig.2b). Likewise, germinability was  
 115 highest ( $90\% \pm 9\%$ ) at the water potential corresponding to saturated soil water conditions (0 MPa) and  
 116 significantly decreased with decreasing water potential ( $p = 0.003$ ) to  $65\% \pm 11\%$  and  $20\% \pm 9\%$  at water  
 117 potentials of -.75 MPa and -1 MPa, respectively (Fig. 2a). Remarkably, at a water potential as low as -1.5  
 118 MPa (permanent wilting point) still  $4\% \pm 1.8\%$  of the seeds germinated. Accordingly, the estimated mean  
 119 base water potentials were -1.533 MPa and -1.451 MPa for the normal and log-logistic distribution,  
 120 respectively (Fig. 3), and the estimated hydrotime constant was .0607 MPa h (Table 2).

121 In figure 4 we plotted the germinability of Brigalow seeds in relation to the osmotic pressure based  
 122 on solutions of sodium chloride as applied by Reichman et al. (2006), and solutions of Polyethylene  
 123 Glycol as applied in this study. While no significant differences ( $p < 0.05$ ) were observed between the two  
 124 treatments for osmotic pressures above -.4 MPa, germinability was smaller under the sodium chloride  
 125 treatment for osmotic pressures below -.4 MPa.

## 126 4 Discussion

127 The findings of this study allude to the seed water condition of *A. harpophylla*. Together with the  
128 initial soil water conditions, these state variables have crucial implications for the rehabilitation of post-  
129 mining areas under water-limited conditions.

### 130 4.1 Soil and seed water conditions

131 Initial soil water conditions play a critical role when direct seeding is the primary approach to  
132 revegetating post-mining areas. This is even more important in a semi-arid climate, where water is limited  
133 due its scarcity or erratic occurrence ([Rodriguez-Iturbe & Proporato 2004](#)). Seed germination is triggered  
134 by the amount of water the seed can imbibe, which is related to the water potentials of both the soil and  
135 the seed ([Bewley et al. 2013](#); [Bradford 2002](#); [Evans & Etherington 1990](#); [Williams & Shaykewich 1971](#)).  
136 In this regard, water can only enter the seed if the seed water potential is below the water potential of the  
137 surrounding soil material. In general, air-dry seeds have water potential values of -50 to -350 MPa  
138 ([Bewley et al. 2013](#)). The empirical results of this study indicate that seeds of *A. harpophylla* are very  
139 water stress tolerant, that is, their seed water potential is extraordinarily low. For example, radicles still  
140 emerged at a water potential as low as -1.5 MPa (Fig. 2a). Likewise, the mean base water potential of the  
141 seed population ranges between -1.533 MPa and -1.451 MPa (Table 2 and Fig. 3). These are remarkable  
142 values compared with selected Mediterranean ([Köchy & Tielbörger 2007](#))<sup>2</sup> and agricultural plant species  
143 ([Watt et al. 2011](#))<sup>3</sup>. Qualitatively, the low seed water potential corresponds well with other investigative  
144 studies on physiological water relations of *A. harpophylla* ([Doley 2004](#)), which measured foliage water  
145 potentials as low as -15 MPa ([Connor & Tunstall 1968](#)) and shoot water potentials of -7.2 to -6.8 MPa  
146 ([Connor et al. 1971](#); [Tunstall & Connor 1981](#); [Van den Driessche et al. 1971](#)). Also the seed coat, which is  
147 atypically soft compared with other Acacia species, denotes an adaptive mechanism to erratic rainfall  
148 patterns of the Brigalow Belt Bioregion to rapidly overcome dormancy if soil water conditions are  
149 elevated ([Johnson 1964](#); [Reichman et al. 2006](#); [Scott et al. 1984](#)).

150 The parameter estimates of the hydrotime model (Table 2) play a critical role for predicting the time  
151 required to germinate a fraction of the seed population under given soil water conditions (Eq. 5b). In this  
152 regard and together with the physiological parameters of the hydrotime model (i.e., hydrotime constant  
153 and distribution of the base water potential) the soil water potential governs germination and,  
154 consequently, the success of initial vegetation recruitment and early ecosystem establishment. Moreover,  
155 together with empirical data on the effect of temperature on the germination of Brigalow seeds ([Reichman  
156 et al. 2006](#)), the findings of this study can be utilised to parameterise hydrothermal models ([Bradford  
157 2002](#); [Bullied et al. 2012](#); [Gummerson 1986](#); [Köchy & Tielbörger 2007](#); [Watt et al. 2011](#)) for predictive  
158 modelling of germination in relation to the two environmental factors of temperature and water  
159 availability.

160 The results of this study show that germinability decreases and the time required for maximum  
161 germination increases with decreasing soil water potential (Fig. 2). Moreover, the strong negative  
162 correlation between germinability and mean germination time (Fig. 1) underpins how important a rather  
163 short germination time is to maximise germination success. Thus, topsoil restoration at post-mining land  
164 in the Brigalow Belt Bioregion should target to maximise the initial soil water potential while explicitly  
165 considering the erratic character of rainfall patterns in Central Queensland ([Audet et al. 2013](#); [Audet et al.  
166 2012](#)). This can be accomplished by optimising soil attributes such as depth, texture, compaction, organic

3  $\psi_b(P_{50}) = -1.39 - -.59 \text{ MPa}$  (based on 36 species)

4  $\psi_b(P_{50}) = -1.42 - -1.13 \text{ MPa}$  (based on 4 species)

amendments, etc ([Arnold 2012](#); [Arnold et al. 2013](#); [Zipper et al. 2013](#)). Apart from physical soil restoration, pre-treatment of seeds, i.e. seed priming, also plays a critical role to enhance germination ([Jisha et al. 2013](#)). Amongst the broad range of seed priming techniques, hydropriming and osmopriming are the most promising approaches for plant establishment in semi-arid climate to increase seedling growth ([Yagmur & Kaydan 2008](#)), and root and shoot length ([Kaur et al. 2002](#)). Although the exact mechanisms behind pre-treatments of seeds are not fully understood, seed priming seems to activate cell signalling pathways and cellular responses to environmental stressors resulting in faster plant defence responses ([Jisha et al. 2013](#)).

Despite plant available water being the primary environmental factor in the Brigalow Belt Bioregion ([Arnold et al. 2013](#)), due to hot summers and highly saline mine spoils secondary stressors such as temperature and salinity may also play a critical role for the germination success of *A. harpophylla*, which was tested by [Reichman et al. \(2006\)](#). Their findings indicate no significant trend in germination among the temperature range of 15 – 38°C<sup>4</sup>. Likewise, seeds of *A. harpophylla* showed remarkable tolerance to salinity up to an electrical conductivity of 30 dS m<sup>-1</sup>, however, with significant reduction in germination at salinity greater than 20 dS m<sup>-1</sup>. The authors speculated “*it seems unlikely that the reduced germination at 25 and 30 dS/m were due to osmotic effects*” (Reichman 2006). While the present study confirms this conclusion for high values of salinity (Table 1) corresponding to osmotic pressure values greater than -4 MPa (Fig. 4), no significant differences could be found between treatments of sodium chloride and PEG (section 2) for small values of osmotic pressure corresponding to high salinity (Fig. 4). That said, we conclude that under low to moderate levels of salinity the osmotic pressure plays the primary role for germination of *A. harpophylla* seeds rather than the toxic nature of the predominant salt (here sodium chloride), whereas salinity becomes the primary environmental stressor under high salt concentrations. More generally, seeds of *A. harpophylla* seem to germinate quite uniformly over a broad range of environmental conditions related to temperature, salinity, and water availability<sup>5</sup>.

## 4.2 Alternative rehabilitation approaches

Despite the opportunistic germination capability of *A. harpophylla* seeds, the question remains whether direct seeding denotes the optimal approach to rehabilitate native Brigalow ecosystems given the hydro-pedological<sup>6</sup>, climatic, and plant physiological attributes and conditions of the Brigalow Belt Bioregion.

Hydro-pedological processes are fundamental for the proliferation of Brigalow plant communities ([Arnold et al. 2013](#)). The predominant clay soils ([Isbell 2002](#)) comprise fine-textured non-cracking Grey and Black Dermosols (Lixisols ([Rees et al. 2010](#); [WRB 2006](#))), and uniform dark cracking Grey and Black Vertosols (Vertisols ([Rees et al. 2010](#))). The latter form “gilgais” ([Cowie et al. 2007](#); [Radford et al. 2007](#); [Thornton et al. 2007](#)), which denote ephemeral water storages if filled during intensive storm events. The climate is characterised by erratically distributed rainfall patterns with short and intensive storm events occurring during summer ([Cowie et al. 2007](#)), associated with the risk of water logging or soil erosion; whereas the very arid conditions during the winter season generally involve periods of water deficit ([Audet et al. 2013](#); [Audet et al. 2012](#); [Dalton 1993](#)). In combination with these erratic climatic conditions the soil properties facilitate rather low soil water potentials on the long-term ([Tunstall & Connor 1981](#)), and as a consequence, these landscapes can be colonised by a few plant species only, which

<sup>4</sup>  $G = 90\%$  after 14 days

<sup>5</sup> Note that soil hydraulic conductivity can become a limiting factor in dry soils (Bewley et al. 2013).

<sup>6</sup> interface between the pedosphere and the hydrosphere (Li et al. 2012)

is reflected in relatively low species richness and total vegetative biomass ([Isbell 2002](#); [Johnson 1980](#)). As elaborated in the previous section, among the species in the Brigalow Belt Bioregion, *A. harpophylla* developed very well adapted mechanisms to proliferate under these harsh conditions. The plants flower only sporadically ([Benson et al. 2006](#)) and thus seeds and seedlings are only produced in large numbers during years of extraordinary rainfall ([Butler 2007](#); [Johnson 1997](#)). However, *A. harpophylla* is able to reproduce asexually, i.e. through root suckering or sprouting even if aboveground parts of the plant are damaged dramatically, as long as belowground biomass and hydopedology stay intact ([Arnold et al. 2013](#)) and references therein). The extent of this vegetative reproduction is most pronounced if trees are young and severely damaged, and under dry conditions ([Johnson 1964](#)). In Colorado (USA) circumstances are similar with regard to the re-establishment of vegetatively regenerating Aspen (*Populus tremuloides*) on surface-mined land ([Musselman et al. 2012](#)), which initially failed due to severe damage to the root system and thus the limited access to water and nutrients ([Shepperd & Mata 2005](#)). However, rehabilitation was more successful when more comprehensive soil-root compartments were transplanted from local sources in combination with weed control and light irrigation with non-saline water ([Musselman et al. 2012](#)). In this regard, it seems to be crucial to keep the delicate balance between soil attributes (depth, compaction, texture) and root extension in balance. This innovative rehabilitation approach of transplanting the whole soil-root compartment may also be of interest for restoration ecologists engaged with re-establishment of Brigalow ecosystems in Central Queensland to achieve safe, stable, and non-polluting ecosystems ([Australian Government 2006](#)). However, the advantage of direct seeding over asexual propagation such as transplantation is the gain of genetic diversity – critical if ecosystems are forced to adapt to the projected changing climate of Central Queensland ([Low 2011](#)).

228 **Acknowledgments**

229 The authors would like to thank Steve Adkins and David Doley for critical discussions, as well as the two  
 230 reviewers Ana Vasques and Teresa Eyre for constructive comments. Further, we thank Stuart Irvine-Brown  
 231 for collection of *A. harpophylla* seeds – a pivotal contribution to this study.

## Table 2<sub>(on next page)</sub>

### Parameters estimates

Parameters estimates of the the hydrotime constant (Bradford 2002), and the log-logistic distribution (scale  $\alpha$ , shape  $\beta$ ) and normal distribution (mean  $\mu$ , standard deviation  $\sigma$ ) based on the germination trials of *A. harpophylla*.

**Table 2.** Parameters estimates of the the hydrotic constant ([Bradford 2002](#)), and the log-logistic distribution (scale  $\alpha$ , shape  $\beta$ ) and normal distribution (mean  $\mu$ , standard deviation  $\sigma$ ) based on the germination trials of *A. harpophylla*.

Parameter	Estimated value	Standard error
$\theta_H$ (MPa h)	.0607	.0117
<i>Normal distribution</i>		
$\mu$ (MPa)	-1.533	.798
$\sigma$ (MPa)	.642	.257
<i>Log-logistic distribution</i>		
$\alpha$ (MPa)	- 1.451	.0012
$\beta$ (-)	1.28	1.09

# Figure 1

Negative correlation between mean germination time and germinability. Spearman's correlation coefficient  $r_s$  is significantly different from zero ( $p = 10^{-4}$ ).

# Figure 2

## Germination results

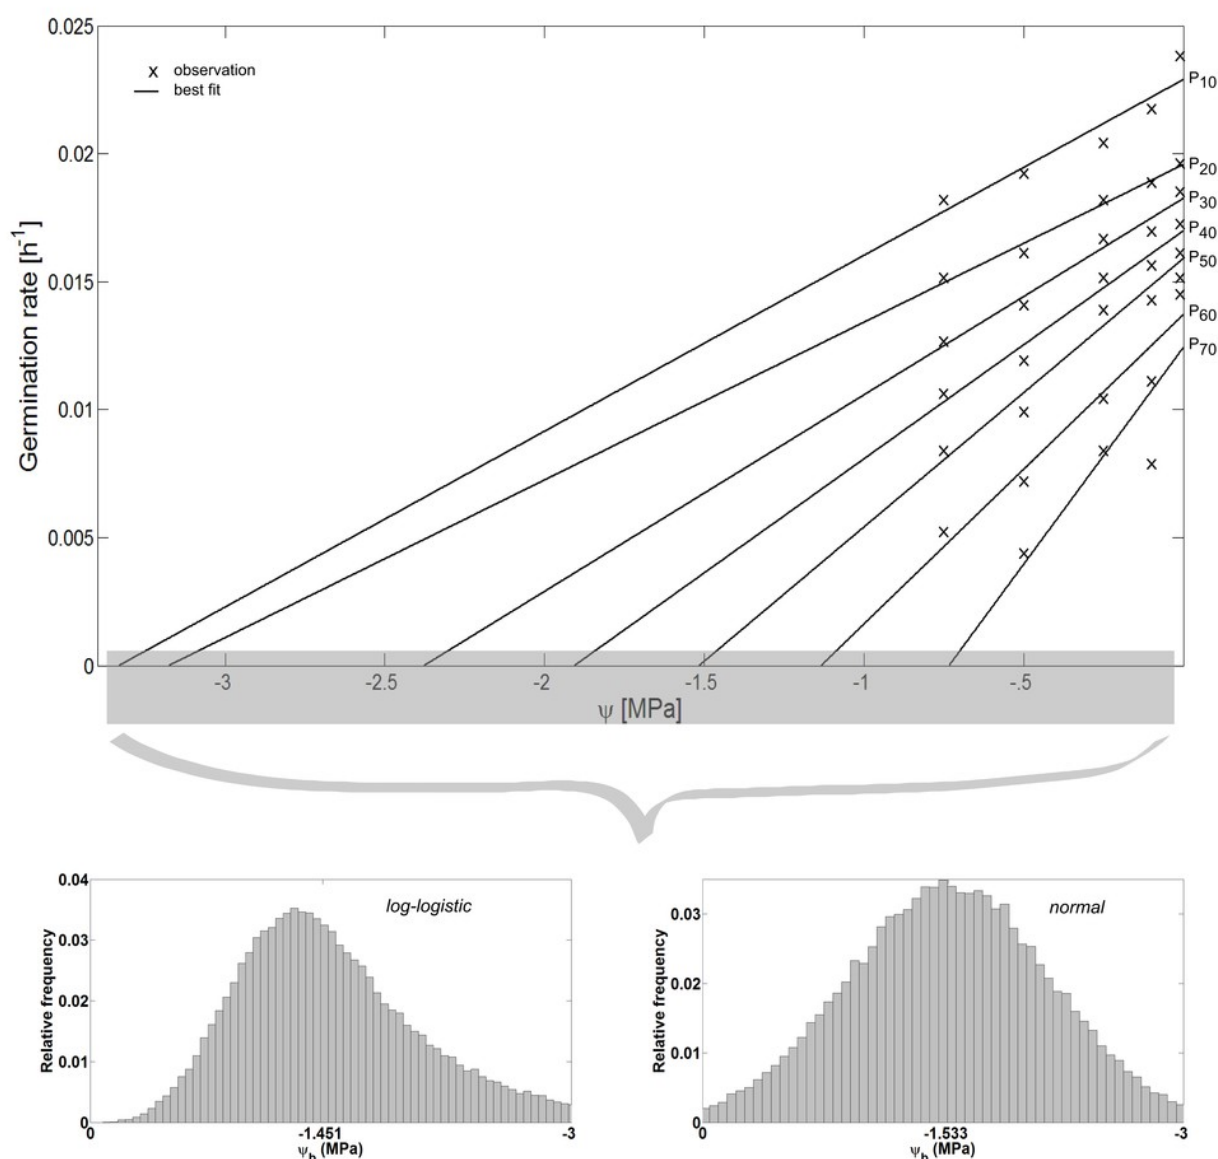

(a) Germinability  $G$  and (b) time required for maximum germination  $\bar{t}$  of *A. harpophylla* in relation to the water potential  $\psi$ . Error bars indicate the standard deviation across 3 replicates of 50 seeds.

# Figure 3

## Hydrotime model - parameters

Germination rate in relation to water potential  $\psi$  (adapted according to Bradford (2002)). While the slopes of the curves correspond to the reciprocal of the hydrotime constant  $\theta_H^{-1}$ , the interceptions with the  $\psi$ -axis correspond to the base water potential  $\psi_b$  for a given percentage  $P$  of the seed population. The values of  $\psi_b$  can be described by a range of frequency distributions (Mesgaran et al. 2013) among the seeds of a lot (inset). Parameter estimates of the log-logistic ( $\alpha$ ,  $\beta$ ) and normal distribution ( $\mu$ ,  $\sigma$ ), and  $\theta_H$  are presented in Table 2.

# Figure 4

## Water potential vs salinity

Germinability  $G$  of *A. harpophylla* in relation to the osmotic pressure  $\psi_o$  based on solutions of sodium chloride (squares (Reichman et al. 2006)) and PEG (crosses). Error bars indicate the standard error across 4 replicates of 20 seeds (Reichman et al. 2006) and 3 replicates of 50 seeds for salinity and soil water potential, respectively.
