Corvids (birds in the crow family) are hypothesised to have a general cognitive tool-kit because they show a wide range of transferrable skills across social, physical and temporal tasks, despite differences in socioecology. However, it is unknown whether relatively asocial corvids differ from social corvids in their use of social information in the context of copying the choices of others, because only one such test has been conducted in a relatively asocial corvid. We investigated whether relatively asocial Eurasian jays (*Garrulus glandarius*) use social information (i.e., information made available by others). Previous studies have indicated that jays attend to social context in their caching and mate provisioning behaviour; however, it is unknown whether jays copy the choices of others. We tested the jays in two different tasks varying in difficulty, where social corvid species have demonstrated social information use in both tasks. Firstly, an object-dropping task was conducted requiring objects to be dropped down a tube to release a food reward from a collapsible platform, which corvids can learn through explicit training. Only one rook and one New Caledonian crow have learned the task using social information from a demonstrator. Secondly, we tested the birds on a simple colour discrimination task, which should be easy to solve, because it has been shown that corvids can make colour discriminations. Using the same colour discrimination task in a previous study, all common ravens and carrion crows copied the demonstrator. After observing a conspecific demonstrator, none of the jays solved the object-dropping task, though all jays were subsequently able to learn to solve the task in a non-social situation through explicit training, and jays chose the demonstrated colour at chance levels. Our results suggest that social and relatively asocial corvids differ in social information use, indicating that relatively asocial species may have secondarily lost this ability due to lack of selection pressure from an asocial environment.

13 **ABSTRACT**

14 Corvids (birds in the crow family) are hypothesised to have a general cognitive tool-kit because
15 they show a wide range of transferrable skills across social, physical and temporal tasks, despite
16 differences in socioecology. However, it is unknown whether relatively asocial corvids differ
17 from social corvids in their use of social information in the context of copying the choices of
18 others, because only one such test has been conducted in a relatively asocial corvid. We
19 investigated whether relatively asocial Eurasian jays (*Garrulus glandarius*) use social
20 information (i.e., information made available by others). Previous studies have indicated that jays
21 attend to social context in their caching and mate provisioning behaviour; however, it is
22 unknown whether jays copy the choices of others. We tested the jays in two different tasks
23 varying in difficulty, where social corvid species have demonstrated social information use in
24 both tasks. Firstly, an object-dropping task was conducted requiring objects to be dropped down
25 a tube to release a food reward from a collapsible platform, which corvids can learn through
26 explicit training. Only one rook and one New Caledonian crow have learned the task using social
27 information from a demonstrator. Secondly, we tested the birds on a simple colour
28 discrimination task, which should be easy to solve, because it has been shown that corvids can
29 make colour discriminations. Using the same colour discrimination task in a previous study, all
30 common ravens and carrion crows copied the demonstrator. After observing a conspecific
31 demonstrator, none of the jays solved the object-dropping task, though all jays were
32 subsequently able to learn to solve the task in a non-social situation through explicit training, and
33 jays chose the demonstrated colour at chance levels. Our results suggest that social and relatively
34 asocial corvids differ in social information use, indicating that relatively asocial species may
35 have secondarily lost this ability due to lack of selection pressure from an asocial environment.

36 Introduction

37 A wide range of corvid species (e.g., crows, ravens, jays) are known for their complex
38 cognitive abilities, which are hypothesised to have been present in their common ancestor, thus
39 forming a ‘general cognitive tool-kit’ across this taxa (Emery & Clayton, 2004). For example,
40 even though rooks (*Corvus frugilegus*) do not make or use tools in the wild, they are able to
41 spontaneously innovate these behaviours in the lab (Bird & Emery, 2009b). Further, there is
42 evidence that some corvid species show cognitive competence across a wide range of social,
43 physical and temporal tasks. For instance, California scrub-jays (*Aphelocoma californica*) show
44 proficiency in cognitive tasks relating to memory (Clayton & Dickinson, 1998), future planning
45 (Clayton, Emery & Dickinson, 2006; Raby et al. 2007), and social cognition through cache
46 protection tactics (Clayton, Dally & Emery, 2007). As another example, rooks, in addition to
47 their tool abilities, cooperate with each other to solve novel problems (Seed et al. 2008) and
48 appear to understand support relationships because they look longer at impossible scenarios (e.g.,
49 a ball suspended in mid-air rather than sitting on a table; Bird & Emery 2010). Additionally,
50 New Caledonian crows reason about hidden causal agents (Taylor, Miller & Gray 2012), reason
51 by exclusion (Jelbert et al. 2015), and learn socially about novel foraging problems (Logan et al.
52 2016).

53 It is unknown whether this cognitive tool-kit includes the ability to use social information
54 specifically in the form of copying the choices of others, which is distinct from changing
55 behaviour when solving problems in different social contexts (several examples are given
56 below). The corvid common ancestor is hypothesised to have been social (Clayton & Emery,
57 2007). If this assumption is correct, rather than the common ancestor being asocial with sociality
58 having evolved several times in extant lineages, then there is reason to expect that relatively

59 asocial corvids could have retained the capacity to use social information. For example, it could
60 be adaptive by improving foraging and mate searching efficiency (e.g., Valone & Templeton,
61 2002). Alternatively, this ability could have been secondarily lost because of the lack of selection
62 pressure from an asocial environment, in a similar manner to the secondary loss of caching (food
63 hiding) in jackdaws (de Kort & Clayton, 2006). For example, in the absence of conspecifics for
64 most of the year, there might have been an increased selection pressure to rely solely on personal
65 information when foraging.

66 Most studies of corvid social information use, in the form of copying the choices of others,
67 have occurred in social species (species that live in groups of at least pairs year-round), which
68 makes it difficult to determine whether this ability is part of their general cognitive tool-kit.
69 Evidence of social information use, specifically copying the choices of others, has been found in
70 social corvid species, including pinyon jays (*Gymnorhinus cyanocephalus*; Templeton, Kamil &
71 Balda, 1999), rooks (Dally, Clayton & Emery, 2008), jackdaws (*Corvus monedula*; Schwab,
72 Bugnyar & Kotrschal, 2008a), common ravens (*Corvus corax*; Fritz & Kotrschal, 1999; Schwab
73 et al., 2008b), carrion crows (*Corvus corone corone*, *C. c. cornix*; Miller, Schwab & Bugnyar,
74 2016) and New Caledonian crows (*Corvus moneduloides*; Logan et al., 2016). Social species are
75 predicted to be better at acquiring new skills in a social context than in a non-social context
76 (Lefebvre & Giraldeau 1996), because they may attend more to conspecifics than asocial species
77 (Balda, Kamil & Bednekoff, 1997).

78 However, we are aware of only two tests of social information use in the form of copying
79 the choices of others in a relatively asocial corvid. Clark's nutcrackers (*Nucifraga columbiana*)
80 did not learn a motor or a discrimination task faster in a social learning condition than in an
81 individual learning condition, indicating that they did not use social information (Templeton,

82 Kamil & Balda, 1999). This was in contrast with highly social pinyon jays that did learn faster in
83 the social learning conditions (Templeton, Kamil & Balda, 1999). Additionally, Clark's
84 nutcrackers more accurately recovered caches they made rather than caches they observed others
85 make, in contrast with social Mexican jays that were accurate in both conditions (Bednekoff &
86 Balda 1996). These results suggest that relatively asocial corvids attend less to social information
87 than social corvids.

88 Outside of corvids, social learning in the form of copying conspecifics has been found in a
89 number of asocial species including red-footed tortoises (*Geochelone carbonaria*; Wilkinson et
90 al. 2010), black river stingrays (*Potamotrygon falkneri*; Thonhauser et al. 2013; Garrone Neto &
91 Uieda 2012), bearded dragons (*Pogona vitticeps*; Kis, Huber & Wilkinson 2014), and in juvenile,
92 but not adult, golden hamsters (*Mesocricetus auratus*; Lupfer, Frieman & Coonfield 2003) and
93 eastern water skinks (*Eulamprus quoyii*; Noble, Byrne & Whiting 2014). These non-corvid
94 species are likely to have had asocial ancestors, which suggests that social cues are not costly to
95 attend to and can evolve outside of a social context in these taxa. However, at present, the sample
96 size of the relatively asocial corvid species is too small to draw general conclusions about the
97 influence of a corvid's social system on their use of social information.

98 We addressed this gap by investigating whether the relatively asocial Eurasian jays
99 (*Garrulus glandarius*) used social information provided by a conspecific. Eurasian jays do not
100 live in social groups except during the breeding season when mated pairs defend a territory
101 (Goodwin 1951; Snow & Perrins, 1997; Clayton & Emery, 2007). There is evidence that socially
102 housed Eurasian jays attend to social context to modify their caching and mate provisioning
103 (courtship feeding) behaviour. For example, they prefer to cache in quiet rather than noisy
104 substrates when in the presence of conspecifics that could hear but not see the subject (Shaw &

105 Clayton, 2013); they attend to spatial and auditory cues when competitors are caching to later
106 pilfer those caches (Shaw & Clayton, 2014); and subordinates inhibit caching in front of
107 dominants and prefer to cache in less exposed areas (Shaw & Clayton, 2012). They also adjust
108 their behaviour appropriately depending on whether they are caching or pilfering (Shaw &
109 Clayton 2014), and whether they compete with a dominant or subordinate (Shaw & Clayton
110 2012). Furthermore, they prefer to cache out-of-sight behind an opaque barrier and at a distance
111 when observed by conspecifics (Legg & Clayton, 2014; Legg, Ostojic & Clayton, 2016). During
112 the breeding season, males are attentive to which foods their mates might prefer based on how
113 much of which foods she has already eaten (Ostojic et al., 2013; Ostojic et al., 2014).

114 These jays were socially raised and housed, which differs from their relatively asocial
115 system in the wild. The artificially social environment likely enhances their utilisation of any
116 innate social skills because these skills will have been given the opportunity to develop from an
117 early age. Therefore, if social skills are found in these conditions, it demonstrates the potential
118 flexibility of this species to use social cues (if social cues are used). As such, the social capacities
119 shown by socially raised and housed jays might differ from wild individuals. Despite the
120 evidence that socially housed Eurasian jays can respond to social context in caching and mate
121 provisioning paradigms, no study has yet tested whether this species uses social information to
122 copy the choices of others, which could be useful for learning about foraging opportunities even
123 in a relatively asocial species.

124 We tested whether socially housed Eurasian jays would use social information from a
125 conspecific demonstrator when learning to solve a novel problem – an object-dropping task
126 where an object must be dropped into a tube to release a food reward from a collapsible platform.
127 Further, if the birds did not use social information to solve the task, we tested whether there was

128 any evidence that they had attended to the demonstrator (as indicated by differences between
129 groups with differing levels of social learning opportunities), and what they might have learned
130 during this exposure. The object-dropping task has been used previously during pre-test training
131 for Aesop's Fable tasks in this species (Cheke, Bird & Clayton, 2011) as well as in a number of
132 other bird species (rooks: Bird & Emery, 2009a; New Caledonian crows: Jelbert et al., 2014;
133 Logan et al., 2014; Californian scrub-jays, Logan et al., 2016; great-tailed grackles, *Quiscalus*
134 *mexicanus*, Logan 2016). Aesop's Fable tasks require subjects to insert objects into water-filled
135 tubes to obtain out-of-reach floating rewards.

136 In the corvids that have been tested using this object-dropping task so far, we see a common
137 pattern, irrespective of whether they are habitual tool users. Namely, they are capable of learning
138 the object-dropping task, but only once they have experienced an object falling into a tube,
139 which usually occurs when they accidentally knock an object off the ledge into the tube. This
140 finding suggests that the birds need to see the object fall, and once they have, they can learn to
141 solve the rest of the task. This raises the question of whether they need direct experience of
142 manipulating the objects and observing them fall into the tube or whether witnessing another
143 individual's solution to the problem will suffice in learning the task. So far, only two birds have
144 solved the object-dropping task after observing a conspecific demonstrator: one rook (Bird &
145 Emery, 2009b) and one New Caledonian crow (Mioduszevska, Auersperg & von Bayern, 2015),
146 though only the latter study aimed to explicitly test for influences of social information use on
147 learning this task. New Caledonian crows are habitual tool users in the wild (Hunt, 1996), whilst
148 rooks - like Eurasian jays - are not, though rooks have shown tool-use and manufacture
149 proficiency in the lab (Bird & Emery, 2009b). Both rooks and crows are more social than jays, in
150 that rooks form large flocks for breeding, foraging and roosting, while New Caledonian crows

151 tend to form extended family groups that are fairly tolerant of their neighbours (Goodwin, 1986;
152 St Clair et al., 2015).

153 We also investigated whether Eurasian jays would choose the colour that was demonstrated
154 to be rewarded in a two-choice colour discrimination test. Unlike the object-dropping task, this is
155 a fairly simple task and corvids, including Eurasian jays, have been shown to be capable of
156 making colour discriminations (ravens: Range, Bugnyar & Kotrschal, 2008; Eurasian jays:
157 Clayton & Krebs, 1994; Davidson et al., Under Review). Furthermore, this test has explicitly
158 been used previously to demonstrate use of social information in other corvids, namely common
159 ravens and carrion crows, where all the individuals that were tested chose the demonstrated
160 colour (Miller, Schwab & Bugnyar, 2016). Ravens and crows are social species with high
161 fission-fusion dynamics, being highly social in non-breeding season, and territorial in the
162 breeding season (Goodwin, 1986). We conducted the task in a comparable manner to Miller,
163 Schwab & Bugnyar (2016) to allow for direct comparison between these two corvid studies. The
164 inclusion of both tasks in the present study allowed us to compare jay performances with social
165 corvid species that have been shown to use social information on the same tasks. Furthermore,
166 the use of both tasks enabled us to control for potential influences of task affordances, such as
167 difficulty. Namely, even if the object-dropping task was too difficult to learn socially, we would
168 still be able to detect whether the jays use social information in the simpler colour-discrimination
169 task.

170 The general tool-kit hypothesis (Emery & Clayton, 2005) may predict that relatively asocial
171 jays, like the more social New Caledonian crows, rooks, ravens and crows, would use the
172 information provided by the demonstrator, as they may have retained the capacity to use social
173 information (i.e., information made available by others). Alternatively, jays may differ from the

174 more social corvids in their use of social information, as they may have secondarily lost this
175 ability due to lack of selection pressure from an asocial environment.

176

177 **Methods**

178 **Subjects**

179 The subjects were 16 hand-reared juvenile Eurasian jays (8 females, 8 males) hatched in
180 May 2015. The birds were hand-reared as a group in 2015, and socially housed within a large
181 outdoor aviary (9x16.5x6m) at the Sub-department of Animal Behaviour in Madingley,
182 Cambridge. Birds were sourced from wild nests at 10 days old by a registered breeder under a
183 Natural England License to NSC (20140062). The subjects consisted of 5 sibling groups (one
184 pair, three groups of 3 birds, and one group of 4 birds), with 1 individual that had no siblings.
185 Testing took place in indoor test compartments (2x2x1m), with which the birds were familiar, as
186 they were fed their daily diet within these compartments and had constant access to them outside
187 of testing sessions. The birds could be separated individually, in pairs or sub-groups within these
188 compartments as required. One female bird ('Sjoika') did not participate in either experiment, as
189 she could not reliably be separated individually in the compartments. Subjects were identifiable
190 using unique colour leg-ring combinations. Prior to and during testing, subjects had access to
191 their daily diet, which consisted of soaked dog pellet and boiled vegetables, and water. Rewards
192 for both experiments were live mealworms, which are a highly valued food item, reserved only
193 for training and testing. Experiment 1 was conducted in October 2015 and Experiment 2 in
194 November 2015.

195

196 **EXPERIMENT 1: Object dropping task**

197 Materials

198 The testing apparatus was a clear Perspex ‘object insertion’ apparatus (total height=13cm)
199 consisting of a tube and a box (height=10.5cm, depth=6.5cm, width=11cm) containing a
200 collapsible platform (based on the design in Bird & Emery 2009b). Objects could be inserted into
201 a tube (length=8cm, diameter=5cm), causing the collapsible platform at the bottom of the tube to
202 release from a small magnet holding it in place. Once released from the magnet, a food reward
203 was dispensed to the subject (Figure 1). Several clear, plastic rings and one additional removable
204 platform (length=13cm, width=13cm) that attached to the exterior of the tube were used for the
205 earlier training stages. A blue ring was added to the top of the tube to increase the salience of this
206 area. Only one object was required to drop the collapsible platform and release the reward.
207 Spherical, black metal, hollow objects were used (measuring 2cm in diameter and weighing 4-
208 5g; Figure 1), with 3 thin pieces of black plastic string woven through the middle of each object
209 and tied in a knot on each side, to allow the birds to pick up the object more easily and prevent
210 them from rolling away.

211

212 Procedure

213 Subjects were separated into 3 groups: a trained group that had no prior experience with the
214 apparatus and had never seen another solve it, but were trained to correctly solve it by the
215 experimenter (3 males, 3 females); an observer group that observed a trained conspecific solve
216 the task (3 males, 3 females); and a control group that received no training on the task and did
217 not see any bird interact with the task (2 males, 1 female).

218

219 Habituation and spontaneous object dropping

220 All subjects were habituated to the apparatus and the object separately by presenting them
221 with small food rewards on top and beside the apparatus and object. Subjects were first presented
222 with a baited object on the table until they retrieved the reward in 5 consecutive trials. They were
223 then presented with the object insertion apparatus in the stages outlined in Table 1 and Figure 1.
224 Namely, the apparatus was presented in three scenarios to aid in learning how to correctly solve
225 the apparatus. 1. The removable platform was placed at the top of the tube (Figure 1a) to allow
226 the object to be placed on the rim of the tube so the bird could easily accidentally knock the
227 object into the tube by nudging it when attempting to obtain bait from under the object. 2. The
228 removable platform was placed at the bottom of the tube (Figure 1b) to encourage the bird to
229 pick up the object and lift it up to the top of the tube to insert it. 3. The removable platform was
230 removed (i.e., final stage apparatus; Figure 1c) so the bird had to pick up the object from the
231 table to insert it into the top of the tube. Rewards were placed on the apparatus, as well as
232 underneath it, with the collapsible platform in the dropped position, until subjects retrieved all
233 available rewards per trial in 5 consecutive trials.

234 All subjects were then given one 5 min test trial to determine whether they would
235 spontaneously pick up and drop the object into the tube prior to being allocated to a group.
236 During this test, the final stage apparatus (Figure 1c) was presented to each subject with the
237 object placed on the table beside the apparatus. No birds spontaneously solved the apparatus
238 within the 5 min, therefore they were randomly assigned to one of three groups: trained, observer
239 or control. Birds were allocated to groups by choosing names from a container: one ‘male only’
240 and one ‘female only’ container ensured a balanced sex ratio in each group (3 males, 3 females
241 for the trained and observer groups; 2 males, 1 female for the control group).

242

243 Trained group

244 We first trained birds in the ‘trained group’ to successfully solve the task by inserting
245 objects from the table into the tube and obtaining the reward. We used the training stages
246 outlined in Table 1 and Figure 1 to gradually increase their proficiency from accidentally
247 inserting baited objects balanced on the rim of the tube to nudging objects down the tube with
248 the use of a removable platform attached to the outside of the tube (stages 1-2; Table 1), until
249 they picked up objects from the table to insert into the tube without the removable platform
250 present (stage 3; Table 1). In training stage 1, the object was baited with an insect on intermittent
251 insertions for the first 1-2 training sessions (3-21 insertions, mean=11 insertions). A session for
252 the trained group lasted 5-10 minutes and was not restricted to a specific number of object
253 insertions, but rather determined by the subject’s motivation and performance in that particular
254 session. A maximum of 2 training sessions were run per day. An object insertion was considered
255 proficient if it was nudged or dropped directly into the tube, as opposed to being knocked in
256 accidentally by removing the baited insect, or first pushing it around on the platform or dropping
257 it onto the table from the platform.

258 Subjects moved from stage 1 to stage 2 when they had accidentally knocked the object into
259 the tube on 10 consecutive insertions (Figure 1a). The removable platform was then gradually
260 moved down the tube during stage 2 until the subject inserted the object from the platform when
261 it was placed at the bottom of the tube on 10 consecutive insertions (Figure 1b). If subjects
262 struggled with progression to the next stage (e.g., stopped inserting the object), they returned to
263 the previous stage, with the aim for each training session to ‘end on a high’ (i.e., with a reward
264 for inserting the object). A bird was considered to have solved the task when they had inserted

265 the object from the table into the final stage apparatus and obtained the reward in 10 consecutive
266 insertions (Figure 1c).

267 We then selected one bird from the trained group (Homer) to demonstrate how to solve the
268 apparatus to the observer group. This bird was selected to be the demonstrator because he was
269 motivated and reliable during training (e.g., he was easy to call into the test compartments and
270 comfortable being close to humans), and solved the task during training fairly quickly. Homer
271 was 100% accurate when he demonstrated for observers; therefore observers never saw failed
272 attempts.

273

274 **Observer group**

275 Observers saw the demonstrator successfully solve the apparatus 40 times per stage, using
276 the following stage order: 3-1-2-3 (e.g., observers saw 40 demonstrations of stage 3, then 40
277 demonstrations of stage 1, etc.; Table 1). This resulted in a total of 160 observations of
278 successful solves per observer bird. Observers were given 4 demonstration sessions of 10 solves
279 per session per stage. The stages were the same as those used for the trained group (Table 1;
280 Figure 1). As these stages facilitated the training of the trained group to solve the task, we might
281 expect that aspects of these stages are helpful for learning the task, hence including
282 demonstrations of each stage. Each demonstration session lasted approx. 3 min, with a maximum
283 of 2 sessions run per day. The demonstrations took place on a table in one compartment, with the
284 observers located in an adjacent, but separate compartment with free visual access between
285 compartments via mesh panels. There were 3-4 observer birds per adjacent compartment and
286 there were sufficient perches for all observers to view the demonstrations at the same time. The
287 observer group was split into 2 smaller sub-groups of 3 birds per group for observations to

288 ensure each bird had sufficient visual access of the demonstrator and to reduce crowding within
289 the test compartments. Each observer subject had the opportunity to watch 16 demonstration
290 sessions, with one or two sessions per day, ensuring that each observer had ample opportunities
291 to observe demonstrations.

292 Immediately after an observer saw 40 demonstrated solves of a particular stage, observer
293 were visually isolated and presented with the object insertion apparatus at the final stage (i.e., no
294 removable platform and with the object on the table). They were then given one 5-min test trial
295 to determine whether they had learnt to solve the task. Observer subjects received five 5-min test
296 trials: one pre-demonstration test trial that all birds received to determine whether they
297 spontaneously solve the task, and observer birds received four test trials immediately after
298 observing demonstrations at each stage (stages 3-1-2-3; Table 1). Each test trial therefore took
299 place on a separate day, over a period of 15 days. During all test trials, the observer subject was
300 presented with the final stage apparatus with the object on the table. To solve the task, the
301 subject was required to pick up the object from the table and insert it into the tube to release the
302 collapsible platform and obtain the reward. The longest time that any subject waited between
303 observing the last demonstration session of each stage and their own test trial was 10 minutes.

304

305 **Control group**

306 The control group did not receive any object insertion apparatus training or demonstrations,
307 and were presented with the ‘final stage’ object insertion apparatus the same number of times
308 that the observer group received the apparatus (i.e., 5 test trials). Test trials were run on the same
309 test days as the observer group to avoid any potential differences between the groups due to age
310 or other environmental factors.

311

312 **Data analysis**

313 All training and demonstration sessions and test trials were videotaped, as well as being live
314 coded. We recorded the number of (accidental and proficient) insertions required for the trained
315 group individuals to complete each training stage and solve the task (i.e., to insert an object from
316 the table into the tube at the final apparatus stage in 10 consecutive insertions). For the observer
317 and control groups, we recorded whether the subject solved the task (i.e., inserted an object from
318 the table into the tube at the final apparatus stage, and interacted with the apparatus or object).

319 To determine whether individuals in the observer group interacted with the apparatus and
320 object more than individuals in the control group during tests, we conducted a generalised linear
321 model (GLM) using a Poisson distribution with a log link in R v3.2.1 (function: glm; R Core
322 Team 2015). We combined the total number of times a bird touched the apparatus and object per
323 trial (response variable) to examine whether it varied by trial number or group (control or
324 observer; explanatory variables). We conducted a generalised linear mixed model (GLMM)
325 using a Poisson distribution with a log link (R package: lmerTest, function: glmer, Kuznetsova,
326 Brockhoff & Christensen, 2015) to determine whether the observer group interacted more with
327 particular parts of the apparatus or object after having seen the demonstrator solve the task. We
328 examined whether the number of touches (response variable) varied according to the location
329 that was touched (apparatus base, apparatus tube, or object) by group (control or observer;
330 explanatory variables) with bird ID as a random effect. To examine whether observer jays
331 touched the apparatus/object sooner than control jays, we conducted the same GLMM just
332 mentioned, but with a different response variable: the latency (in seconds) to touch the apparatus
333 or object per test trial per bird.

334 To examine the level of certainty associated with each model, the respective models were
335 compared with all model combinations and their Akaike weights, which sum to 1 across the
336 models, considered (R package: MuMIn, function: dredge; Bates, Maechler & Bolker, 2011). A
337 model was considered highly likely given the data if it had a high Akaike weight (>0.89) relative
338 to the other models (Burnham & Anderson, 2002).

339 Once Experiment 1 had been conducted, all of the birds in the control and observer groups
340 were trained to insert objects into the object insertion apparatus. We recorded the number of
341 (accidental and proficient) insertions required for the observer and control group to complete
342 each training stage and solve the task. We examined whether birds in the observer group solved
343 the task faster than birds in the trained or control groups using a GLM in R. The number of
344 object insertions required to complete stage 3 (insert the object from the table into the tube in 10
345 consecutive insertions; response variable) was compared across conditions (trained, observer,
346 control; explanatory variable) using a Poisson family with a log link.

347

348 **Results**

349 None of the jays solved the task spontaneously in the initial trial (i.e., prior to any training,
350 demonstrations or frequent exposure to the apparatus). In the trained group, all 6 jays learned to
351 drop objects over a period of 8 to 21 training sessions (4-11 days). In the observer group, 0 of 6
352 jays learned to drop objects by observing the demonstrator. In the control group, 0 of 3 jays
353 learned to drop objects without training or demonstrations. Only one bird ('Gizmo' – observer
354 bird), on her final test trial, lifted the object high up while standing near the tube, but she did not
355 insert it into the tube.

356 All observer and control subjects generally interacted with the apparatus and/or object
357 during test trials (in 44 of 45 test trials; with the apparatus in 39 trials and the object in 34 trials).

358 Individuals in the observer group did not touch the apparatus or object more than individuals in
359 the control group (mean touches=11 and 9, respectively; Table 2: Model 1). The Akaike weight
360 for this model was very low (0.11), and it was the third ranked model, indicating a high level of
361 uncertainty, therefore it is likely that there was not enough data for the model to draw strong
362 conclusions, or the effects were too small to detect.

363 While the number of interactions decreased with increasing trial number in control
364 individuals, there is weak evidence that observer individuals had relatively more interactions
365 with the apparatus and object in later trials than control individuals (Table 2: Model 1). There
366 was only weak evidence because the Akaike weight for the top-ranked model, which was the full
367 model, was only 0.46, indicating that there was a high degree of uncertainty in this model. There
368 was no evidence that birds in the observer group interacted more with particular parts of the
369 apparatus or object after seeing the demonstrator solve the task compared with control birds
370 (mean touches=4 and 3, respectively; Table 2: Model 2). When comparing the latency to the first
371 touch between control and observer groups, observer birds touched the apparatus/object
372 significantly sooner than control birds (mean=23 and 83 seconds, respectively; Table 2, Model 3;
373 Figure 3). This model was highly likely given the data because its Akaike weight was 0.99. The
374 data in Figure 3 shows that there was no initial difference in latencies between control and
375 observer groups during their spontaneous test trial (trial 1), which was before the observer group
376 had access to social information about the apparatus. The difference between the two groups
377 occurred in trials 2-5 where, after the social demonstrations, observer latencies stayed the same,
378 while the control group's latencies increased.

379 Following this experiment, all 9 jays in the observer and control groups underwent training
380 to drop objects over a period of 8-12 training sessions (5 to 7 days). Therefore, the number of

381 object insertions required to reach proficiency was compared between the trained, observer, and
382 control groups. Birds in the trained group required more insertions to solve the task (i.e., to insert
383 objects from the table into the tube of the final stage apparatus; mean insertions to solve=167,
384 GLM estimate=0.39, SE=0.06, $z=6.26$, $p<0.001$), than observer and control birds. Birds in the
385 observer (mean insertions to solve=114, GLM estimate=0.01, SE=0.07, $z=0.20$, $p=0.84$) and
386 control (mean insertions to solve=113, GLM [intercept] estimate=4.72, SE=0.05, $z=86.86$,
387 $p<0.001$) groups did not differ in the number of insertions (Figure 4; ESM1 Table S1).

388

389 **EXPERIMENT 2: Two-choice colour discrimination task**

390 **Materials**

391 This set up consisted of two plastic cups – one black and one white (diameter=6cm,
392 height=14.5cm). Cups were spaced 30cm apart on a wooden board (50cm x 15cm). Each cup
393 was attached to its own metal rod so they could move up and down independently, but they were
394 prevented from being removed entirely from the rod by a bolt. Cups could be lifted upwards to
395 reveal a hidden reward (Figure 2). Two live mealworms were placed underneath each cup.

396

397 **Procedure**

398 **Demonstrator training**

399 One bird acted as a demonstrator - ‘Homer’ - the same demonstrator as in Experiment 1. In
400 visual isolation from the observer group, Homer received 4 sessions (5-10 mins per session) of
401 10 trials per session, where only one cup - the white cup - was baited (‘demonstrated’ cup) and
402 the other cup - the black cup - was locked down using the bolt so it could not be lifted. To pass
403 demonstrator training, Homer had to consistently lift only the demonstrated cup in all 10
404 consecutive trials within a session and not touch or try to lift to other cup before he could move

405 on to the demonstrations for observers. Homer touched both cups in session 1 and 2, but passed
406 criterion in session 3. He was given 4 training sessions in total to ensure comparability with the
407 number of demonstrator training sessions used for the carrion crows and ravens in Miller,
408 Schwab & Bugnyar (2016). Homer chose the white cup 100% of the time during demonstrators
409 for observers; therefore observers did not see any incorrect choices.

410

411 **Demonstrations for observers**

412 The observer group consisted of 7 birds in order to be comparable with the sample size in
413 Miller and colleagues (2016): 4 females and 3 males. These individuals also participated in
414 Experiment 1: 3 from the trained group, 3 from the observer group, and 1 from the control group.
415 In an adjacent compartment with visual access to the observers, the demonstrator lifted the
416 demonstrated cup (white) and obtained the reward in 4 sessions, with 10 trials per session. Both
417 cups were baited and could potentially be lifted, though the demonstrator only lifted the
418 demonstrated cup. The demonstrated cup location (left or right) was counterbalanced across
419 trials. Each observer watched one session per day.

420

421 **Testing observers**

422 After observers had seen Homer lifting the demonstrator cup 40 times, they were tested in
423 visual isolation from the group. Each observer was presented with the cups, both cups were
424 baited out-of-sight of the observer and we recorded which cup they touched first. They were
425 given one test trial, which lasted up to 3 minutes (all subjects interacted with the cups within 3
426 minutes). They were allowed to touch both cups. The location of the demonstrated cup was

427 randomized across subjects. If they touched the demonstrated cup (white) first, we considered
428 this to be using social information from the demonstrator.

429

430 **Data analysis**

431 We recorded the colour and latency of the cup first touched by the demonstrator during
432 training and demonstration trials, and by the observers during the test. The data were analysed
433 using SPSS version 21 for the exact two-tailed Binomial tests, and R for the t-test. RM and KL
434 both coded 20% of all videos across both experiments, with KL acting as a naïve coder, and
435 inter-observer reliability was excellent (Cohen's kappa $k=0.989$, $p < 0.001$).

436

437 **Results**

438 Jays did not choose the demonstrated colour above chance levels (Binomial test: $p=0.453$).
439 Two of 7 jays (1 male, 1 female) chose the same coloured cup (white) as the demonstrator (i.e.,
440 copied the demonstrator), while the other 5 jays (3 females, 2 males) chose the non-demonstrated
441 coloured cup (black; Table 3). In comparison, Miller, Schwab & Bugnyar (2016) found that 8 of
442 8 crows (5 females, 3 males) and 8 of 8 ravens (3 females, 5 males) copied the conspecific
443 demonstrator, which was significant (Binomial test: $p=0.008$ for each species). We additionally
444 examined whether there was a difference in the latency to make the first choice between the birds
445 that chose the demonstrated colour versus those that did not. The jays that chose the
446 demonstrated colour did not have shorter latencies to their first choice (Welch two-sample t-test:
447 $t=0.88$, $p=0.47$, $n=7$, 95% confidence interval=-36-57; data in ESM1 Table S1). We also
448 explored whether relatedness influenced likelihood to copy the demonstrator. 0 of 2 jays that
449 selected the demonstrated coloured cup (Binomial test: $p=0.5$, $n=2$) and 2 of 5 jays that did not

450 select the demonstrated coloured cup were siblings of the demonstrator bird (Binomial test:
451 $p=1.00$, $n=5$). The birds did not appear to show a group side bias because they did not select the
452 cup on the same side regardless of colour (Table 3: Binomial test: $p=1.00$, $n=7$).

453

454 **Animal ethics**

455 The study was conducted under approval from University of Cambridge Psychology
456 Research Ethics Committee (application number: pre.2013.109) and the European Research
457 Council Executive Agency Ethics Team (application: 339993-CAUSCOG-ERR).

458

459 **Video summary**

460 A video shows examples from both experiments: <https://youtu.be/L3IQy8cbqUQ>.
461 Experiment 1: Trained group, Solving Task ('Stuka'); Experiment 1: Observer Group, Test Trial
462 5 ('Gizmo'); Experiment 2: Observer Group, Test Trial (Gizmo).

463

464 **Discussion**

465 We found that relatively asocial Eurasian jays did not use social information (i.e.,
466 information made available by a conspecific) in the form of copying the choices of others in
467 either task. In Experiment 1 (object-dropping task), birds in the observer group first touched the
468 apparatus and object significantly sooner than birds in the control group, indicating a form of
469 social learning called stimulus enhancement. Stimulus enhancement attracts the attention of an
470 observer towards a specific object where the model acts (Giraldeau, 1997). However, observing a
471 conspecific demonstrator did not facilitate solving the object-dropping task in Experiment 1, or
472 result in colour choice copying in Experiment 2.

473 Although corvids, including Eurasian jays, can be trained in the object-dropping task, it is
474 possible that this task is too difficult for social learning to facilitate the solution, except for the
475 occasional individual (i.e., one rook: Bird and Emery, 2009b; and one New Caledonian crow:
476 Mioduszezwska, Auersperg & von Bayern, 2015), thus masking whether Eurasian jays are able to
477 use social information by observing, and thus learning from, a demonstrator. In the present study,
478 solving this task required the observer birds to copy several actions of the demonstrator: lifting
479 the object from the table to insert into the tube to drop the collapsible platform and obtain the
480 reward, rather than just knocking an object into the tube from the tube ledge, which is typically
481 stage 1 of training. In further support of the suggestion that this task is difficult for birds to learn
482 is that only one bird has spontaneously solved the object-dropping task in a previous study (one
483 New Caledonian crow; Mioduszezwska, Auersperg & von Bayern, 2015), without any
484 demonstrations or training. Additionally, birds, including corvids, typically require a relatively
485 large number of training trials to learn to solve this task, indicating that it is fairly difficult to
486 learn even with explicit training (e.g., 90-275 trials in present study; 135-362 trials in grackles:
487 Logan, 2016; 76-255 trials in scrub-jays: Logan et al., 2016 – though note that definitions for
488 reaching proficiency differ between these studies and the current study).

489 It is therefore possible that the jays obtained some information from the demonstrator, but
490 potentially this information was not sufficient to enable them to complete the task (i.e., to insert
491 the object from the table into the tube). Therefore, we assessed whether there was any evidence
492 that the jays attended to the demonstrator, despite not being able to solve the task following the
493 demonstrations, by measuring differences in the number of interactions with the apparatus and
494 object between the control and observer groups. Individuals in the observer group were not more
495 likely to touch the apparatus or object than individuals in the control group. Observer individuals

496 touched the apparatus and object in later trials more than control individuals, indicating that jays
497 may have been more persistent after having seen another bird solve the task. However, it should
498 be noted that the models showed only weak evidence for these two findings.

499 We also found that the observer group solved the object-dropping task significantly more
500 quickly than the trained group; however, there was no difference in the rate of learning (i.e., total
501 number of insertions required to solve the task) between the observer and control groups. The
502 strongest evidence of any form of social learning was in the form of stimulus enhancement:
503 observer birds that had seen a demonstrator interact with the apparatus and object first touched
504 these elements significantly sooner than control birds that had never observed another touching
505 the apparatus. It is possible that increased exposure to the apparatus may have facilitated learning
506 in both the observer and control groups, perhaps by removing neophobia of the apparatus
507 (although all birds were habituated to the apparatus prior to testing), and/or some social
508 facilitation of attraction or attention to the apparatus, as opposed to learning the actions to
509 perform the task. However, it is unclear whether observers attended to social information
510 provided by the conspecific or whether they would have learned about the task by observing a
511 ‘ghost control’ where the object was inserted into the tube in the absence of a conspecific. Future
512 research incorporating ghost controls could distinguish between whether jays attend to social
513 information about what to attend to or whether they solely attend to the relevant object
514 movements and reward outcomes.

515 In Experiment 2, in comparison with the object-dropping task, the colour discrimination task
516 was relatively simple as corvids are capable of making colour discriminations (Clayton & Krebs,
517 1994; Range, Bugnyar & Kotrschal, 2008). For example, there is evidence that juvenile Eurasian
518 jays can discriminate between colours in similar two-choice discrimination tasks. Davidson and

519 colleagues (Under Review) trained half of a group of Eurasian jays to associate a yellow
520 coloured object with a reward and a green coloured object with no reward, and the other half to
521 associate the green object with a reward and the yellow object with no reward. The jays then
522 demonstrated proficiency by flying to the perch where the rewarded colour was located.

523 Further, the same task used in Experiment 2 was used previously in 8 ravens and 8 carrion
524 crows, and all birds chose the demonstrated colour (Miller, Schwab & Bugnyar, 2016). While the
525 methods have some limitations (e.g., no counterbalancing of rewarded cup color, using only one
526 demonstrator whose characteristics might have made him less likely for observers to attend to,
527 low statistical power from only one trial per bird), we ran this task in a comparable manner to
528 Miller, Schwab & Bugnyar (2016) to allow for direct comparison between these two studies,
529 including the use of one male, same-age conspecific demonstrator to an observer group and one
530 test trial. Additionally, all birds were hand-reared in species groups in a similar manner, tested by
531 the same experimenter (RM) and similar sample sizes were used (8 ravens, 8 crows, 7 jays). We
532 also similarly controlled for the influence of spatial location by randomizing the location of the
533 demonstrated cup across subjects, and we found no group-level bias for one location (right/left)
534 over the other (Table 3).

535 There were two notable differences between these studies. Firstly, the colour discrimination
536 task used different colours: blue and yellow cups in Miller, Schwab & Bugnyar (2016) compared
537 with white and black cups in the present study. The justification for this difference was the need
538 to avoid a possible overlap between this study and the prior experience of the jays with several
539 different colours in differing reward scenarios during previous studies (e.g., Davidson et al.,
540 Under Review). Furthermore, Shaw and colleagues (2015) suggest that colour discrimination
541 tasks should aim to use gray scale cues (e.g., light vs. dark gray) to avoid innate species-level

542 colour preferences. We cannot entirely rule out innate colour preferences, because we did not
543 transfer birds to novel colour combinations. However, innate preferences would likely have been
544 expressed at the species level, which did not occur here because jays randomly chose white and
545 black cups in their first trials.

546 Secondly, the jays were juveniles, whereas the ravens and crows were sub-adults. Therefore,
547 it is possible that social learning in the jays may not have developed by this early stage.
548 However, this is unlikely given that juveniles in other relatively asocial species exhibited social
549 learning whereas adults did not (Lupfer, Frieman & Coonfield 2003; Noble, Byrne & Whiting
550 2014). To our knowledge, no corvid studies have compared juvenile and adult social information
551 use. However, object permanence in Eurasian jays, which relates to caching development,
552 develops at a similar stage as in other corvids (ravens: Bugnyar, Stowe & Heinrich, 2007; scrub-
553 jays: Salwiczek et al., 2009). Specifically, jays reach a full (i.e., stage 6 Piagetian) understanding
554 of object permanence within their first few months of life (Zucca, Milos & Vallortigara, 2007).
555 As the jays we tested were more than a few months of age, we do not expect their behaviour to
556 differ from adult behaviour with regard to social learning. The finding that the jays behaved
557 differently from the more social carrion crows and ravens in the use of social information in this
558 task is important. It raises the question of whether these more social species - as with the more
559 social rook (Bird & Emery, 2009b) and New Caledonian crow (Mioduszezewska, Auersperg & von
560 Bayern, 2015) - might be able to learn to copy the demonstrator in the object-dropping task
561 (Experiment 1).

562 Previous studies have indicated that Eurasian jays do attend to social context in caching and
563 mate provisioning (Shaw & Clayton, 2012; Shaw & Clayton, 2013; Ostojić et al., 2013; Shaw &
564 Clayton, 2014; Ostojić et al., 2014; Legg, Ostojić & Clayton, 2016). It is therefore still possible

565 that jays use social information, but not for copying others' choices, as none of the previous
566 studies required the birds to copy a demonstrator. Jays may also be more likely to pay attention
567 to and copy different demonstrators, such as an older, more affiliated or related individuals, as
568 model identity has been found to influence social learning in other corvids (ravens, jackdaws:
569 Schwab, Bugnyar & Kotrschal 2008a; Schwab et al., 2008b). For example, presence of siblings
570 enhances social learning in ravens (Schwab et al., 2008b). Our demonstrator was a sibling of
571 some of the observers, which suggests that there was no influence of relatedness to demonstrator
572 on likelihood of copying in Experiment 2. However, our study was not designed to test the
573 relationship between relatedness and social learning and we do not have the statistical power to
574 make a firm conclusion on this point.

575 The use of social information is a process with several stages, which are likely to be
576 sequential and distinct: acquisition (observing another), application (performing the observed
577 behaviour, not necessarily successfully) and exploitation (successfully performing the observed
578 behaviour in a way that gives the individual an advantage; Carter, Tico & Cowlshaw, 2016;
579 Guillette, Scott & Healy, 2016). For instance, in chacma baboons (*Papio ursinus*), the average
580 individual only acquired social information on <25% of occasions and exploited social
581 information on <5% of occasions, and information use was dependent on phenotypic constraints
582 such as network position and dominance status (Carter, Tico & Cowlshaw, 2016). The results of
583 Experiments 1 and 2 demonstrated that Eurasian jays did not appear to apply or exploit the social
584 information available even though they had the opportunity to acquire it. Though we reiterate
585 that social species also do not show a strong capacity to socially learn the object-dropping task in
586 Experiment 1.

587 In conclusion, Eurasian jays did not appear to use social information in the form of copying
588 the decisions of a conspecific in the object-dropping and colour discrimination tasks, which vary
589 in difficulty. However, their attention was drawn to the apparatus and object in the object-
590 dropping task as indicated by observers touching these components sooner than control birds. In
591 previous studies with social corvids, the birds have only been explicitly tested for influences of
592 social information on learning the object-dropping task in one study, with only one New
593 Caledonian crow learning the task following a conspecific demonstration (Mioduszezwska,
594 Auersperg & von Bayern, 2015). We also know that, when tested using very similar procedures,
595 including the same lead experimenter, ravens and crows use social information in the colour
596 discrimination task, in contrast to the jays. These corvid species vary in sociality, but all are
597 more social than the jays. Our results from relatively asocial Eurasian jays are therefore
598 consistent with those from relatively asocial Clark's nutcrackers (Bednekoff & Balda 1996,
599 Templeton, Kamil & Balda, 1999) in that social and relatively asocial corvids appear to differ in
600 their use of social information with regard to copying the choices of others. The present study
601 may indicate that Eurasian jays secondarily lost the ability to copy social information provided
602 by a conspecific, at least in some contexts, while maintaining the ability to attend to the general
603 movements of others, due to lack of selection pressure from an asocial environment. However,
604 more comparisons between social and relatively asocial corvids are needed to confirm this
605 hypothesis.

606

607 **Data Availability**

608 Data for the social learning GLMMs is available at the KNB Data Repository at:
609 https://knb.ecoinformatics.org/#view/corina_logan.45.5 (Miller & Logan, 2016).

610

611 **Acknowledgements**

612 We thank Elsa Loissel and Natalie Williams for their help in the early stages of preparing for
613 Experiment 1 and discussion. Thank you to Maggie Dinsdale, Sam Melvin, Sarah Manley, Ivan
614 Vakrilov for animal care, to Ian Millar for help in apparatus construction, and to Mark Ghobain
615 for assistance in hand-rearing the Eurasian jays.

Table 1 (on next page)

Stages of the object insertion apparatus.

Training stages: training the trained group, and subsequent to their tests, the observer and control groups, to insert objects into the tube to release the food reward. Training stages occurred in the following sequence: 1-2-3. Demonstrator stages: birds in the observer group watched the demonstrator solve the apparatus 40 times per stage before being presented with the final stage apparatus in a test trial. Demonstration stages occurred in the following sequence: 3-1-2-3.

8

Table 2 (on next page)

Did observers learn what to attend to from the demonstrator?

Results from the GLM (Model 1) and GLMM (Model 2) examining whether individuals in the observer group **touched** the apparatus and object more than control individuals (Model 1) or whether they interacted more with particular parts of the apparatus (base or tube) or object (Model 2). Model 3 (GLMM) examined **latencies** to first touch per trial to determine whether individuals in the observer group first touched the apparatus/object sooner than control birds. SE: standard error, z: z value, p: p value, the rows in italics list the variance and standard deviation of the random effect.
