The non-feeding postlarva (puerulus) of spiny lobsters actively swims from the open ocean to the coastal habitats where it settles and molts to the first-stage juvenile (J1). Because pueruli use much of their energy reserves swimming and preparing for the post-settlement molt, the survival of J1s presumably depends on resuming feeding as soon as possible. To test this hypothesis, the resistance to starvation of J1s of the Caribbean spiny lobster, *Panulirus argus*, was evaluated by measuring their point-of-no-return (PNR, minimum time of initial starvation preventing recovery after later feeding) and point-of-reserve-saturation (PRS, minimum time of initial feeding allowing for food-independent development through the rest of the molting cycle) in a warm and a cold season. Each experiment consisted of continuously fed and starved control groups (FC and SC, respectively) and six groups subjected to differential periods of initial starvation and subsequent feeding (PNR experiments) or initial feeding and subsequent starvation (PSR experiments). No J1s molted under continuous absence of food (SC). In both PNR experiments (temperature in warm season: $29.79 \pm 0.07^\circ\text{C}$, mean \pm 95% CI; in cold season: $25.63 \pm 0.12^\circ\text{C}$) mortality increased sharply after 9 d of initial starvation and intermolt periods increased with period of initial starvation, but were longer in the cold season. The PNR₅₀ was longer in the warm season (12.1 ± 1.2 d, mean \pm 95% CI) than in the cold season (9.5 ± 2.1 d). In PRS experiments (temperature in warm season: $29.54 \pm 0.07^\circ\text{C}$; in cold season: $26.20 \pm 0.12^\circ\text{C}$), J1s that molted did so near the end of the feeding period; all J1s initially fed for up to 6 d succumbed, and no J1s molted after 13 d of starvation despite having fed previously. The PRS₅₀ did not differ between the cold (13.1 ± 0.7 d) and warm seasons (12.1 ± 1.1 d). J1s of *P. argus* exhibit a remarkable resistance to starvation considering that the previous non-feeding, energy-demanding puerulus phase lasts for ~3 weeks. However, J1s appear to have a relatively higher degree of dependence on food to complete development to J11 during the cold season than during the warm season. Therefore, J1s of *P. argus* would appear to be more resistant to starvation during the warm season.

25 **ABSTRACT**

26 The non-feeding postlarva (puerulus) of spiny lobsters actively swims from the open ocean to the
27 coastal habitats where it settles and molts to the first-stage juvenile (JI). Because pueruli use
28 much of their energy reserves swimming and preparing for the post-settlement molt, the survival
29 of JIs presumably depends on resuming feeding as soon as possible. To test this hypothesis, the
30 resistance to starvation of JIs of the Caribbean spiny lobster, *Panulirus argus*, was evaluated by
31 measuring their point-of-no-return (PNR, minimum time of initial starvation preventing recovery
32 after later feeding) and point-of-reserve-saturation (PRS, minimum time of initial feeding
33 allowing for food-independent development through the rest of the molting cycle) in a warm and
34 a cold season. Each experiment consisted of continuously fed and starved control groups (FC and
35 SC, respectively) and six groups subjected to differential periods of initial starvation and
36 subsequent feeding (PNR experiments) or initial feeding and subsequent starvation (PSR
37 experiments). No JIs molted under continuous absence of food (SC). In both PNR experiments
38 (temperature in warm season: $29.79 \pm 0.07^\circ\text{C}$, mean \pm 95% CI; in cold season: $25.63 \pm 0.12^\circ\text{C}$)
39 mortality increased sharply after 9 d of initial starvation and intermolt periods increased with
40 period of initial starvation, but were longer in the cold season. The PNR₅₀ was longer in the
41 warm season (12.1 ± 1.2 d, mean \pm 95% CI) than in the cold season (9.5 ± 2.1 d). In PRS
42 experiments (temperature in warm season: $29.54 \pm 0.07^\circ\text{C}$; in cold season: $26.20 \pm 0.12^\circ\text{C}$), JIs
43 that molted did so near the end of the feeding period; all JIs initially fed for up to 6 d succumbed,
44 and no JIs molted after 13 d of starvation despite having fed previously. The PRS₅₀ did not differ
45 between the cold (13.1 ± 0.7 d) and warm seasons (12.1 ± 1.1 d). JIs of *P. argus* exhibit a
46 remarkable resistance to starvation considering that the previous non-feeding, energy-demanding
47 puerulus phase lasts for ~3 weeks. However, JIs appear to have a relatively higher degree of

48 dependence on food to complete development to JII during the cold season than during the warm
49 season. Therefore, JIs of *P. argus* would appear to be more resistant to starvation during the
50 warm season.

51

52 INTRODUCTION

53 The Caribbean spiny lobster, *Panulirus argus* (Latreille, 1804) is widely distributed in the
54 wider Caribbean region (Holthuis, 1991), where it constitutes one of the most important fishing
55 resource (Phillips et al., 2013). However, in various parts of the Caribbean, including Mexico,
56 catches of *P. argus* have suffered a substantial decline since the late 1990s (Aguilar et al., 2003;
57 Ehrhardt, Puga & Butler, 2011).

58 In the warm Caribbean waters, *P. argus* breeds throughout most of the year, with a major
59 peak during the spring and a secondary peak in the fall (Briones et al., 1997). The larval phase
60 consists of 10 flattened planktonic stages, the phyllosomata (Goldstein et al., 2008). Larval
61 development takes place in oceanic waters and lasts 5-9 months, conferring an enormous
62 dispersion potential. The final larval stage undergoes a drastic metamorphosis into the postlarval
63 phase, which consists of a single nektonic stage, the puerulus, which is more similar in shape to
64 an adult lobster but is completely transparent (Phillips et al., 2006). Unlike phyllosomata, which
65 are planktotrophic, pueruli do not feed, i.e., they represent a secondary lecithotrophic phase that
66 depends on its own energy reserves (Kittaka, 1994; Lemmens, 1994; McWilliam & Phillips,
67 1997; Cox, Jeffs & Davies, 2008). Pueruli actively swim towards the shore and settle in shallow
68 coastal vegetated habitats, such as seagrass and macroalgal beds (Butler & Herrnkind, 2000;
69 Briones-Fourzán & Lozano-Álvarez, 2001). A few days after settling, pueruli molt into the first
70 juvenile stage, also known as post-puerulus (e.g. Limbourn et al., 2008), which resumes feeding.

71 Under laboratory conditions, the total duration of the non-feeding puerulus phase of *P.*
72 *argus* has been 16 to 26 d at 25° C and 11 to 18 d at 27° C (Goldstein et al., 2008). During this
73 period most of the puerulus energy is allocated to swimming and preparing for the post-
74 settlement molt into the first juvenile stage (JI), which involves further morphological changes
75 (Lewis, Moore & Babis, 1952; Goldstein et al., 2008; Ventura et al., 2015). Swimming for
76 distances of up to tens of kilometers to the settlement site can severely deplete the energy stores
77 of the puerulus, potentially compromising its ability to molt into the JI (Jeffs, Willmott & Wells,
78 1999; Jeffs, Chiswell & Booth, 2001). Moreover, resumption of feeding by the JI may depend
79 on local food availability and predation risk (Lozano-Álvarez, 1996; Weiss, Lozano-Álvarez &
80 Briones-Fourzán, 2008). If the JI cannot restore sufficient energy reserves quickly enough, it
81 could starve to death (Fitzgibbon, Jeffs & Battaglione, 2014a). Therefore, it is important to
82 determine the resistance to starvation (*sensu* Sulkin, 1978) of JIs of *P. argus*. This information,
83 in addition to increasing knowledge regarding the biology of the early benthic stages of this
84 species, is important for its potential in aquaculture and for the generation of predictive models
85 of local lobster production based on levels of puerulus settlement (Phillips et al., 2000).

86 In the present study, resistance to starvation of JIs of *P. argus* was experimentally
87 determined via two physiological indices, the point-of-no-return (PNR) and the point-of-reserve-
88 saturation (PRS). The PNR is the duration of initial food deprivation that will cause irreversible
89 damage, i.e., that will not allow recovery even after later re-feeding (Blaxter & Hempel, 1963;
90 Anger & Dawirs, 1981); the PRS is the minimum time of initial feeding after which a later food-
91 independent development to the next stage is possible (Anger, 1987, 1995). To our knowledge,
92 the PRS has not been determined for JIs of any spiny lobster species, and the only one for which
93 the PNR of JIs has been determined is *P. cygnus* (Limbourn et al., 2008). In the present study,

94 the PNR was determined by subjecting JIs of *P. argus* to a range of initial starvation periods
95 shortly after molting, followed by continuous feeding. The PRS was determined by feeding JIs
96 initially for diverse periods before food was permanently withheld. Each index was estimated
97 during a warm season (summer-autumn) and a cold season (winter-spring) because the metabolic
98 and growth rates of crustaceans in general (e.g. Anger, 2001), and of *P. argus* in particular
99 (Perera et al., 2007), increase with temperature, potentially affecting the PNR and PRS (Anger et
100 al., 1981; Paschke et al., 2004; Bas, Spivak & Anger, 2008; Gebauer, Pashke & Anger, 2010).

101

102 **MATERIALS AND METHODS**

103 Given the long larval duration and extremely high rates of mortality of phyllosomata
104 under laboratory conditions (Goldstein et al., 2008), our study was conducted using wild
105 postlarvae as in Limbourn et al. (2008). Pueruli of *P. argus* were obtained from a set of 12
106 artificial seaweed GuSi collectors (Gutiérrez-Carbonell, Simonín-Díaz & Briones-Fourzán,
107 1992) permanently deployed in the reef lagoons of Puerto Morelos (20°52'07" N, 86°52'04" W)
108 and Bahía de la Ascensión (19°49'50" N, 87°27'09" W), Mexico. These collectors are only
109 checked once a month because they are used for long-term monitoring of monthly pueruli
110 settlement. Although monthly settlement in collectors can vary by an order of magnitude within
111 a year, the average catch is 16 individuals per collector per month in Puerto Morelos, and 4
112 individuals per collector per month in Bahía de la Ascensión (Briones-Fourzán, Candela &
113 Lozano-Álvarez, 2008). Therefore, to increase the number of pueruli, a large mat (1 m × 8 m) of
114 the same artificial seaweed was moored off a dock at Puerto Morelos and checked for pueruli
115 every morning throughout the dark phase of the moon, when settlement levels are typically
116 higher (Briones-Fourzán, 1994). Within 1 h of collection, the pueruli were transported in aerated

117 seawater to the laboratory where the experiments were conducted. The necessary permits for
118 pueruli collection were obtained from Comisión Nacional de Acuacultura y Pesca
119 (DGOPA.06695.190612.1737).

120 The pueruli were individually placed in small covered cylindrical plastic baskets (0.5 l) to
121 allow free water exchange. Each basket was lined with black nylon mesh to prevent escape of the
122 puerulus and to reduce the light level. The baskets were partially submerged and supported by
123 ethylene vinyl acetate (“foamy”) floats to provide buoyancy, and were distributed among three
124 tanks (2 m in diameter) with a water level of 0.7 m (approximately 2,800 l each), with 6–7
125 baskets allotted to each treatment in each tank. The tanks received seawater from an open-flow
126 system. The inflow water was pumped from the Puerto Morelos reef lagoon and passed through
127 an ozone chamber to a reservoir tank (6,300 l), then pumped through a sand filter (Hayward high
128 rate sand filter, S-244T) to remove suspended particles before its distribution to the experimental
129 tanks. The outflowing water was passed again through an ozone chamber. Water temperature in
130 the tanks was recorded twice a day with an YSI Environmental 556 multi-probe system.

131 Because each experiment required 160 pueruli (see below) but the number of pueruli that
132 could be collected during any given season (warm or cold) was limited, it was not possible to
133 conduct more than one experiment per season. Therefore, the PNR experiments were conducted
134 in June–October 2012 (warm season) and January–April 2013 (cold season), and the PRS
135 experiments were conducted in January–April 2014 (cold season) and July–November 2014
136 (warm season). For each experiment, 160 pueruli were divided into eight groups of 20
137 individuals each. All individuals were checked twice daily, in the morning and evening. When a
138 puerulus molted into a JI, the exuvia was removed. One group of recently molted JIs was
139 continuously fed (fed control, FC) until all individuals molted into second-stage juveniles (JIIs).

140 Another group remained unfed until all the individuals succumbed (starved control, SC). In the
141 PNR experiments, the six remaining groups of recently molted JIs were subjected to different
142 treatments (periods of starvation in multiples of 3 d) and then fed continuously. Thus, one group
143 was starved for 3 d and then fed (treatment S3), another group was starved for 6 d and then fed
144 (treatment S6), etc. (up to 18 d of initial starvation) (Fig. 1). In the PRS experiment, the six
145 remaining groups of recently molted JIs were also subjected to different treatments, consisting of
146 feeding periods (also in multiples of 3 d) and then starved. Thus, one group was fed for 3 d and
147 then starved (treatment F3), another group was fed for 6 d and then starved (treatment F6), etc.
148 (up to 18 d of initial feeding) (Fig. 1). Food, when provided, consisted of a piece of mussel meat
149 (*Perna canaliculus*) changed daily. Mussels are a good food source for early juveniles of
150 *Panulirus* in laboratory conditions, at least during the first four weeks after the molt to JI (e.g., *P.*
151 *cygnus*: Glencross et al., 2001; *P. ornatus*: Smith, Williams & Irvin, 2005; *P. interruptus*: Diaz-
152 Iglesias et al., 2011). Three-day periods were used to optimize the use of experimental individuals
153 (which are difficult to obtain in large numbers) given that, in the laboratory, the average
154 intermolt period of well-fed JIs of *P. argus* varied between 17 and 31 d depending on water
155 temperature (Lellis & Russell, 1990), whereas the maximal starvation time for JIs of *P. cygnus*
156 from which recovery was observed was 22 d (Limbourn et al., 2008). Therefore, JIs of *P. argus*
157 were expected to endure relatively long starvation periods.

158 For each individual, the first experimental day was one day after molting to JI (Limbourn
159 et al., 2008). The influence of the initial starvation periods (in the PNR experiments) or the initial
160 feeding periods (in the PRS experiments) was measured as percent mortality and the average
161 duration of the JI stage of individuals that molted to JII (intermolt period). For the PNR and PRS
162 experiments, duration of stage JI in days (logarithmically transformed to increase homogeneity

163 of variance) was separately subjected to a factorial ANOVA with season and treatment as fixed
164 factors. Starvation tolerance was quantified as the median point-of-no-return (PNR_{50}) and point-
165 of-reserve-saturation (PRS_{50}). PNR_{50} is the time when 50% of initially starved JIs lost the
166 capability to recover, even after subsequent feeding, and died without molting to JIII; PRS_{50} is the
167 time when 50% of initially fed JIs attained the capability to develop through the rest of the
168 molting cycle using internally stored energy reserves (Anger & Dawirs, 1981). PNR_{50} and PRS_{50}
169 were estimated by fitting sigmoidal dose-response curves of cumulative mortality to the time of
170 initial starvation or feeding, respectively (Paschke et al., 2004; Gutow et al., 2007; Bas, Spivak
171 & Anger, 2008). Each index was compared between seasons (warm versus cold).

172

173 RESULTS

174 Throughout the text, results are reported as mean \pm 95% CI unless otherwise stated.

175 Statistical results were considered as significant at $p < 0.05$.

176

177 Point-of-no-return (PNR)

178 In the PNR experiments, water temperature differed significantly between the warm
179 (29.79 ± 0.07 °C) and cold seasons (25.63 ± 0.12 °C) ($t_{176} = 28.65$, $p < 0.001$). The duration of
180 stage JI in continuously fed individuals (i.e., the FC) was longer in the cold season (24.5 ± 3.6 d,
181 $n = 17$) than in the warm season (18.2 ± 1.3 d, $n = 20$) ($t_{35} = 3.44$, $p < 0.001$). In general, the
182 duration of stage JI was significantly affected by season ($F_{1,148} = 68.04$, $p < 0.001$) and treatment
183 ($F_{5,148} = 22.32$, $p < 0.001$) but not by the interaction term ($F_{5,148} = 0.37$, $p = 0.87$); i.e., it
184 increased with the duration of the initial period of starvation in both seasons but was longer for
185 each period in the cold season (Fig. 2). Overall, mortality of JIs increased with number of initial

186 days of starvation, but tended to be higher in a few treatments of the cold season experiment (FC,
187 S3, S6, S12) than in the same treatments of the warm season experiment. The PNR_{50} was $12.1 \pm$
188 1.2 d in the warm season and 9.5 ± 2.1 d in the cold season (Fig. 3), a significant difference ($F_{1,$
189 $12 = 7.924, p = 0.015$).

190

191 **Point-of-reserve-saturation (PRS_{50})**

192 In the PRS experiments, water temperature differed significantly between the cold season
193 (26.20 ± 0.12 °C) and the warm season (29.54 ± 0.07 °C) ($t_{285} = 24.23, p < 0.001$). The duration
194 of stage JI in individuals from the FC was significantly longer in the cold season (25.7 ± 2.3 d, n
195 $= 20$) than in the warm season (16.3 ± 1.3 d, $n = 20$) ($t_{38} = 7.05, p < 0.001$). Overall, the duration
196 of stage JI was significantly affected by season ($F_{1,119} = 37.9, p < 0.001$) and treatment ($F_{4,119} =$
197 $8.71, p < 0.001$), but the interaction term was also significant ($F_{4,119} = 3.76, p < 0.001$),
198 indicating that the intermolt period in the different treatments did not follow the same pattern in
199 both seasons (Fig. 4). In particular, the intermolt period was significantly longer in treatments
200 F15 and F18 and in the FC of the cold season than in the same treatments of the warm season
201 (Fig. 4).

202 Mortality of JIs decreased with increasing period of initial feeding, but was higher in
203 almost all treatments of the cold season than in those of the warm season. In both seasons, all
204 individuals in the SC and in treatments F3 and F6 succumbed. In both experiments, with the
205 exception of the fed control group, most JIs molted near the end of the initial feeding period,
206 with a maximum of 13 d between the end of the initial feeding period and molting. The PRS_{50}
207 was 13.1 ± 0.7 d in the cold season and 12.1 ± 1.1 d in the warm season (Fig. 5). These values
208 did not differ significantly ($F_{1,12} = 3.603, p = 0.082$).

209

210 **DISCUSSION**

211 Temperature has an important effect on the physiology and ecology of ectotherms such as
212 spiny lobsters. For example, in Florida, USA, Witham (1973) reported that small juveniles of
213 *Panulirus argus* were intolerant of sustained temperatures below 15.6°C or above 30.0°C, and
214 that lobsters held below 20°C exhibited relatively little growth. In laboratory experiments held in
215 Cuba, oxygen consumption and metabolism of early benthic and older juveniles of *P. argus*
216 increased with temperature within the range of 19 to 30°C (Brito et al., 1991; Perera et al., 2007).
217 Lellis & Russell (1990) examined growth and survival of postpueruli and early juveniles of *P.*
218 *argus* at different temperatures and found that these stages grew faster at 30°C due to shorter
219 intermolt periods and greater size increments than at 24, 27, or 33°C. In our study, mean water
220 temperature during the PNR and PRS experiments was 25.9 and 26.2°C in the cold season,
221 respectively, and 29.8 and 29.5°C in the warm season, respectively. Consequently, in both types
222 of experiment the duration of stage JI of continuously fed individuals (FC) was significantly
223 longer in the cold season than in the warm season.

224 Limbourn et al. (2008) estimated the PNR₅₀ of JIs of *P. cygnus*, a subtropical species, at
225 22 d, which is about twice the PNR₅₀ estimated for the tropical *P. argus* in the present study.
226 Regardless, the resistance to starvation of JIs of *P. argus* is remarkable, considering the energetic
227 demand imposed on the non-feeding pueruli during their transit from oceanic waters to the coast
228 (e.g. Fitzgibbon, Jeffs & Battaglene, 2014a). As previously found by Limbourn et al. (2008) for
229 *P. cygnus*, no JIs of *P. argus* were able to molt in complete absence of food (SC). Dependence
230 on exogenous food of JIs to complete development has also been found in other decapods, even
231 in some species with facultative lecithotrophic postlarvae (Calado et al., 2010). An exception is

232 the red cherry shrimp, *Neocaridina davidi*, in which JIs were able to molt even in complete
233 absence of food, probably because this species has a much abbreviated post-hatching
234 development (Pantaleão et al., 2015). In our two PNR experiments, the duration of stage JI
235 increased with increasing period of initial starvation. A delay in molting caused by lack of food
236 has been documented in early life stages of other marine and freshwater crustacean species (e.g.,
237 Anger & Dawirs, 1981; Mikami, Greenwood & Gillespie, 1995; Abrunhosa & Kittaka, 1997;
238 Stumpf et al., 2010; Calvo et al., 2012) except *N. davidi*, in which the duration of stages JI and
239 JIII was not affected by the duration of initial starvation periods (Pantaleão et al., 2015).

240 In the PRS experiments, the few individuals that molted to JII in treatments F9 and F12
241 did so near the end of the feeding period, and no individuals molted after 13 d of starvation
242 despite having been previously fed, resulting in an apparent increase in duration of stage JI with
243 duration of initial feeding period. This result contrasts with the results of the PNR experiments,
244 in which seven individuals from treatments S15 and S18 of the warm season experiment and
245 eight from treatments S15 and S18 of the cold season experiment were able to molt. The higher
246 tolerance to starvation of individuals from the PNR experiments may be due to a suspension of
247 the molting cycle, i.e., an arrest of development in the intermolt stage (stage C in Drach's molt
248 classification system) of individuals subjected to initial starvation, with a subsequent shift to
249 premolt stage (stage D) with further feeding (Anger, 1987). However, in PRS experiments, if
250 individuals reach the premolt stage during the period of initial feeding and then are subjected to
251 continuous starvation, an unsuccessful attempt to molt will lead to death because an arrest of
252 development in premolt is not possible (Anger, 2001).

253 The PRS occurs during the transition between late intermolt (stage C₄) and early premolt
254 (stage D₀), which is also known as the “D₀ threshold”, a critical period for crustaceans in terms

255 of nutritional requirements (Anger, 1987, 2001). The D_0 threshold has been confirmed in early
256 life stages of decapod crustaceans from different families, e.g., Crangonidae (Paschke et al.,
257 2004), Diogenidae (Harms, 1992), Majidae (Figueiredo et al., 2008; Guerao et al., 2012), and
258 Portunidae (Harms et al., 1990). In our study, results of both PRS experiments, with high
259 mortality rates in individuals subjected to treatments F3, F6 and F9, and shorter intermolt periods
260 and higher mortality rates than in PNR experiments, as well as the similarity in PRS_{50} values
261 between seasons (unlike in PNR_{50} values), suggest that feeding in *P. argus* JIs is more important
262 near the PRS (or D_0 threshold) than immediately after molting to the first-stage juvenile.

263 Although PRS_{50} values did not differ with season, the ratio of the PRS to the total
264 duration of stage JI in individuals from the FC was higher during the warm season (74%) than in
265 the cold season (51%). Therefore, despite the significantly longer duration of stage JI in the cold
266 season, the PRS was reached earlier than in the warm season. A similar pattern was observed in
267 the zoea I of the shrimp *Crangon crangon*, in which the ratio of the PRS to the stage duration
268 was 32% in the summer and 23% in the winter (Paschke et al., 2004). However, the PRS
269 represents about one-third of the total intermolt time in the early phases of many crustaceans,
270 including *C. crangon*, the zoeae I and II of the spider crab *Hyas araneus* (Anger & Dawirs,
271 1981), the zoeae I of the intertidal crab *Neohelice granulata* (Bas, Spivak & Anger, 2008), the
272 phyllosoma I of *Panulirus cygnus* (Liddy, Phillips & Maguire, 2003), and stage JIII of the
273 crayfish *Cherax quadricarinatus* (Stumpf et al., 2010).

274 The percent ratio of the PNR to the JI stage duration of individuals from the FC was 66%
275 in the warm season and 39% in the cold season. Therefore, JIs of *P. argus* would appear to be
276 more resistant to starvation during the warm season, consistent with the optimum temperature of
277 $\sim 30^\circ\text{C}$ for development of this stage (Lellis & Russell, 1990). This finding has implications for

278 *P. argus* in the context of climate change. For example, in the packhorse lobster *Sagmariasus*
279 *verreauxii*, a species that lives in waters ranging in temperature from 12 to 28 °C, the upper pejus
280 range of the puerulus is between 24 and 27° C, with a significant decrease in metabolic rates
281 between 27 and 30°C (Fitzgibbon et al. 2014b). To our knowledge, the thermal tolerance of the
282 puerulus or JIs of *P. argus* has not been determined, but Lellis & Russel (1990) found that, after
283 10 weeks in the laboratory, JIs of *P. argus* reared abt 33 °C had lower survival, smaller molting
284 increments, and lower feed conversion than JIs reared at 30°C. This finding would appear to
285 suggest that 33°C is beyond the upper pejus range of the early benthic juveniles of *P. argus*.
286 Evidence from several studies suggests that the species of marine ectotherms that would be
287 impacted the most with increased warming would be those from tropical areas because they are
288 already living close to their upper temperature limits (e.g. Silliman, 2003; Nguyen et al. 2011).
289 Although most species have some phenotypic plasticity for environmental tolerance (e.g. Kelly
290 et al., 2012), this issue also remains to be determined for *P. argus* postlarvae and small juveniles.

291 Despite the commercial importance of *P. argus*, the present study is the first to address
292 resistance to starvation in the early benthic juveniles of this species after they have undergone a
293 protracted lecithotrophic stage that may lead to their return to coastal waters from distances of up
294 to tens of kilometers offshore. Determination of the resistance to starvation of early juveniles of
295 this and other spiny lobsters could prove useful not only through its contribution to the
296 knowledge of biological aspects of life cycles, but also through provision of information that
297 could lead to the establishment of successful rearing protocols for aquaculture or to the
298 generation of predictive models for capture.

299

300 **ACKNOWLEDGEMENTS**

301 The authors wish to acknowledge the invaluable technical assistance provided by F.
302 Negrete-Soto and C. Barradas-Ortiz in the set-up of experiments and throughout the study. J.P.
303 Huchin-Mian, R. Martínez-Calderón, R. Candia-Zulbarán, R. Muñoz de Cote-Hernández, L. Cid-
304 González, and H. Canizales-Flores provided additional help. We also thank Ann Grant for her
305 assistance in reviewing the English.

Figure 1

Experimental Design of PNR and PRS.

Design of point-of-no-return (PNR; initial starvation, followed by feeding) and point-of-reserve-saturation (PRS; initial feeding, followed by starvation) experiments. FC: continuously fed control; SC: continuously starved control; S3-S18: no. of days of starvation, followed by continuous feeding; F3-F18: no. of days of feeding, followed by continuous starvation. Initial number of *Panulirus argus* pueruli per treatment, FC and SC groups, $n = 20$.

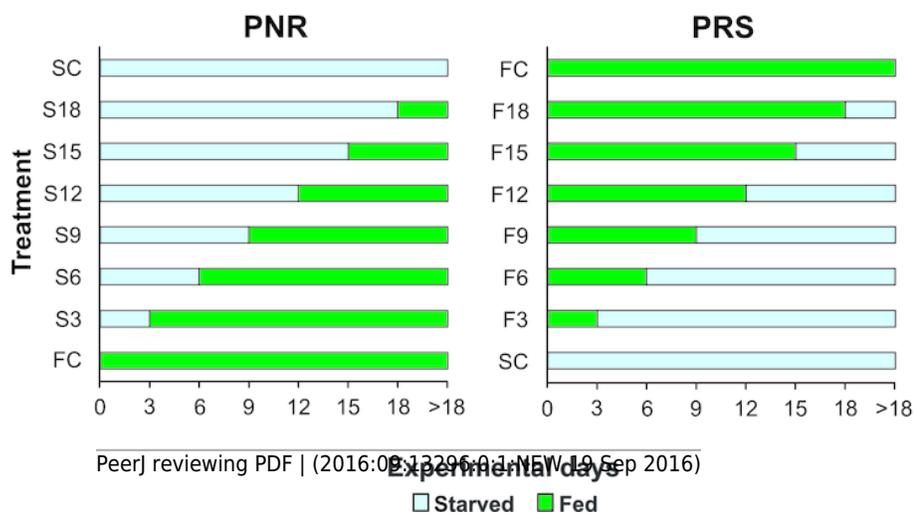

Figure 2

Intermolt period in PNR experiments.

Intermolt period (days) between JI and JII stages of *Panulirus argus* subjected to different periods of starvation followed by continuous feeding in experiments to determine the point-of-no-return. Red columns, warm season, June-October 2012; blue columns, cold season, January-April 2013. Results from treatments with two survivors or fewer were omitted. Error bars, 95% CI.

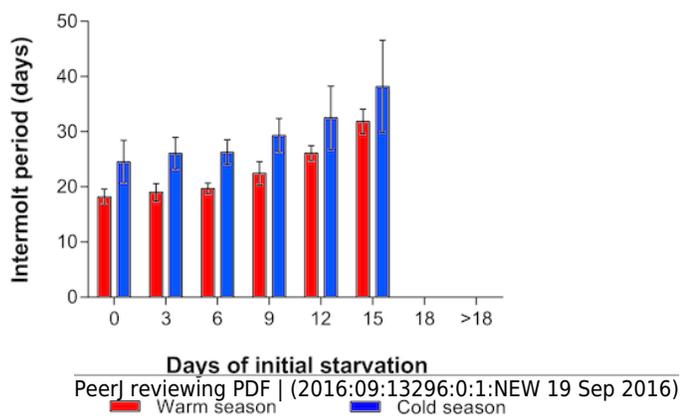

Figure 3

Sigmoidal dose-response curves - PNR experiments.

Sigmoidal dose-response curves fitted to the mortality (%) of JIs of *Panulirus argus* subjected to a period of starvation before being fed. Triangles, warm season, June-October 2012; circles, cold season, January-April 2013. PNR_{50} values: 12.1 ± 1.2 d in the warm season and 9.5 ± 2.1 d in the cold season.

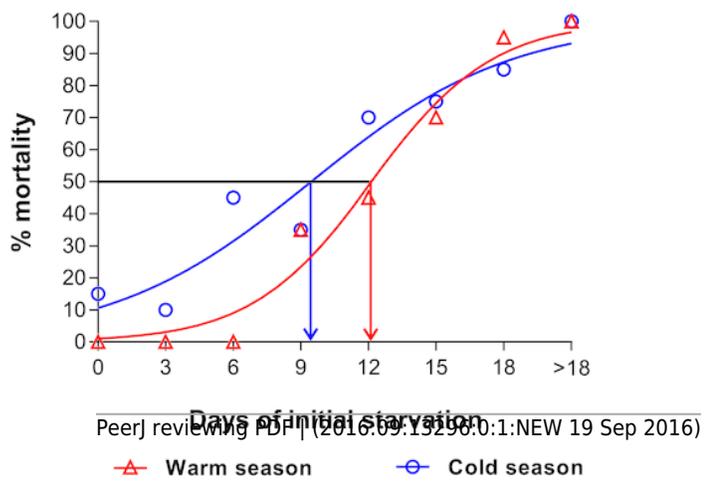

Figure 4

Intermolt period in PRS experiments.

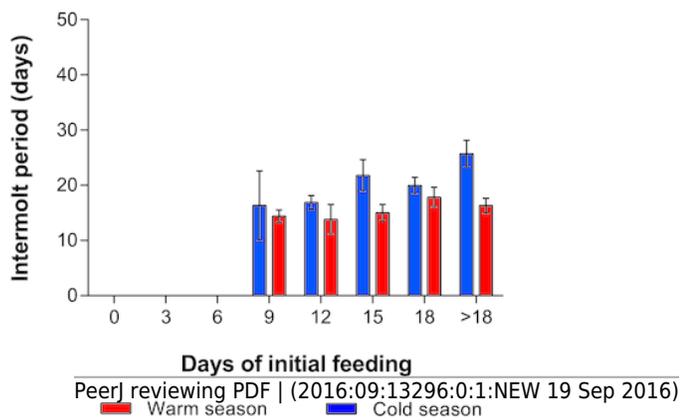

Figure 5

Sigmoidal dose-response curves - PRS experiments.

Sigmoidal dose-response curves fitted to the mortality (%) of JIs of *Panulirus argus* allowed periods of feeding before being starved. Circles, cold season, January-April 2014; triangles, warm season, July-November 2014. PRS₅₀ values: 13.1 ± 0.7 d in the cold season and 12.1 ± 1.1 d in the warm season.
