Corvids (birds in the crow family) are hypothesised to have a general cognitive tool-kit because they show a wide range of transferrable skills across social, physical and temporal tasks, despite differences in socioecology. However, it is unknown whether relatively asocial corvids differ from social corvids in their use of social information in the context of copying the choices of others, because only one such test has been conducted in a relatively asocial corvid. We investigated whether relatively asocial Eurasian jays (*Garrulus glandarius*) use social information (i.e., information made available by others). Previous studies have indicated that jays attend to social context in their caching and mate provisioning behaviour; however, it is unknown whether jays copy the choices of others. We tested the jays in two different tasks varying in difficulty, where social corvid species have demonstrated social information use in both tasks. Firstly, an object-dropping task was conducted requiring objects to be dropped down a tube to release a food reward from a collapsible platform, which corvids can learn through explicit training. Only one rook and one New Caledonian crow have learned the task using social information from a demonstrator. Secondly, we tested the birds on a simple colour discrimination task, which should be easy to solve, because it has been shown that corvids can make colour discriminations. Using the same colour discrimination task in a previous study, all common ravens and carrion crows copied the demonstrator. After observing a conspecific demonstrator, none of the jays solved the object-dropping task, though all jays were subsequently able to learn to solve the task in a non-social situation through explicit training, and jays chose the demonstrated colour at chance levels. Our results suggest that social and relatively asocial corvids differ in social information use, indicating that relatively asocial species may have secondarily lost this ability due to lack of selection pressure from an asocial environment.

13 **ABSTRACT**

14 Corvids (birds in the crow family) are hypothesised to have a general cognitive tool-kit because
15 they show a wide range of transferrable skills across social, physical and temporal tasks, despite
16 differences in socioecology. However, it is unknown whether relatively asocial corvids differ
17 from social corvids in their use of social information in the context of copying the choices of
18 others, because only one such test has been conducted in a relatively asocial corvid. We
19 investigated whether relatively asocial Eurasian jays (*Garrulus glandarius*) use social
20 information (i.e., information made available by others). Previous studies have indicated that jays
21 attend to social context in their caching and mate provisioning behaviour; however, it is
22 unknown whether jays copy the choices of others. We tested the jays in two different tasks
23 varying in difficulty, where social corvid species have demonstrated social information use in
24 both tasks. Firstly, an object-dropping task was conducted requiring objects to be dropped down
25 a tube to release a food reward from a collapsible platform, which corvids can learn through
26 explicit training. Only one rook and one New Caledonian crow have learned the task using social
27 information from a demonstrator. Secondly, we tested the birds on a simple colour
28 discrimination task, which should be easy to solve, because it has been shown that corvids can
29 make colour discriminations. Using the same colour discrimination task in a previous study, all
30 common ravens and carrion crows copied the demonstrator. After observing a conspecific
31 demonstrator, none of the jays solved the object-dropping task, though all jays were
32 subsequently able to learn to solve the task in a non-social situation through explicit training, and
33 jays chose the demonstrated colour at chance levels. Our results suggest that social and relatively
34 asocial corvids differ in social information use, indicating that relatively asocial species may
35 have secondarily lost this ability due to lack of selection pressure from an asocial environment.

36 Introduction

37 A wide range of corvid species (e.g., crows, ravens, jays) are known for their complex
38 cognitive abilities, which are hypothesised to have been present in their common ancestor, thus
39 forming a ‘general cognitive tool-kit’ across this taxa (Emery & Clayton, 2004). For example,
40 even though rooks (*Corvus frugilegus*) do not make or use tools in the wild, they are able to
41 spontaneously innovate these behaviours in the lab (Bird & Emery, 2009b). Further, there is
42 evidence that some corvid species show cognitive competence across a wide range of social,
43 physical and temporal tasks. For instance, California scrub-jays (*Aphelocoma californica*) show
44 proficiency in cognitive tasks relating to memory (Clayton & Dickinson, 1998), future planning
45 (Clayton, Emery & Dickinson, 2006; Raby et al. 2007), and social cognition through cache
46 protection tactics (Clayton, Dally & Emery, 2007). As another example, rooks, in addition to
47 their tool abilities, cooperate with each other to solve novel problems (Seed et al. 2008) and
48 appear to understand support relationships because they look longer at impossible scenarios (e.g.,
49 a ball suspended in mid-air rather than sitting on a table; Bird & Emery 2010). Additionally,
50 New Caledonian crows (*Corvus moneduloides*) reason about hidden causal agents (Taylor,
51 Miller & Gray 2012), reason by exclusion (Jelbert et al. 2015), and learn socially about novel
52 foraging problems (Logan et al. 2016).

53 It is unknown whether this cognitive tool-kit includes the ability to use social information
54 specifically in the form of copying the choices of others, which is distinct from changing
55 behaviour when solving problems in different social contexts (several examples are given
56 below). The corvid common ancestor is hypothesised to have been social (Clayton & Emery,
57 2007). If this assumption is correct, rather than the common ancestor being asocial with sociality
58 having evolved several times in extant lineages, then there is reason to expect that relatively

59 asocial corvids could have retained the capacity to use social information. For example, it could
60 be adaptive by improving foraging and mate searching efficiency (e.g., Valone & Templeton,
61 2002). Alternatively, this ability could have been secondarily lost because of the lack of selection
62 pressure from an asocial environment, in a similar manner to the secondary loss of caching (food
63 hiding) in jackdaws (*Corvus monedula*; de Kort & Clayton, 2006). For example, in the absence
64 of conspecifics for most of the year, there might have been an increased selection pressure to rely
65 solely on personal information when foraging.

66 Most studies of corvid social information use, in the form of copying the choices of others,
67 have occurred in social species (species that live in groups of at least pairs year-round), which
68 makes it difficult to determine whether this ability is part of their general cognitive tool-kit.
69 Evidence of social information use, specifically copying the choices of others, has been found in
70 social corvid species, including pinyon jays (*Gymnorhinus cyanocephalus*; Templeton, Kamil &
71 Balda, 1999), rooks (Dally, Clayton & Emery, 2008), jackdaws (*Corvus monedula*; Schwab,
72 Bugnyar & Kotrschal, 2008a), common ravens (*Corvus corax*; Fritz & Kotrschal, 1999; Schwab
73 et al., 2008b), carrion crows (*Corvus corone corone*, *C. c. cornix*; Miller, Schwab & Bugnyar,
74 2016) and New Caledonian crows (Logan et al., 2016). Social species are predicted to be better
75 at acquiring new skills in a social context than in a non-social context (Lefebvre & Giraldeau
76 1996), because they may attend more to conspecifics than asocial species (Balda, Kamil &
77 Bednekoff, 1997).

78 However, we are aware of only two tests of social information use in the form of copying
79 the choices of others in a relatively asocial corvid. Clark's nutcrackers (*Nucifraga columbiana*)
80 did not learn a motor or a discrimination task faster in a social learning condition than in an
81 individual learning condition, indicating that they did not use social information (Templeton,

82 Kamil & Balda, 1999). This was in contrast with highly social pinyon jays that did learn faster in
83 the social learning conditions (Templeton, Kamil & Balda, 1999). Additionally, Clark's
84 nutcrackers more accurately recovered caches they made rather than caches they observed others
85 make, in contrast with social Mexican jays that were accurate in both conditions (Bednekoff &
86 Balda 1996). These results suggest that relatively asocial corvids attend less to social information
87 than social corvids.

88 Outside of corvids, social learning in the form of copying conspecifics has been found in a
89 number of asocial species including red-footed tortoises (*Geochelone carbonaria*; Wilkinson et
90 al. 2010), black river stingrays (*Potamotrygon falkneri*; Thonhauser et al. 2013; Garrone Neto &
91 Uieda 2012), bearded dragons (*Pogona vitticeps*; Kis, Huber & Wilkinson 2014), and in juvenile,
92 but not adult, golden hamsters (*Mesocricetus auratus*; Lupfer, Frieman & Coonfield 2003) and
93 eastern water skinks (*Eulamprus quoyii*; Noble, Byrne & Whiting 2014). These non-corvid
94 species are likely to have had asocial ancestors, which suggests that social cues are not costly to
95 attend to and can evolve outside of a social context in these taxa. However, at present, the sample
96 size of the relatively asocial corvid species is too small to draw general conclusions about the
97 influence of a corvid's social system on their use of social information.

98 We addressed this gap by investigating whether the relatively asocial Eurasian jays
99 (*Garrulus glandarius*) used social information provided by a conspecific. Eurasian jays do not
100 live in social groups except during the breeding season when mated pairs defend a territory
101 (Goodwin 1951; Snow & Perrins, 1997; Clayton & Emery, 2007). There is evidence that socially
102 housed Eurasian jays attend to social context to modify their caching and mate provisioning
103 (courtship feeding) behaviour. For example, they prefer to cache in quiet rather than noisy
104 substrates when in the presence of conspecifics that could hear but not see the subject (Shaw &

105 Clayton, 2013); they attend to spatial and auditory cues when competitors are caching to later
106 pilfer those caches (Shaw & Clayton, 2014); and subordinates inhibit caching in front of
107 dominants and prefer to cache in less exposed areas (Shaw & Clayton, 2012). They also adjust
108 their behaviour appropriately depending on whether they are caching or pilfering (Shaw &
109 Clayton 2014), and whether they compete with a dominant or subordinate (Shaw & Clayton
110 2012). Furthermore, they prefer to cache out-of-sight behind an opaque barrier and at a distance
111 when observed by conspecifics (Legg & Clayton, 2014; Legg, Ostojić & Clayton, 2016). During
112 the breeding season, males are attentive to which foods their mates might prefer based on how
113 much of which foods she has already eaten (Ostojić et al., 2013; Ostojić et al., 2014).

114 These jays were socially raised and housed, which differs from their relatively asocial
115 system in the wild. The artificially social environment likely enhances their utilisation of any
116 innate social skills because these skills will have been given the opportunity to develop from an
117 early age. Therefore, if social skills are found in these conditions, it demonstrates the potential
118 flexibility of this species to use social cues (if social cues are used). As such, the social capacities
119 shown by socially raised and housed jays might differ from wild individuals. Despite the
120 evidence that socially housed Eurasian jays can respond to social context in caching and mate
121 provisioning paradigms, no study has yet tested whether this species uses social information to
122 copy the choices of others, which could be useful for learning about foraging opportunities even
123 in a relatively asocial species.

124 We tested whether socially housed Eurasian jays would use social information from a
125 conspecific demonstrator when learning to solve a novel problem – an object-dropping task
126 where an object must be dropped into a tube to release a food reward from a collapsible platform.
127 Further, if the birds did not use social information to solve the task, we tested whether there was

128 any evidence that they had attended to the demonstrator (as indicated by differences between
129 groups with differing levels of social learning opportunities), and what they might have learned
130 during this exposure. The object-dropping task has been used previously during pre-test training
131 for Aesop's Fable tasks in this species (Cheke, Bird & Clayton, 2011) as well as in a number of
132 other bird species (rooks: Bird & Emery, 2009a; New Caledonian crows: Jelbert et al., 2014;
133 Logan et al., 2014; California scrub-jays, Logan et al., 2016; great-tailed grackles, *Quiscalus*
134 *mexicanus*, Logan 2016). Aesop's Fable tasks require subjects to insert objects into water-filled
135 tubes to obtain out-of-reach floating rewards.

136 In the corvids that have been tested using this object-dropping task so far, we see a common
137 pattern, irrespective of whether they are habitual tool users. Namely, they are capable of learning
138 the object-dropping task, but only once they have experienced an object falling into a tube,
139 which usually occurs when they accidentally knock an object off the ledge into the tube. This
140 finding suggests that the birds need to see the object fall, and once they have, they can learn to
141 solve the rest of the task. This raises the question of whether they need direct experience of
142 manipulating the objects and observing them fall into the tube or whether witnessing another
143 individual's solution to the problem will suffice in learning the task. So far, only two birds have
144 solved the object-dropping task after observing a conspecific demonstrator: one rook (Bird &
145 Emery, 2009b) and one New Caledonian crow (Mioduszevska, Auersperg & von Bayern, 2015),
146 though only the latter study aimed to explicitly test for influences of social information use on
147 learning this task. New Caledonian crows are habitual tool users in the wild (Hunt, 1996), whilst
148 rooks - like Eurasian jays - are not, though rooks have shown tool-use and manufacture
149 proficiency in the lab (Bird & Emery, 2009b). Both rooks and crows are more social than jays, in
150 that rooks form large flocks for breeding, foraging and roosting, while New Caledonian crows

151 tend to form extended family groups that are fairly tolerant of their neighbours (Goodwin, 1986;
152 St Clair et al., 2015).

153 We also investigated whether Eurasian jays would choose the colour that was demonstrated
154 to be rewarded in a two-choice colour discrimination test. Unlike the object-dropping task, this is
155 a fairly simple task and corvids, including Eurasian jays, have been shown to be capable of
156 making colour discriminations (ravens: Range, Bugnyar & Kotrschal, 2008; Eurasian jays:
157 Clayton & Krebs, 1994; Davidson et al., Under Review). Furthermore, this test has explicitly
158 been used previously to demonstrate use of social information in other corvids, namely common
159 ravens and carrion crows, where all the individuals that were tested chose the demonstrated
160 colour (Miller, Schwab & Bugnyar, 2016). Ravens and crows are social species with high
161 fission-fusion dynamics, being highly social in non-breeding season, and territorial in the
162 breeding season (Goodwin, 1986). We conducted the task in a comparable manner to Miller,
163 Schwab & Bugnyar (2016) to allow for direct comparison between these two corvid studies. The
164 inclusion of both tasks in the present study allowed us to compare jay performances with social
165 corvid species that have been shown to use social information on the same tasks. Furthermore,
166 the use of both tasks enabled us to control for potential influences of task affordances, such as
167 difficulty. Namely, even if the object-dropping task was too difficult to learn socially, we would
168 still be able to detect whether the jays use social information in the simpler colour-discrimination
169 task.

170 The general tool-kit hypothesis (Emery & Clayton, 2005) may predict that relatively asocial
171 jays, like the more social New Caledonian crows, rooks, ravens and crows, would use the
172 information provided by the demonstrator, as they may have retained the capacity to use social
173 information (i.e., information made available by others). Alternatively, jays may differ from the

174 more social corvids in their use of social information, as they may have secondarily lost this
175 ability due to lack of selection pressure from an asocial environment.

176

177 **Methods**

178 **Subjects**

179 The subjects were 16 hand-reared juvenile Eurasian jays (eight females, eight males)
180 hatched in May 2015. The birds were hand-reared as a group in 2015, and socially housed within
181 a large outdoor aviary (9x16.5x6m) at the Sub-department of Animal Behaviour in Madingley,
182 Cambridge. Birds were sourced from wild nests at 10 days old by a registered breeder under a
183 Natural England License to NSC (20140062). The subjects consisted of five sibling groups (one
184 pair, three groups of three birds, and one group of four birds), with one individual that had no
185 siblings. Testing took place in indoor test compartments (2x2x1m), with which the birds were
186 familiar, as they were fed their daily diet within these compartments and had constant access to
187 them outside of testing sessions. The birds could be separated individually, in pairs or sub-groups
188 within these compartments as required. One female bird ('Sjoika') did not participate in either
189 experiment, as she could not reliably be separated individually in the compartments. Subjects
190 were identifiable using unique colour leg-ring combinations. Prior to and during testing, subjects
191 had access to their daily diet, which consisted of soaked dog pellet and boiled vegetables, and
192 water. Rewards for both experiments were live mealworms, which are a highly valued food item,
193 reserved only for training and testing. Experiment 1 was conducted in October 2015 and
194 Experiment 2 in November 2015.

195

196 **Animal ethics**

197 These experiments were conducted under approval from University of Cambridge
198 Psychology Research Ethics Committee (application number: pre.2013.109) and the European
199 Research Council Executive Agency Ethics Team (application: 339993-CAUSCOG-ERR).

200

201 **Video summary**

202 A video shows examples from both experiments: <https://youtu.be/L3IQy8cbqUQ>.
203 Experiment 1: Trained group, Solving Task ('Stuka'); Experiment 1: Observer Group, Test Trial
204 5 ('Gizmo'); Experiment 2: Observer Group, Test Trial (Gizmo).

205

206 **EXPERIMENT 1: Object dropping task**

207 **Materials**

208 The testing apparatus was a clear Perspex 'object insertion' apparatus (total height=13cm)
209 consisting of a tube and a box (height=10.5cm, depth=6.5cm, width=11cm) containing a
210 collapsible platform (based on the design in Bird & Emery 2009b). Objects could be inserted into
211 a tube (length=8cm, diameter=5cm), causing the collapsible platform at the bottom of the tube to
212 release from a small magnet holding it in place. Once released from the magnet, a food reward
213 was dispensed to the subject (Figure 1). Several clear, plastic rings and one additional removable
214 platform (length=13cm, width=13cm) that attached to the exterior of the tube were used for the
215 earlier training stages. A blue ring was added to the top of the tube to increase the salience of this
216 area. Only one object was required to drop the collapsible platform and release the reward.
217 Spherical, black metal, hollow objects were used (measuring 2cm in diameter and weighing 4-
218 5g; Figure 1), with three thin pieces of black plastic string woven through the middle of each

219 object and tied in a knot on each side, to allow the birds to pick up the object more easily and
220 prevent them from rolling away.

221

222 **Procedure**

223 Subjects were separated into three groups: a trained group that had no prior experience with
224 the apparatus and had never seen another solve it, but were trained to correctly solve it by the
225 experimenter (three males, three females); an observer group that observed a trained conspecific
226 solve the task (three males, three females); and a control group that received no training on the
227 task and did not see any bird interact with the task (two males, one female).

228

229 **Habituation and spontaneous object dropping**

230 All subjects were habituated to the apparatus and the object separately by presenting them
231 with small food rewards on top and beside the apparatus and object. Subjects were first presented
232 with a baited object on the table until they retrieved the reward in five consecutive trials. They
233 were then presented with the object insertion apparatus in the stages outlined in Table 1 and
234 Figure 1. Namely, the apparatus was presented in three scenarios to aid in learning how to
235 correctly solve the apparatus. 1. The removable platform was placed at the top of the tube
236 (Figure 1a) to allow the object to be placed on the rim of the tube so the bird could easily
237 accidentally knock the object into the tube by nudging it when attempting to obtain bait from
238 under the object. 2. The removable platform was placed at the bottom of the tube (Figure 1b) to
239 encourage the bird to pick up the object and lift it up to the top of the tube to insert it. 3. The
240 removable platform was removed (i.e., final stage apparatus; Figure 1c) so the bird had to pick
241 up the object from the table to insert it into the top of the tube. Rewards were placed on the

242 apparatus, as well as underneath it, with the collapsible platform in the dropped position, until
243 subjects retrieved all available rewards per trial in five consecutive trials.

244 All subjects were then given one five min test trial to determine whether they would
245 spontaneously pick up and drop the object into the tube prior to being allocated to a group.
246 During this test, the final stage apparatus (Figure 1c) was presented to each subject with the
247 object placed on the table beside the apparatus. No birds spontaneously solved the apparatus
248 within the five minutes, therefore they were randomly assigned to one of three groups: trained,
249 observer or control. Birds were allocated to groups by choosing names from a container: one
250 ‘male only’ and one ‘female only’ container ensured a balanced sex ratio in each group (three
251 males, three females for the trained and observer groups; two males, one female for the control
252 group).

253

254 **Trained group**

255 We first trained birds in the ‘trained group’ to successfully solve the task by inserting
256 objects from the table into the tube and obtaining the reward. We used the training stages
257 outlined in Table 1 and Figure 1 to gradually increase their proficiency from accidentally
258 inserting baited objects balanced on the rim of the tube to nudging objects down the tube with
259 the use of a removable platform attached to the outside of the tube (stages 1-2; Table 1), until
260 they picked up objects from the table to insert into the tube without the removable platform
261 present (stage 3; Table 1). In training stage 1, the object was baited with an insect on intermittent
262 insertions for the first 1-2 training sessions (3-21 insertions, mean=11 insertions). A session for
263 the trained group lasted 5-10 minutes and was not restricted to a specific number of object
264 insertions, but rather determined by the subject’s motivation and performance in that particular

265 session. A maximum of two training sessions were run per day. An object insertion was
266 considered proficient if it was nudged or dropped directly into the tube, as opposed to being
267 knocked in accidentally by removing the baited insect, or first pushing it around on the platform
268 or dropping it onto the table from the platform.

269 Subjects moved from stage one to stage two when they had accidentally knocked the object
270 into the tube on 10 consecutive insertions (Figure 1a). The removable platform was then
271 gradually moved down the tube during stage two until the subject inserted the object from the
272 platform when it was placed at the bottom of the tube on 10 consecutive insertions (Figure 1b). If
273 subjects struggled with progression to the next stage (e.g., stopped inserting the object), they
274 returned to the previous stage, with the aim for each training session to ‘end on a high’ (i.e., with
275 a reward for inserting the object). A bird was considered to have solved the task when they had
276 inserted the object from the table into the final stage apparatus and obtained the reward in 10
277 consecutive insertions (Figure 1c).

278 We then selected one bird from the trained group (Homer) to demonstrate how to solve the
279 apparatus to the observer group. This bird was selected to be the demonstrator because he was
280 motivated and reliable during training (e.g., he was easy to call into the test compartments and
281 comfortable being close to humans), and solved the task during training fairly quickly. Homer
282 was 100% accurate when he demonstrated for observers; therefore observers never saw failed
283 attempts.

284

285 **Observer group**

286 Observers saw the demonstrator successfully solve the apparatus 40 times per stage, using
287 the following stage order: 3-1-2-3 (e.g., observers saw 40 demonstrations of stage three, then 40

288 demonstrations of stage one, etc.; Table 1). This resulted in a total of 160 observations of
289 successful solves per observer bird. Observers were given four demonstration sessions of 10
290 solves per session per stage. The stages were the same as those used for the trained group (Table
291 1; Figure 1). As these stages facilitated the training of the trained group to solve the task, we
292 might expect that aspects of these stages are helpful for learning the task, hence including
293 demonstrations of each stage. Each demonstration session lasted approx. three min, with a
294 maximum of two sessions run per day. The demonstrations took place on a table in one
295 compartment, with the observers located in an adjacent, but separate compartment with free
296 visual access between compartments via mesh panels. There were three to four observer birds
297 per adjacent compartment and there were sufficient perches for all observers to view the
298 demonstrations at the same time. The observer group was split into two smaller sub-groups of
299 three birds per group for observations to ensure each bird had sufficient visual access of the
300 demonstrator and to reduce crowding within the test compartments. Each observer subject had
301 the opportunity to watch 16 demonstration sessions, with one or two sessions per day, ensuring
302 that each observer had ample opportunities to observe demonstrations.

303 Immediately after an observer saw 40 demonstrated solutions at a particular stage, observer
304 were visually isolated and presented with the object insertion apparatus at the final stage (i.e., no
305 removable platform and with the object on the table). They were then given one five-min test
306 trial to determine whether they had learnt to solve the task. Observer subjects received five five-
307 min test trials: one pre-demonstration test trial that all birds received to determine whether they
308 spontaneously solve the task, and observer birds received four test trials immediately after
309 observing demonstrations at each stage (stages 3-1-2-3; Table 1). Each test trial therefore took
310 place on a separate day, over a period of 15 days. During all test trials, the observer subject was

311 presented with the final stage apparatus with the object on the table. To solve the task, the
312 subject was required to pick up the object from the table and insert it into the tube to release the
313 collapsible platform and obtain the reward. The longest time that any subject waited between
314 observing the last demonstration session of each stage and their own test trial was 10 minutes.

315

316 **Control group**

317 The control group did not receive any object insertion apparatus training or demonstrations,
318 and were presented with the ‘final stage’ object insertion apparatus the same number of times
319 that the observer group received the apparatus (i.e., five test trials). Test trials were run on the
320 same test days as the observer group to avoid any potential differences between the groups due to
321 age or other environmental factors.

322

323 **Data analysis**

324 All training and demonstration sessions and test trials were videotaped, as well as being live
325 coded. We recorded the number of (accidental and proficient) insertions required for the trained
326 group individuals to complete each training stage and solve the task (i.e., to insert an object from
327 the table into the tube at the final apparatus stage in 10 consecutive insertions). For the observer
328 and control groups, we recorded whether the subject solved the task (i.e., inserted an object from
329 the table into the tube at the final apparatus stage, and interacted with the apparatus or object).

330 To determine whether individuals in the observer group interacted with the apparatus and
331 object more than individuals in the control group during tests, we conducted a generalised linear
332 model (GLM) using a Poisson distribution with a log link in R v3.2.1 (function: glm; R Core
333 Team 2015). We combined the total number of times a bird touched the apparatus and object per
334 trial (response variable) to examine whether it varied by trial number or group (control or

335 observer; explanatory variables). We conducted a generalised linear mixed model (GLMM)
336 using a Poisson distribution with a log link (R package: lmerTest, function: glmer, Kuznetsova,
337 Brockhoff & Christensen, 2015) to determine whether the observer group interacted more with
338 particular parts of the apparatus or object after having seen the demonstrator solve the task. We
339 examined whether the number of touches (response variable) varied according to the location
340 that was touched (apparatus base, apparatus tube, or object) by group (control or observer;
341 explanatory variables) with bird ID as a random effect. To examine whether observer jays
342 touched the apparatus/object sooner than control jays, we conducted the same GLMM just
343 mentioned, but with a different response variable: the latency (in seconds) to touch the apparatus
344 or object per test trial per bird.

345 To examine the level of certainty associated with each model, the respective models were
346 compared with all model combinations and their Akaike weights, which sum to one across the
347 models, considered (R package: MuMIn, function: dredge; Bates, Maechler & Bolker, 2011). A
348 model was considered highly likely given the data if it had a high Akaike weight (>0.89) relative
349 to the other models (Burnham & Anderson, 2002).

350 Once Experiment 1 had been conducted, all of the birds in the control and observer groups
351 were trained to insert objects into the object insertion apparatus. We recorded the number of
352 (accidental and proficient) insertions required for the observer and control group to complete
353 each training stage and solve the task. We examined whether birds in the observer group solved
354 the task faster than birds in the trained or control groups using a GLM in R. The number of
355 object insertions required to complete stage three (insert the object from the table into the tube in
356 10 consecutive insertions; response variable) was compared across conditions (trained, observer,
357 control; explanatory variable) using a Poisson family with a log link.

358

359 **Results**

360 None of the jays solved the task spontaneously in the initial trial (i.e., prior to any training,
361 demonstrations or frequent exposure to the apparatus). In the trained group, all six jays learned to
362 drop objects over a period of eight to 21 training sessions (4-11 days). In the observer group,
363 zero of six jays learned to drop objects by observing the demonstrator. In the control group, zero
364 of three jays learned to drop objects without training or demonstrations. Only one bird ('Gizmo'
365 – observer bird), on her final test trial, lifted the object high up while standing near the tube, but
366 she did not insert it into the tube.

367 All observer and control subjects generally interacted with the apparatus and/or object
368 during test trials (in 44 of 45 test trials; with the apparatus in 39 trials and the object in 34 trials).
369 Individuals in the observer group did not touch the apparatus or object more than individuals in
370 the control group (mean touches=11 and 9, respectively; Table 2: Model 1). The Akaike weight
371 for this model was very low (0.11), and it was the third ranked model, indicating a high level of
372 uncertainty, therefore it is likely that there was not enough data for the model to draw strong
373 conclusions, or the effects were too small to detect.

374 While the number of interactions decreased with increasing trial number in control
375 individuals, there is weak evidence that observer individuals had relatively more interactions
376 with the apparatus and object in later trials than control individuals (Table 2: Model 1). There
377 was only weak evidence because the Akaike weight for the top-ranked model, which was the full
378 model, was only 0.46, indicating that there was a high degree of uncertainty in this model. There
379 was no evidence that birds in the observer group interacted more with particular parts of the
380 apparatus or object after seeing the demonstrator solve the task compared with control birds
381 (mean touches=4 and 3, respectively; Table 2: Model 2). When comparing the latency to the first

382 touch between control and observer groups, observer birds touched the apparatus/object
383 significantly sooner than control birds (mean=23 and 83 seconds, respectively; Table 2, Model 3;
384 Figure 3). This model was highly likely given the data because its Akaike weight was 0.99. The
385 data in Figure 3 shows that there was no initial difference in latencies between control and
386 observer groups during their spontaneous test trial (trial 1), which was before the observer group
387 had access to social information about the apparatus. The difference between the two groups
388 occurred in trials 2-5 where, after the social demonstrations, observer latencies stayed the same,
389 while the control group's latencies increased.

390 Following this experiment, all nine jays in the observer and control groups underwent
391 training to drop objects over a period of 8-12 training sessions (five to seven days). Therefore,
392 the number of object insertions required to reach proficiency was compared between the trained,
393 observer, and control groups. Birds in the trained group required more insertions to solve the task
394 (i.e., to insert objects from the table into the tube of the final stage apparatus; mean insertions to
395 solve=167, GLM estimate=0.39, SE=0.06, $z=6.26$, $p<0.001$), than observer and control birds.
396 Birds in the observer (mean insertions to solve=114, GLM estimate=0.01, SE=0.07, $z=0.20$,
397 $p=0.84$) and control (mean insertions to solve=113, GLM [intercept] estimate=4.72, SE=0.05,
398 $z=86.86$, $p<0.001$) groups did not differ in the number of insertions (Figure 4; ESM1 Table S1).

399

400 **EXPERIMENT 2: Two-choice colour discrimination task**

401 **Materials**

402 This set up consisted of two plastic cups – one black and one white (diameter=6cm,
403 height=14.5cm). Cups were spaced 30cm apart on a wooden board (50cm x 15cm). Each cup
404 was attached to its own metal rod so they could move up and down independently, but they were

405 prevented from being removed entirely from the rod by a bolt. Cups could be lifted upwards to
406 reveal a hidden reward (Figure 2). Two live mealworms were placed underneath each cup.

407

408 **Procedure**

409 **Demonstrator training**

410 One bird acted as a demonstrator - ‘Homer’ - the same demonstrator as in Experiment 1. In
411 visual isolation from the observer group, Homer received four sessions (5-10 mins per session)
412 of 10 trials per session, where only one cup - the white cup - was baited (‘demonstrated’ cup)
413 and the other cup - the black cup - was locked down using the bolt so it could not be lifted. To
414 pass demonstrator training, Homer had to consistently lift only the demonstrated cup in all 10
415 consecutive trials within a session and not touch or try to lift the other cup before he could move
416 on to the demonstrations for observers. Homer touched both cups in session one and two, but
417 passed criterion in session three. He was given four training sessions in total to ensure
418 comparability with the number of demonstrator training sessions used for the carrion crows and
419 ravens in Miller, Schwab & Bugnyar (2016). Homer chose the white cup 100% of the time
420 during demonstrations for observers; therefore observers did not see any incorrect choices.

421

422 **Demonstrations for observers**

423 The observer group consisted of seven birds in order to be comparable with the sample size
424 in Miller and colleagues (2016): four females and three males. These individuals also
425 participated in Experiment 1: three from the trained group, three from the observer group, and
426 one from the control group. In an adjacent compartment with visual access to the observers, the
427 demonstrator lifted the demonstrated cup (white) and obtained the reward in four sessions, with

428 10 trials per session. Both cups were baited and could potentially be lifted, though the
429 demonstrator only lifted the demonstrated cup. The demonstrated cup location (left or right) was
430 counterbalanced across trials. Each observer watched one session per day.

431

432 **Testing observers**

433 After observers had seen Homer lifting the demonstrator cup 40 times, they were tested in
434 visual isolation from the group. Each observer was presented with the cups, both cups were
435 baited out-of-sight of the observer and we recorded which cup they touched first. They were
436 given one test trial, which lasted up to three minutes (all subjects interacted with the cups within
437 three minutes). They were allowed to touch both cups. The location of the demonstrated cup was
438 randomized across subjects. If they touched the demonstrated cup (white) first, we considered
439 this to be using social information from the demonstrator.

440

441 **Data analysis**

442 We recorded the colour and latency of the cup first touched by the demonstrator during
443 training and demonstration trials, and by the observers during the test. The data were analysed
444 using SPSS version 21 for the exact two-tailed Binomial tests, and R for the t-test. RM and KL
445 both coded 20% of all videos across both experiments, with KL acting as a naïve coder, and
446 inter-observer reliability was excellent (Cohen's kappa $k=0.989$, $p < 0.001$).

447

448 **Results**

449 Jays did not choose the demonstrated colour above chance levels (Binomial test: $p=0.453$).
450 Two of seven jays (one male, one female) chose the same coloured cup (white) as the

451 demonstrator (i.e., copied the demonstrator), while the other five jays (three females, two males)
452 chose the non-demonstrated coloured cup (black; Table 3). In comparison, Miller, Schwab &
453 Bugnyar (2016) found that eight of eight crows (five females, three males) and eight of eight
454 ravens (three females, five males) copied the conspecific demonstrator, which was significant
455 (Binomial test: $p=0.008$ for each species). We additionally examined whether there was a
456 difference in the latency to make the first choice between the birds that chose the demonstrated
457 colour versus those that did not. The jays that chose the demonstrated colour did not have shorter
458 latencies to their first choice (Welch two-sample t-test: $t=0.88$, $p=0.47$, $n=7$, 95% confidence
459 interval=-36-57; data in ESM1 Table S1). We also explored whether relatedness influenced
460 likelihood to copy the demonstrator. Zero of two jays that selected the demonstrated coloured
461 cup (Binomial test: $p=0.5$, $n=2$) and two of five jays that did not select the demonstrated
462 coloured cup were siblings of the demonstrator bird (Binomial test: $p=1.00$, $n=5$). The birds did
463 not appear to show a group side bias because they did not select the cup on the same side
464 regardless of colour (Table 3: Binomial test: $p=1.00$, $n=7$).

465

466 **Discussion**

467 We found that relatively asocial Eurasian jays did not use social information (i.e.,
468 information made available by a conspecific) in the form of copying the choices of others in
469 either task. In Experiment 1 (object-dropping task), birds in the observer group first touched the
470 apparatus and object significantly sooner than birds in the control group, indicating a form of
471 social learning called stimulus enhancement. Stimulus enhancement attracts the attention of an
472 observer towards a specific object where the model acts (Giraldeau, 1997). However, observing a

473 conspecific demonstrator did not facilitate solving the object-dropping task in Experiment 1, or
474 result in colour choice copying in Experiment 2.

475 Although corvids, including Eurasian jays, can be trained in the object-dropping task, it is
476 possible that this task is too difficult for social learning to facilitate the solution, except for the
477 occasional individual (i.e., one rook: Bird and Emery, 2009b; and one New Caledonian crow:
478 Mioduszewska, Auersperg & von Bayern, 2015), thus masking whether Eurasian jays are able to
479 use social information by observing, and thus learning from, a demonstrator. In the present
480 experiment, solving this task required the observer birds to copy several actions of the
481 demonstrator: lifting the object from the table to insert into the tube to drop the collapsible
482 platform and obtain the reward, rather than just knocking an object into the tube from the tube
483 ledge, which is typically stage one of training. In further support of the suggestion that this task
484 is difficult for birds to learn is that only one bird has spontaneously solved the object-dropping
485 task in a previous study (one New Caledonian crow; Mioduszewska, Auersperg & von Bayern,
486 2015), without any demonstrations or training. Additionally, birds, including corvids, typically
487 require a relatively large number of training trials to learn to solve this task, indicating that it is
488 fairly difficult to learn even with explicit training (e.g., 90-275 trials in the present experiment;
489 135-362 trials in great-tailed grackles: Logan, 2016; 76-255 trials in California scrub-jays: Logan
490 et al., 2016 – though note that definitions for reaching proficiency differ between these studies
491 and the current experiment).

492 It is therefore possible that the jays obtained some information from the demonstrator, but
493 potentially this information was not sufficient to enable them to complete the task (i.e., to insert
494 the object from the table into the tube). Therefore, we assessed whether there was any evidence
495 that the jays attended to the demonstrator, despite not being able to solve the task following the

496 demonstrations, by measuring differences in the number of interactions with the apparatus and
497 object between the control and observer groups. Individuals in the observer group were not more
498 likely to touch the apparatus or object than individuals in the control group. Observer individuals
499 touched the apparatus and object in later trials more than control individuals, indicating that jays
500 may have been more persistent after having seen another bird solve the task. However, it should
501 be noted that the models showed only weak evidence for these two findings.

502 We also found that the observer group solved the object-dropping task significantly more
503 quickly than the trained group; however, there was no difference in the rate of learning (i.e., total
504 number of insertions required to solve the task) between the observer and control groups. The
505 strongest evidence of any form of social learning was in the form of stimulus enhancement:
506 observer birds that had seen a demonstrator interact with the apparatus and object first touched
507 these elements significantly sooner than control birds that had never observed another touching
508 the apparatus. It is possible that increased exposure to the apparatus may have facilitated learning
509 in both the observer and control groups, perhaps by removing neophobia of the apparatus
510 (although all birds were habituated to the apparatus prior to testing), and/or some social
511 facilitation of attraction or attention to the apparatus, as opposed to learning the actions to
512 perform the task. However, it is unclear whether observers attended to social information
513 provided by the conspecific or whether they would have learned about the task by observing a
514 ‘ghost control’ where the object was inserted into the tube in the absence of a conspecific. Future
515 research incorporating ghost controls could distinguish between whether jays attend to social
516 information about what to attend to or whether they solely attend to the relevant object
517 movements and reward outcomes.

518 In Experiment 2, in comparison with the object-dropping task, the colour discrimination task
519 was relatively simple as corvids are capable of making colour discriminations (Clayton & Krebs,
520 1994; Range, Bugnyar & Kotrschal, 2008). For example, there is evidence that juvenile Eurasian
521 jays can discriminate between colours in similar two-choice discrimination tasks. Davidson and
522 colleagues (Under Review) trained half of a group of Eurasian jays to associate a yellow
523 coloured object with a reward and a green coloured object with no reward, and the other half to
524 associate the green object with a reward and the yellow object with no reward. The jays then
525 demonstrated proficiency by flying to the perch where the rewarded colour was located.

526 Further, the same task used in Experiment 2 was used previously in eight ravens and eight
527 carrion crows, and all birds chose the demonstrated colour (Miller, Schwab & Bugnyar, 2016).
528 While the methods have some limitations (e.g., no counterbalancing of rewarded cup color, using
529 only one demonstrator whose characteristics might have made him less likely for observers to
530 attend to, low statistical power from only one trial per bird), we ran this task in a comparable
531 manner to Miller, Schwab & Bugnyar (2016) to allow for direct comparison between these two
532 experiments, including the use of one male, same-age conspecific demonstrator to an observer
533 group and one test trial. Additionally, all birds were hand-reared in species groups in a similar
534 manner, tested by the same experimenter (RM) and similar sample sizes were used (eight ravens,
535 eight crows, seven jays). We also similarly controlled for the influence of spatial location by
536 randomizing the location of the demonstrated cup across subjects, and we found no group-level
537 bias for one location (right/left) over the other (Table 3).

538 There were two notable differences between these experiments. Firstly, the colour
539 discrimination task used different colours: blue and yellow cups in Miller, Schwab & Bugnyar
540 (2016) compared with white and black cups in the present experiment. The justification for this

541 difference was the need to avoid a possible overlap between this experiment and the prior
542 experience of the jays with several different colours in differing reward scenarios during
543 previous studies (e.g., Davidson et al., Under Review). Furthermore, Shaw and colleagues (2015)
544 suggest that colour discrimination tasks should aim to use gray scale cues (e.g., light vs. dark
545 gray) to avoid innate species-level colour preferences. We cannot entirely rule out innate colour
546 preferences, because we did not transfer birds to novel colour combinations. However, innate
547 preferences would likely have been expressed at the species level, which did not occur here
548 because jays randomly chose white and black cups in their first trials.

549 Secondly, the jays were juveniles, whereas the ravens and crows were sub-adults. Therefore,
550 it is possible that social learning in the jays may not have developed by this early stage.
551 However, this is unlikely given that juveniles in other relatively asocial species exhibited social
552 learning whereas adults did not (Lupfer, Frieman & Coonfield 2003; Noble, Byrne & Whiting
553 2014). To our knowledge, no corvid studies have compared juvenile and adult social information
554 use. However, object permanence in Eurasian jays, which relates to caching development,
555 develops at a similar stage as in other corvids (ravens: Bugnyar, Stowe & Heinrich, 2007;
556 California scrub-jays: Salwiczek et al., 2009). Specifically, jays reach a full (i.e., stage six
557 Piagetian) understanding of object permanence within their first few months of life (Zucca,
558 Milos & Vallortigara, 2007). As the jays we tested were more than a few months of age, we do
559 not expect their behaviour to differ from adult behaviour with regard to social learning. The
560 finding that the jays behaved differently from the more social carrion crows and ravens in the use
561 of social information in this task is important. It raises the question of whether these more social
562 species - as with the more social rook (Bird & Emery, 2009b) and New Caledonian crow

563 (Mioduszevska, Auersperg & von Bayern, 2015) - might be able to learn to copy the
564 demonstrator in the object-dropping task (Experiment 1).

565 Previous experiments have indicated that Eurasian jays do attend to social context in caching
566 and mate provisioning (Shaw & Clayton, 2012; Shaw & Clayton, 2013; Ostojić et al., 2013;
567 Shaw & Clayton, 2014; Ostojić et al., 2014; Legg, Ostojić & Clayton, 2016). It is therefore still
568 possible that jays use social information, but not for copying others' choices, as none of the
569 previous experiments required the birds to copy a demonstrator. Jays may also be more likely to
570 pay attention to and copy different demonstrators, such as an older, more affiliated or related
571 individuals, as model identity has been found to influence social learning in other corvids
572 (ravens, jackdaws: Schwab, Bugnyar & Kotrschal 2008a; Schwab et al., 2008b). For example,
573 presence of siblings enhances social learning in ravens (Schwab et al., 2008b). Our demonstrator
574 was a sibling of some of the observers, which suggests that there was no influence of relatedness
575 to demonstrator on likelihood of copying in Experiment 2. However, our experiment was not
576 designed to test the relationship between relatedness and social learning and we do not have the
577 statistical power to make a firm conclusion on this point.

578 The use of social information is a process with several stages, which are likely to be
579 sequential and distinct: acquisition (observing another), application (performing the observed
580 behaviour, not necessarily successfully) and exploitation (successfully performing the observed
581 behaviour in a way that gives the individual an advantage; Carter, Tico & Cowlshaw, 2016;
582 Guillette, Scott & Healy, 2016). For instance, in chacma baboons (*Papio ursinus*), the average
583 individual acquired social information on <25% of occasions and exploited social information on
584 <5% of occasions, and information use was dependent on phenotypic constraints such as network
585 position and dominance status (Carter, Tico & Cowlshaw, 2016). The results of Experiments 1

586 and 2 demonstrated that Eurasian jays did not appear to apply or exploit the social information
587 available even though they had the opportunity to acquire it. Although we reiterate that social
588 species also do not show a strong capacity to socially learn the object-dropping task in
589 Experiment 1.

590 In conclusion, Eurasian jays did not appear to use social information in the form of copying
591 the decisions of a conspecific in the object-dropping and colour discrimination tasks, which vary
592 in difficulty. However, their attention was drawn to the apparatus and object in the object-
593 dropping task as indicated by observers touching these components sooner than control birds. In
594 previous studies with social corvids, the birds had been explicitly tested for influences of social
595 information on learning the object-dropping task in only one study, with only one New
596 Caledonian crow learning the task following a conspecific demonstration (Mioduszevska,
597 Auersperg & von Bayern, 2015). We also know that, when tested using very similar procedures,
598 including the same lead experimenter, ravens and crows use social information in the colour
599 discrimination task, in contrast to the jays. These corvid species vary in sociality, but all are
600 more social than the jays. Our results from relatively asocial Eurasian jays are therefore
601 consistent with those from relatively asocial Clark's nutcrackers (Bednekoff & Balda 1996,
602 Templeton, Kamil & Balda, 1999) in that social and relatively asocial corvids appear to differ in
603 their use of social information with regard to copying the choices of others. The present
604 experiment may indicate that Eurasian jays secondarily lost the ability to copy social information
605 provided by a conspecific, at least in some contexts, while maintaining the ability to attend to the
606 general movements of others, due to lack of selection pressure from an asocial environment.
607 However, more comparisons between social and relatively asocial corvids are needed to confirm
608 this hypothesis.

Table 1 (on next page)

Stages of the object insertion apparatus.

Training stages: training the trained group, and subsequent to their tests, the observer and control groups, to insert objects into the tube to release the food reward. Training stages occurred in the following sequence: 1-2-3. Demonstrator stages: birds in the observer group watched the demonstrator solve the apparatus 40 times per stage before being presented with the final stage apparatus in a test trial. Demonstration stages occurred in the following sequence: 3-1-2-3.

8

Table 2 (on next page)

Did observers learn what to attend to from the demonstrator?

Results from the GLM (Model 1) and GLMM (Model 2) examining whether individuals in the observer group **touched** the apparatus and object more than control individuals (Model 1) or whether they interacted more with particular parts of the apparatus (base or tube) or object (Model 2). Model 3 (GLMM) examined **latencies** to first touch per trial to determine whether individuals in the observer group first touched the apparatus/object sooner than control birds. SE: standard error, z: z value, p: p value, the rows in italics list the variance and standard deviation of the random effect.
