To assess whether closely related host species harbour similar symbiotic communities, we studied two polychaetes, *Chaetopterus* sp. (n=11) and *Chaetopterus* cf. *appendiculatus* (n=83) living in soft sediments of Nhatrang Bay (South China Sea, Vietnam). The former harboured the porcellanid crabs *Polyonyx* cf. *heox* and *Polyonyx* sp., the pinnotherid crab *Tetrias* sp. and the tergipedid nudibranch *Phestilla* sp. The latter harboured the polynoid polychaete *Ophthalmonoe pettiboneae*, the carapid fish *Onuxodon fowleri* and the porcellanid crab *Euleniaios cometes*, all of which, except *O. fowleri*, seemed to be specialized symbionts. The species richness and mean intensity of the symbionts were higher in *Chaetopterus* sp. than in *C. cf. appendiculatus* (1.8 and 1.02 species and 3.0 and 1.05 individuals per host respectively). We suggest that the lower density of *Chaetopterus* sp. may explain the higher number of associated symbionts observed, as well as the 100% prevalence (69.5% in *C. cf. appendiculatus*). Most *Chaetopterus* sp. harboured two symbiotic species, which was extremely rare in *C. cf. appendiculatus*, suggesting lower interspecific interactions in the former. The crab and nudibranch symbionts of *Chaetopterus* sp. often shared a host and lived in pairs, thus partitioning resources. This led to the species coexisting in the tubes of *Chaetopterus* sp., establishing a tightly packed community, indicating high species richness and mean intensity, together with a low species dominance. In contrast, the aggressive, strictly territorial species associated with *C. cf. appendiculatus* established a symbiotic community strongly dominated by single species and, thus, low species richness and mean intensity. Therefore, we suggest that interspecific interactions are determining species richness, intensity and dominance, while intraspecific interactions are influencing only intensity and abundance. It is possible that species composition may have influenced the differences in community structure observed. We hypothesize that both host species could originally be allopatric. The evolutionary specialization of the symbiotic communities would occur in separated

geographical areas, while the posterior disappearance of the existing geographical barriers would lead to the overlapped distribution.

8 **Abstract**

9 To assess whether closely related host species harbour similar symbiotic communities, we
10 studied two polychaetes, *Chaetopterus* sp. (n=11) and *Chaetopterus* cf. *appendiculatus* (n=83)
11 living in soft sediments of Nhatrang Bay (South China Sea, Vietnam). The former harboured the
12 porcellanid crabs *Polyonyx* cf. *heox* and *Polyonyx* sp., the pinnotherid crab *Tetrias* sp. and the
13 tergipedid nudibranch *Phestilla* sp. The latter harboured the polynoid polychaete *Ophthalmonoe*
14 *pettiboneae*, the carapid fish *Onuxodon fowleri* and the porcellanid crab *Euleniaios cometes*, all of
15 which, except *O. fowleri*, seemed to be specialized symbionts. The species richness and mean
16 intensity of the symbionts were higher in *Chaetopterus* sp. than in *C. cf. appendiculatus* (1.8 and
17 1.02 species and 3.0 and 1.05 individuals per host respectively). We suggest that the lower
18 density of *Chaetopterus* sp. may explain the higher number of associated symbionts observed, as
19 well as the 100% prevalence (69.5% in *C. cf. appendiculatus*). Most *Chaetopterus* sp. harboured
20 two symbiotic species, which was extremely rare in *C. cf. appendiculatus*, suggesting lower
21 interspecific interactions in the former. The crab and nudibranch symbionts of *Chaetopterus* sp.
22 often shared a host and lived in pairs, thus partitioning resources. This led to the species
23 coexisting in the tubes of *Chaetopterus* sp., establishing a tightly packed community, indicating
24 high species richness and mean intensity, together with a low species dominance. In contrast, the
25 aggressive, strictly territorial species associated with *C. cf. appendiculatus* established a
26 symbiotic community strongly dominated by single species and, thus, low species richness and
27 mean intensity. Therefore, we suggest that interspecific interactions are determining species

28 richness, intensity and dominance, while intraspecific interactions are influencing only intensity
29 and abundance. It is possible that species composition may have influenced the differences in
30 community structure observed. We hypothesize that both host species could originally be
31 allopatric. The evolutionary specialization of the symbiotic communities would occur in
32 separated geographical areas, while the posterior disappearance of the existing geographical
33 barriers would lead to the overlapped distribution.

34 **1.- Introduction**

35 During the last few decades, significant efforts have been undertaken to study the species
36 composition and structure of marine symbiotic communities associated with different hosts taxa
37 such as scleractinian corals (Hoeksema et al. 2012; Stella et al. 2010), echinoderms (Anker et al.
38 2005), hermit crabs (Williams & McDermott 2004) and echinoderms (Barel & Kramers 1977).
39 Despite this being an interesting aspect of marine ecosystems' functioning and the need to fill in
40 existing gaps in related knowledge, the current focus of scientific interests have shifted to
41 ecological and evolutionary aspects of the establishment of symbiotic communities (Baeza 2015;
42 Duffy 2002; Thiel & Baeza 2001). Accordingly, host characteristics (morphological, ecological
43 and physiological) have been considered as some of the most important parameters driving these
44 processes (e.g., Abele & Patton 1976; Deheyn et al. 2006; Goto & Kato 2011).

45 The coexistence of potential hosts that are taxonomically closely related taxonomically
46 (thus sharing similar morphological and physiological characteristics) may facilitate host
47 switching, leading to the infestation of different host species by the same species of symbiont, as
48 reported for example in freshwater fish (Poulin 1998). Accordingly, we may expect the
49 composition of symbiotic communities established on closely related hosts to be similar. Hence,
50 sympatric coral species belonging to the same family harbour symbiotic communities more
51 similar than those belonging to different families (Stella et al. 2010), while the symbiotic
52 communities associated with two starfish hosts from the same family living in the same area have
53 nearly identical species composition (Antokhina et al. 2012). There seems to be a correlation
54 between increasing taxonomic proximity between hosts and a higher similarity in species
55 composition of the respective symbiotic communities. In other words, we could expect that
56 closely related (i.e., belonging to the same genus) host species sharing the same habitat would
57 harbour very similar (or even identical) symbiotic communities. Therefore, the current study

58 investigated the symbiotic communities associated with two species of *Chaetopterus* in Nhatrang
59 Bay (Vietnam), to assess whether this hypothesis may apply to this particular situation.

60 These two species of *Chaetopterus* appeared to be excellent subjects for the intended
61 comparison due to their highly similar morphology. In fact, the genus has long been long
62 regarded as monospecific and, to date, the morphological identification of species is still
63 considered as rather complex (Britayev & Martin 2016; Nishi et al. 2009; Petersen 1984a;
64 Petersen 1984b). Moreover, these two species share the same habitat and, thus the influence of
65 environmental parameters can be excluded as influential factors on the associated symbiotic
66 communities.

67 The genus *Chaetopterus* (Annelida: Chaetopteridae) includes relatively large animals (up to
68 20–25 cm in length) living in roughly U-shaped tubes embedded into soft sediments or attached
69 to hard surfaces in shallow waters of temperate and tropical seas (Britayev & Martin 2016).
70 Morphologically, they are highly adapted for feeding on plankton using complex mucus-net
71 based mechanisms (Enders 1909). They are also well known as hosts harbouring numerous
72 symbiotic associates (often including complex communities) inside their parchment-like tubes.
73 These tubes provide well-protected shelter with continuous water flow bringing oxygen and food
74 items to the symbionts (Britayev & Martin 2016). To date, approximately 28 species of symbionts
75 have been reported living inside tubes of *Chaetopterus* (Britayev 1993). However, information on
76 the composition of associated communities is lacking, and is currently only available for two
77 species, *C. pergamentaceus* Cuvier, 1830 and *C. cf. cautus* Marenzeller, 1879, which are each
78 host to 3–5 species of crabs and polychaetes (Britayev 1993; Gray 1961).

79 A species of *Chaetopterus* (not confirmed but probably *Chaetopterus cf. appendiculatus*
80 Grube, 1874) inhabiting Vietnamese soft seabed sediments was previously reported as harbouring
81 three species of symbionts within its tubes: the polychaete *Ophthalmonoe pettiboneae* Petersen &
82 Britayev 1997, an unidentified carapid fish and a porcellanid crab (Britayev & Martin 2005). The
83 presence of a second, probably undescribed, species of *Chaetopterus* sharing the same habitat and
84 having its own associated symbiotic community allowed us to investigate the hypothesis that
85 postulates the similarity in composition of symbiotic communities associated with
86 morphologically similar hosts.

87 More specifically, in this paper we analyse: 1) The morphological and ecological
88 characteristics of the two Vietnamese host species of *Chaetopterus*; 2) The composition, species
89 richness and abundance of the symbiotic communities associated with the two host species; and
90 3) The host specificity of all symbiotic species.

91 2.- Material and methods

92 Sampling was conducted between March and April 2016 in four localities of Nhatrang Bay
93 (Vietnam, South China Sea): the western coast of Mun Island, the southern coast of Mot Island,
94 the western coast of Tre Island and Dam Bay (Fig. 1, Table 1). A copy of the letter from the
95 Russian-Vietnamese Tropical Center supporting the collection of samples and animals used in
96 this paper has been provided to PeerJ as a supplementary file.

97 The chaetopterid hosts were collected by SCUBA diving at depths from 6 to 20 m. As their
98 tubes were embedded within the sediment to 15–20 cm depth, extraction was achieved by
99 washing out the sediments by hand. The tubes were then gently removed, immediately placed
100 into individual zip-lock plastic bags to avoid losing symbionts and transferred to seawater tanks,
101 where they were kept until reaching the laboratory facilities.

102 The density of the studied population of *Chaetopterus* was estimated along five 50 m long
103 and 2 m wide transects at Mun Island and Dam Bay. At each site, the transects followed the depth
104 profile and were placed parallel, each one immediately adjacent to the previous one. Two divers
105 were responsible for counting the number of chaetopterid tube syphons, each one on one side (1
106 m) of the transect. A second density estimate was based on the number of chaetopterids sampled
107 per hour at each sampling site (except when diving surveys were used for transect estimates).

108 In the laboratory, tube length was measured to the nearest 5.0 mm (Table S1). Then, tubes
109 were gently opened by hand and carefully checked for presence of symbionts. The species and
110 number of symbionts were recorded (Table S1). Water and sediment from the bag were sieved
111 through a 1 mm mesh and the retained sediments were carefully inspected by eye. The body in
112 *Chaetopterus* is divided into three differentiated regions: the nine-to-ten anterior-most segments,
113 the two-to-three mid-body segments, and an undefined (but usually very numerous) number of
114 posterior segments, which form the regions A, B, and C, respectively (Britayev & Martin 2016).
115 Hosts were extracted and measured either as length and width for region A (n=8) or as displaced
116 water volume in a graduate vessel to the nearest 1 ml (all remaining specimens) (Table S1). As
117 body volume showed a positive linear relationship with tube length (Tube length =
118 $44.084 + 0.503 \cdot \text{Body volume}$, $F = 26.457$, $P < 0.0001$; Table S2), this easy-to-obtain measurement
119 was used to study community structure.

120 All chaetopterid tubes, hosts and symbionts were photographed with Canon digital cameras
121 (G16 and EOS 6D). Selected hosts and all symbionts were fixed either in 70% or 99% ethanol, or
122 in a 4% formaldehyde/seawater solution for further studies. Small fragments of the ventral
123 uncinal tori of both host species have been dissected. To illustrate the shape of the uncini, these
124 fragments were squashed between slides, mounted in glycerine and photographed with the help
125 of a ProgRes C10 Plus digital camera (Jenoptics, Jena) attached to a Zeiss Axioplan compound
126 microscope.

127 All symbionts were measured to the nearest 0.1 mm, using a calibrated ocular micrometer
128 under an Olympus SZX9 stereomicroscope as body length from tip of prostomium to the end of
129 pygidium for polychaetes, as body length from tip of head to the end of caudal peduncle for fish,
130 and as carapace width for crabs. Crabs were sexed according to the abdominal shape.

131 DNA was extracted using Spin Columns Thermo Scientific GeneJET 50 kit, following the
132 manufacturer's standard protocol. 10 ng of genomic DNA was used as a template for polymerase
133 chain reaction (PCR) with special mitochondrial Cox1 primers:
134 TGTA AACGACGGCCAGTGAYTATWTTCAACAAATCATAAAGATATTGG and
135 CAGGAAACAGCTATGACTAMACTTCWGGGTGACCAAARAATCA (Carr et al. 2011). PCR
136 were set up in total volume of 20 μ l. The PCR cycling profiles were as follows: initial
137 denaturation (95°C, 5 min); followed by 35 cycles of denaturation (95°C, 15 sec), annealing
138 (45°C, 15 sec) and extension (72°C, 60 sec). The resulting PCR products were purified by direct
139 purification from the PCR mixture and prepared for sequencing. Overlapping sequence
140 fragments were merged into consensus sequences using MEGA7 (Kumar et al. 2016), the protein
141 coding COI being simple to align. The obtained COI sequences and voucher paragenophores
142 (Pleijel et al. 2008) for the two species of *Chaetopterus* have been deposited in GenBank and in
143 the collections of the Severtsov Institute of Ecology and Evolution RAS, respectively. Seven host
144 specimens were used in genetic analyses to ensure species delineation (Table 2). The genetic
145 differentiation within and between species was assessed by pairwise genetic distances between
146 COI sequences using the Maximum Likelihood Model, which allowed us to show the percentage
147 of replicate trees in which the associated taxa clustered together in the bootstrap test (1000
148 replicates) next to each branch (Felsenstein 1985). The phylogenetic tree was drawn to scale,
149 with branch lengths in the same units as those of the evolutionary distances used to infer it, as
150 computed using the Maximum Composite Likelihood method (Tamura et al. 2004) and are in the
151 units of the number of base substitutions per site. The phylogenetic tree was built using the COI
152 sequences of *Chaetopterus* and *Mesochaetopterus* available from NCBI GenBank, using

153 *Spiocharopterus costarum* (Claparède 1869) as the outgroup, by means of the Neighbor-Joining
154 method (Saitou & Nei 1987) in MEGA7 (Kumar et al. 2016).

155 For the purposes of our study, the following terms are defined: Prevalence, as the ratio
156 between number of infested and total number of hosts; Intensity, as the number of symbionts
157 present in each infested host; Mean intensity, as the mean number of individuals of a particular
158 symbiotic species per infested host in a sample; Abundance, as mean number of symbionts per
159 examined host, infested and non-infested; and Species richness, as mean number of symbiotic
160 species per infested host.

161 The porcellanid crabs were identified by Prof. Bernd Werding, from the Institut für
162 Allgemeine und Spezielle Zoologie of the Justus-Liebig Universität (Giessen, Germany). The
163 pinnotherid crab was identified by Prof. Peter Ng from the Department of Zoology of the
164 National University of Singapore (Republic of Singapore). The carapid fish was identified by Dr.
165 Eric Parmentier from the Laboratoire de Morphologie Fonctionnelle et Evolutive of the Institut
166 de Chimie of the Université de Liege (Belgium). The tergipedid nudibranch was identified by Dr.
167 Irina Ekimova, from the Department of Invertebrate Zoology of the Lomonosov Moscow State
168 University (Russian Federation).

169 The relationship between host body volume and tube length were assessed by linear
170 regression. The species richness and mean intensity, as well as the average length of infested and
171 non-infested tubes of *Chaetopterus*, were compared by Student's t-test. Statistical analyses were
172 performed using Statistica 6.0 and PAST 2.17 software.

173 3.- Results

174 3.1.- Hosts characteristics

175 The two Vietnamese host species of *Chaetopterus* are morphologically similar. However,
176 one of them is significantly bigger than the other, both in terms of tube length (1.4:1, on average)
177 and body volume (2.7:1, on average) (t-test $p < 0.0001$, Table 3). They also differ in the number of
178 chaetigers of region A (9 and 9-11, respectively) (Fig. 2A, 2D) and in the denticles of the
179 neuropodial uncini of region C (25-35 and 9, respectively) (Fig. 3A–D), as well as in tube
180 structure. Tubes of the bigger species are covered by silt, have a parchment-like appearance and
181 the inner lining is iridescent, silver or golden in colour, showing distinct transverse annulations
182 (Fig. 2C). In the smaller species, tubes are covered by sand and small coral and shell fragments,

183 have a paper-like appearance with a semi-transparent inner lining, whitish or brownish in colour
184 and lacking distinct annulations (Fig. 2F).

185 We tentatively identified the bigger host species as *Chaetopterus* cf. *appendiculatus*
186 because, according to the original description, this species has a sand-coloured inner tube surface,
187 showing dense transverse annulations. Additionally, it is the only described species of
188 *Chaetopterus* possessing neuropodial uncini from region C with more than 20 small denticles.
189 *Chaetopterus appendiculatus* was already reported as host of *O. pettiboneae* from the Banda Sea
190 (Indonesia) by Petersen & Britayev (1997). Petersen (1997) proposed the redescription of *C.*
191 *appendiculatus* as a valid species, based on the type material from Ceylon. The fact that formal
192 redescription has never been published does not prevent us from considering the species as valid,
193 whose formal redescription is far beyond the scope of this paper. However, the long geographical
194 distance between Ceylon/Indonesia and Vietnam prevents us in fully assigning the Vietnamese
195 specimens to *C. appendiculatus*, and we refer to the species as *C. cf. appendiculatus* in this paper.
196 The smaller host is likely undescribed.

197 The phylogenetic analysis including the COI sequences of the Vietnamese hosts (Fig. 4)
198 showed low bootstrap values that did not allow us to fully resolve the phylogeny of
199 *Chaetopterus*. However, it clearly revealed that the two Vietnamese hosts are different species
200 included within two separate monophyletic clades (with 100% bootstrap support), thus
201 confirming our morphological inference. Although with low support, the closest clades to those
202 of the two Vietnamese *Chaetopterus* belong to *C. variopedatus* (Renier 1804). However, the
203 specimens joining the *Chaetopterus* sp. clade (42% bootstrap support) originate from the
204 Mediterranean, while those joining the *C. cf. appendiculatus* clade (54% bootstrap support)
205 originate from the Atlantic. As indicated by Martin et al. (2008), our results support the inference
206 that the two populations of *C. variopedatus* belong to different species, with the Mediterranean
207 species described and the Atlantic species still undescribed. The results also confirm that *C.*
208 *variopedatus* sensu Hartman (1959) is not a single cosmopolitan species, but a complex including
209 more than 20 different species (Bhaud 1998; Osborn et al. 2007; Petersen 1984a; Petersen 1984b;
210 Petersen 1997). As is the case for *C. appendiculatus*, some of these species have not yet been
211 formally redescribed. However, as many as nine species have recently been described, and five
212 have been redescribed in the recent literature (Nishi 2001; Nishi et al. 2000; Nishi et al. 2009;
213 Osborn et al. 2007; Sun & Qiu 2014).

214 The two Vietnamese *Chaetopterus* host species were found at the same localities, with their
215 tubes deeply embedded in silty sand sediments. *Chaetopterus* cf. *appendiculatus* outnumbered

216 *Chaetopterus* sp. in all samples, yet their proportion varied depending on the locality, with
217 *Chaetopterus* sp. being relatively more abundant at Mot Islands (St. 2, 25.9%) and substantially
218 less abundant at the other stations (5.0–9.1%) (Table 1).

219 The density of *Chaetopterus* ranged from 0.6 to 1.0 individuals per 100 m² in the transects,
220 while the number of collected worms per diving hour was lower at St. 4 in Dam Bay and higher
221 at St. 1 in Point Nam, Tre Island (Table 1).

222 3.2.- Taxonomic composition of the symbiotic communities

223 91 individuals of seven species of animals occurred in association with the two host species
224 of *Chaetopterus*. Among them, the polynoid polychaete *Ophthalmonoe pettiboneae* (Fig. 5C), the
225 tergipedid nudibranch *Phestilla* sp. (Fig. 6G), the carapid fish *Onuxodon fowleri* (Smith 1964)
226 (Fig. 5D), and four species of decapods, three porcellanids, *Euleniaios cometes* (Walker 1887)
227 (Fig. 5A, 5B), *Polyonyx* cf. *heox* Osawa & Ng, 2016 (Fig. 6A, 6B) and *Polyonyx* sp. (Fig. 6E,
228 6F), and the pinnotherid *Tetrias* sp. (Fig. 6C, 6D) (Table 4).

229 Four and three species were found inside the tubes of *Chaetopterus* sp. and *C.* cf.
230 *appendiculatus*, respectively. Surprisingly, the symbiotic communities associated with the two
231 hosts did not have any species in common, with the only similarity at a higher taxonomic level
232 being the presence of porcellanid crabs (Table 4). Despite the lower sample size of *Chaetopterus*
233 sp., the diversity of its associated community was higher than that of *C.* cf. *appendiculatus*.
234 Accordingly, it may be expected that the number of species associated with *Chaetopterus* sp.
235 would increase with an increasing number of analysed host individuals. Conversely, the diversity
236 of the community associated with *C.* cf. *appendiculatus* showed an almost saturated species
237 accumulation curve (Fig. 7A).

238 *Ophthalmonoe pettiboneae* is the single symbiotic species previously known from
239 Vietnamese waters and from the same host species. The other six are here reported for the first
240 time from the Vietnamese coasts. Moreover, *O. fowleri* is herein reported as a symbiont of
241 chaetopterids for the first time, as well as *Tetrias* sp., *Polyonyx* sp., *P.* cf. *heox* and *Phestilla* sp.,
242 which are new to science and will be described at later dates in specialized papers. The tergipedid
243 nudibranch is also, to the best of our knowledge, the first known nudibranch living in symbiosis
244 with a polychaete host. It shows a posterior end functioning as a sucker (Fig. 6F) allowing it to
245 attach to the smooth inner surface of the host tube, while the rest of the body can move freely
246 (https://www.researchgate.net/publication/310159685_Phestilla_sp). Its flattened body, together
247 with the lack of cnidosacs and the uniserial radula with long lateral denticles on the rachidian

248 tooth clearly place it within the genus *Phestilla*. However, it differs from all known species of
249 this genus by having a small central denticle of the radula, a wider foot and cerata arranged one
250 per row only (Deart and Ekimova, personal communication). Moreover, its appearance and
251 colouring (Fig. 6F) mimics, to some extent, that of the very posterior end of the chaetopterid host.

252 3.3.- Structure of the symbiotic communities

253 56 (69.5%) out of 83 individuals of *C. appediculatus* and all 11 (100%) *Chaetopterus* sp.
254 were infested. Among the species associated with *C. appediculatus*, *O. pettiboneae* showed a
255 higher prevalence than the two other symbionts (Table 4). Among the associates with
256 *Chaetopterus* sp., the prevalence ranged from 11% to almost 90%, with the maximum
257 corresponding to *P. cf. heox* (Table 4).

258 The number of species inhabiting the same tube varied from 0 to 2 in *C. cf. appediculatus*,
259 and from 1 to 2 in *Chaetopterus* sp. However, the species richness was significantly higher in the
260 latter ($p > 0.001$, Fig. 7A, 7B) due to the common coexistence of two symbiont species in the same
261 host tube. In fact, the small-sized *Polyonyx* sp. and *Phestilla* sp. (Fig. 6E–6G) were found in all
262 observed cases living with other crab species, mostly with the large sized *P. cf. heox* (Fig. 6A,
263 6B). Only in one case, *Polyonyx* sp. shared the host tube with *Tetrias* sp. (Table 6). In contrast,
264 most tubes of *C. appediculatus* were occupied by a single symbiotic species, either *O.*
265 *pettiboneae* or *O. fowleri*. Only in one case two species of symbionts (*O. pettiboneae* and *E.*
266 *cometes*) were present sharing the same host tube (Table 6).

267 The number of symbiont individuals infesting one host varied from 0 to 3 in *C. cf.*
268 *appediculatus*, and from 1 to 5 in *Chaetopterus* sp., while the mean intensity was nearly three
269 times lower in the former than in the later ($p > 0.001$, Table 5). Accordingly, most *C. cf.*
270 *appediculatus* were infested by one symbiotic individual, while multiple infestation (two, three,
271 or even four symbionts) was common in *Chaetopterus* sp. (Fig. 7B).

272 The distribution pattern of the symbionts among their hosts was primarily regular, as all *O.*
273 *pettiboneae* and most *O. fowleri* lived solitary inside their host tubes. In turn, *Polyonyx cf. heox*,
274 *Polyonyx* sp., *E. cometes*, *Tetrias* sp. were found in host tubes usually as male/female pair. The
275 number of nudibranchs varied from 1 to 3 per hosts (Table 6) and, in one case, a couple was
276 observed near to a recently spawned egg-mass attached to the inner side of the host tube (Fig.
277 6H).

278 The component communities differed also in the relative abundance of a particular species.
279 In the community associated with *C. cf. appediculatus*, *O. pettiboneae* was dominant in terms of

280 both prevalence and abundance. In the community associated with *Chaetopterus* sp., the
281 dominance of the most abundant symbiont, *P. cf. heox* is less distinctive, with the role that other
282 species had in the community structure being more relevant (Fig. 7C).

283 The average length of infested and non-infested tubes of *C. appediculatus* does not differ
284 significantly (41.2–42.3, t-test, $p=0.65$). The number of both symbiotic species and individuals do
285 not show any significant correlation with host tube length in both chaetopterid species.

286 4.- Discussion

287 4.1.- Community dissimilarity

288 Our results demonstrate a strict segregation in species composition of the communities
289 associated with the two Vietnamese syntopic species of *Chaetopterus*, which had no species in
290 common. However, at higher taxonomic levels (i.e., family, order and class), they were similar to
291 each other and also resembled the symbiotic communities associated with other species of
292 *Chaetopterus* and, even, echiuran worms in harbouring scale-worms, pocellanid and pinnotherid
293 decapods and fishes (*Anker et al. 2005; Gray 1961; Ng & Sasekumar 1993; Petersen & Britayev*
294 *1997*).

295 The two Vietnamese species of *Chaetopterus* are very similar in body morphology and tube
296 shape, as well as in their trophic-functional characteristics. Thus, no reasons linked to host
297 morphology were evident allowing us to explain the dissimilarity in symbiotic species
298 composition. We suggest therefore that community composition appears to be determined by
299 historical events rather than by the physical or biological habitat characteristics. We may
300 hypothesize that both host species were originally allopatric. Thus, the evolutionary
301 establishment of the respective specialized symbiotic associations would likely occur in different,
302 separated geographical areas, with the posterior disappearance of geographical barriers leading to
303 the current overlapping distribution. Once established, the respective symbiotic communities
304 would be maintained by interspecific competition, leading to symbiont specialization to their
305 respective host species as well as to preventing the exchange of symbionts between hosts when
306 becoming sympatric, even being as closely related as is the case for these two species of
307 *Chaetopterus*. However, our hypothesis does not exclude the possible existence of differences in
308 host physiology or behaviour that would enhance the ability of the specialized symbionts to

309 compete with possible invaders, thus contributing to maintain the differences in community
310 composition.

311 Further assessment of this hypothesis would require an experimental approach to analyse
312 the possible existence of a host-factor allowing the respective symbiont to recognize their own
313 hosts, as well as to check the ability of the symbionts from one host to infest the other. In parallel,
314 the regularity of the community segregation would have to be checked by more extensive field
315 sampling addressed to discard (or reveal) the presence of additional symbionts on the alternative
316 host species. This is particularly relevant for *Chaetopterus* sp. whose accumulation curve (Fig.
317 7A) supports an expected increase in the respective number of symbiotic species with sampling
318 size. An additional, but not less pertinent question would be to assess the degree of specialization
319 of the symbionts found in the two species of *Chaetopterus*, either based on previously published
320 data or on our own observations. Therefore, it would be particularly relevant to consider whether
321 they are obligatory or facultative and, in the case of obligatory symbionts, to further assess their
322 degree of specificity (which may range from species-specific to opportunistic).

323 4.2.- Symbionts' specialization

324 Among the seven species of macroinvertebrates associated with *C. cf. appendiculatus* and
325 *Chaetopterus* sp., four (i.e., one polychaete *O. pettiboneae*, one crab, *E. cometes*, and one fish, *O.*
326 *fowleri*) are known as obligatory symbionts of chaetopterids and other benthic organisms.
327 *Onuxodorn fowleri* also lives in the mantle cavity of bivalves and inside holothurians (Markle &
328 Olney 1990; Parmentier et al. 2002). In our samples, five of six individuals were juveniles, which
329 allows us to suggest that they are employing *C. cf. appendiculatus* as temporal or intermediate
330 hosts. The porcellanid *E. cometes* was reported from shallow waters off Singapore, living in
331 association with a species of *Chaetopterus*, identified as *C. variopedatus* but this identification is
332 undoubtedly incorrect (Ng & Nakasone 1993). In turn, the scale-worm *O. pettiboneae* was first
333 reported from Ambon Island (Indonesia) and later from the coasts of Vietnam, always in
334 association with *C. cf. appendiculatus* (Britayev & Martin 2005; Petersen & Britayev 1997; this
335 paper).

336 The four other species appear to be undescribed and are now being analyzed by the
337 corresponding specialists. However, we may infer some considerations on their degree of
338 specialization based on existing papers dealing with the ecology and morphology of some closely
339 related taxa. Concerning the symbiotic crabs, the porcellanid *Polyonyx* sp. belongs to the
340 "*Polyonyx sinensis*" species complex, usually obligatory associates of tubicolous polychaetes,

341 mainly with species of *Chaetopterus* (B. Werding, unpublished data), while *Polyonyx* cf. *heox*
342 belongs to the “*Polyonyx pedalis*” complex and the same or a very similar species has been
343 recently reported from Singapore living in association with *Chaetopterus* cf. *pacificus* (Osawa &
344 Ng 2016). This suggests that both porcellanids are obligate and, probably, specialized symbionts
345 of *Chaetopterus* sp. In turn, *Tetrias* sp. belongs to the Pinnotheridae, a family that mainly
346 includes symbiotic species living as endo- or ectosymbionts in mollusc mantle cavities,
347 polychaete burrows, echinoid integuments or tunicate branchial sacs (Drake et al. 2014). Among
348 them, two species of *Tetrias* are currently known. *Tetrias fischerii* (Milne-Edwards 1867) has
349 been reported as symbiont of bivalves and annelids, while the host of *Tetrias scabripes* Rathbun,
350 1898 is unknown (Schmitt et al. 1973). Although this cannot be assessed from our data, we
351 suggest that the species associated with the Vietnamese *Chaetopterus* sp. is a specialized
352 obligatory symbiont.

353 The third undescribed species, the nudibranch *Phestilla* sp., has several behavioural (i.e.,
354 two or more individuals sharing the same host, egg-masses attached to the inner tube surface) and
355 morphological (i.e., posterior end working as a sucker, overall body shape mimicking that of the
356 host) features clearly pointing toward a specialized symbiotic mode of life. This lead us to
357 consider the species as the first know nudibranch living as a symbiont with a marine annelid host.
358 Nudibranchs are well known as aposematic or mimetic organisms (Edmunds 1987; Gosliner &
359 Behrens 1989; Rudman 1991), some of them being considered as true symbionts. Among them,
360 there are some species of *Phestilla*, which lives in association with corals and are highly
361 specialized predators (Faucci et al. 2007; Robertson 1970), while the exact nature of the
362 association of the Vietnamese *Phestilla* sp. and *Chaetopterus* sp. would need further research to
363 be defined. The single related association occurred between the goniodorid nudibranch
364 *Lophodoris scala* Er. Marcus & Ev. Marcus, 1970 and the innkeeper echiurid *Lissomyema exilii*
365 (Müller 1883). In this case, the nudibranch lives inside the host burrow, sometimes creeping
366 along the host trunk and feeding, possibly exclusively, on *Loxosomella* spp., an entoproct that
367 colonizes the burrow walls (Ditadi 1982; Marcus & Marcus 1970), which seems not to be the
368 case for the Vietnamese species.

369 Accordingly, all symbionts found in association with *Chaetopterus* sp. and *C.* cf.
370 *appendiculatus* have to be considered as obligatory symbionts. Among them, the less specialized
371 is *O. fowleri*, which is known to infest hosts belonging to different types of animals (molluscs
372 and polychaetes). The porcellanid crabs *E. cometes* and *P.* cf. *heok* are probably genus-specific
373 symbionts, while the scale-worm *O. pettiboneae*, together with the other porcellanid crab

374 *Polyonyx* sp. and the tergipedid nudibranch *Phestilla* sp., must be considered as species-specific
375 symbionts. The specificity of the pinnotherid crab *Tetrias* sp. is not clear at this time. However,
376 taking into account the relative abundance of pinnotherids among symbionts of *Chaetopterus*
377 species (Petersen & Britayev 1997; Schmitt et al. 1973), we could also propose that it should be
378 considered as a specialized symbiont, at least at family level.

379 Therefore, we consider all symbionts found in association with the two Vietnamese species
380 of *Chaetopterus* as being, or tending to be, specialized symbionts, the single exception being the
381 carapid fish.

382 4.3.- Possible causes of observed differences in community structure

383 We found substantial differences in the structure of the symbiotic communities associated
384 with *Chaetopterus* sp. and *C. cf. appendiculatus*. The first shows a significantly higher species
385 richness and mean abundance than the second, while the second was clearly dominated by the
386 presence of a single species, both in terms of abundance and frequency (Table 5, Fig. 6C). Taking
387 into account that body size and tube length of *Chaetopterus* sp. are significantly lower than those
388 of *C. cf. appendiculatus*, this situation is particularly unexpected. Usually, species richness and
389 abundance increase with the increasing host size (e.g., Abele & Patton 1976; Ribeiro et al. 2003).
390 Thus, the situation of the Vietnamese partnership requires specific considerations.

391 We suggest that several factors are shaping the differences in the structure of the
392 symbiotic communities associated with *Chaetopterus* sp. and *C. cf. appendiculatus*. Despite both
393 host species having low population densities in Nhatrang Bay, that of *Chaetopterus* sp. was
394 significantly lower, which would likely force the associated symbionts to use (and share) the few
395 available hosts. This would possible explain the higher number of species in its associated
396 community, as well as the fact that all host individuals of *Chaetopterus* sp. found in Nhatrang
397 Bay harboured symbionts, in contrast to *C. appendiculatus* whose maximum prevalence was
398 around 70%. Alternatively, the low density of both host populations may impede the secondary
399 dispersion of the symbionts, which has been considered as a key mechanisms shaping the
400 establishment and functioning of marine symbiotic communities (Mekhova et al. 2015) and raises
401 the question on the adults' ability of long-distance migration.

402 Based on species and individual's distributions among hosts, we also hypothesized that
403 another factor determining the observed differences in symbiotic community structure could be
404 the existence of inter- and intraspecific competition. In fact, most tubes of *Chaetopterus* sp. were
405 occupied by a minimum of two symbiotic species, this co-occurrence being very rare in *C. cf.*

406 *appendiculatus*, where each host individual was infested by one symbiotic species (Fig. 7B). The
407 single exception was a host tube shared by *O. pettiboneae* and *E. cometes*. Accordingly, we
408 suggest that the main driving factors may be resource partitioning between symbiotic species
409 having different sizes, in the case of *Chaetopterus* sp., and strong interspecific interactions, in the
410 case of *C. cf. appendiculatus* as previously reported for holothurian hosts (Lyskin & Britayev
411 2005).

412 The characteristics of the symbiotic community structure associated with *C. cf.*
413 *appendiculatus*, in which one host was usually occupied by one symbiotic species (Table 6),
414 suggest the existence of interspecific competition between the polychaete and fish symbionts. In
415 turn, the fact that there was a single symbiont per host (Table 6) supports the existence of
416 intraspecific competition among polychaetes and fish individuals, respectively. At least for the
417 polychaete, this hypothesis was supported by our direct observations in experimental aquaria,
418 where individuals of *O. pettiboneae* were found to fight when trying to occupy the same host
419 tube, as well as by the high frequency of body traumas present (Britayev and Martin, unpublished
420 data). In contrast, the bulk of *Chaetopterus* sp. symbionts were crabs (Fig. 7C). Territorial
421 defence is a well-known phenomenon in symbiotic decapods too (Baeza et al. 2002; Huber 1987;
422 Vannini 1985). However, their behaviour has a sexual component, as they often form
423 heterosexual pairs consisting of gravid males and females co-inhabiting the same host (Castro
424 2015; Patton 1994), which was exactly the case of most porcellanid and pinnotherid crabs
425 inhabiting the tubes of the two Vietnamese species of *Chaetopterus* (Table 6). This behaviour
426 lead to a significant increase in the abundance of symbiotic individuals in the community
427 associated with *Chaetopterus* sp. Therefore, while interspecific interactions seemed to affect both
428 species richness and abundance, the intraspecific ones only affected the abundance.

429 Our observations support two main factors determining the structure of symbiotic
430 communities associated with *Chaetopterus* sp. and *C. cf. appendiculatus* in Nhatrang Bay: the
431 density of host populations and competition (both inter- and intraspecific). Moreover, the
432 observed differences in community structure appear to be strictly related to the respective species
433 composition. Accordingly, living in pairs and resource partitioning led to species coexisting in the
434 tubes of *Chaetopterus* sp. and establish a tightly packed component community showing high
435 species richness and mean intensity, together with a low species dominance. In contrast, the
436 aggressive, strictly territorial species associated with *C. cf. appendiculatus* established a
437 component community strongly dominated by host being inhabited by a single species and, thus,
438 low species richness and mean intensity.

439 The existence of two closely related host species with overlapping distributions but
440 harbouring very different symbiotic communities seems to be unusual. We suggest that it may
441 probably be related with the scarcity of data currently available on the structure of symbiotic
442 communities in marine environments. However, the situation is certainly not unique, as at least
443 an additional example has been recently reported from Nhatrang Bay. In this case, the hosts were
444 comatulid crinoids *Comanthus gisleni* Rowe, Hoggett, Birtles & Vail, 1986 and *C. parvicirrus*
445 (Müller, 1841) (Mekhova & Britayev 2012). Consequently, we expect further worldwide studies
446 to discover more syntopic hosts harbouring symbiotic communities with contrasted composition
447 and structure.

448 5.- Conclusions

449 Two symbiotic communities inhabit the morphologically similar and syntopic species of
450 the tube-dwelling chaetopterid polychaetes *Chaetopterus* sp. and *C. cf. appendiculatus* in
451 Nhatrang Bay. They are mostly composed of specifically specialized species and show a very
452 different composition. The current situation has been attributed to an initially allopatric host
453 distribution allowing the symbiotic communities to be established independently. This is then
454 followed by the subsequent disappearance of the original geographical barriers leading to the
455 current sympatry. The present symbiotic communities differ in structural characteristics (i.e.,
456 species richness, mean intensity and species dominance) as a consequence of the differences in
457 host density but also of the existing intra- and interspecific interactions that, in turn, depends on
458 the behaviour of the respective symbiotic species. Mating pairs and partitioned resources lead to a
459 high diversity and intensity in the community associated with *Chaetopterus* sp., while the
460 aggressive and territorial species associated with *C. cf. appendiculatus* led to a community with
461 low diversity and intensity but with a strong dominance of a single species.

462 The hypotheses postulating a similar composition for the symbiotic communities
463 established on closely related hosts seems to reflect a rather common situation in marine
464 ecosystems and, certainly, our results do not allow us to reject it. In fact, the opposite situation
465 was observed within our data, with two taxonomically related hosts living in the same habitat that
466 harbour symbiotic communities with contrasted species composition. Therefore, we hypothesize
467 on the possible reasons explaining their establishment. We also highlight that the situation of the
468 Vietnamese partnerships is certainly not unique and should be considered as an interesting model

469 to further assess different evolutionary and ecological aspects of the establishment of a symbiotic
470 community.

471 Our results also highlight the importance of studying previously unknown symbiotic
472 associations, which may provide key information allowing the complex network of relationships
473 driving the functioning of the marine ecosystems, particularly in benthic environments, to be
474 understood. Moreover, they are crucial in revealing the hidden biodiversity of the oceans, as
475 supported by the fact that at least five of the nine species herein studied are currently
476 undescribed.

477 **Acknowledgements**

478 We would like to thank our colleagues from the Coastal Branch of the Russian-Vietnamese
479 Tropical Centre, Mrs Hai Thanh Nguyen, Mr Tchan Than Kuang and Mr N.L. Filichev for their
480 help in conducting field and experimental studies, Dr V.N. Mikheev for fruitful discussion and
481 constructive advices in preparing the manuscript, Dr K. Mortimer-Jones for kindly checking the
482 English style of the last version of the manuscript and Dr X. Turon for suggesting improvements
483 on the interpretation of the phylogenetic tree. We would also like to thank Professors B. Werding
484 and P. Ng Kee Lin, and Drs. E. Permentier and Irina Ekimova for kindly identifying the
485 porcellanid, pinnotherid, carapid and nudibranch symbionts.

680 Table 3. Number of individuals, mean tube length (min – max), cm and mean body volume (min
681 – max) of *Chaetopterus* cf. *appendiculatus* and *Chaetopterus* sp.

682

Species	Number	Tube length (cm)	Body volume (cm ³)
<i>Chaetopterus</i> cf. <i>appendiculatus</i>	83	64.6 (41–88)	41.9 (23–72)
<i>Chaetopterus</i> sp.	11	44.8 (23–58)	15.8(2–32)

683 Table 4. Prevalence (%) and mean intensity (mean number of individuals per infested host) of the
 684 symbiotic species associated with the two host *Chaetopterus*. P – Polychaeta, D – Decapoda, G –
 685 Gastropoda, A – Actinopteri.

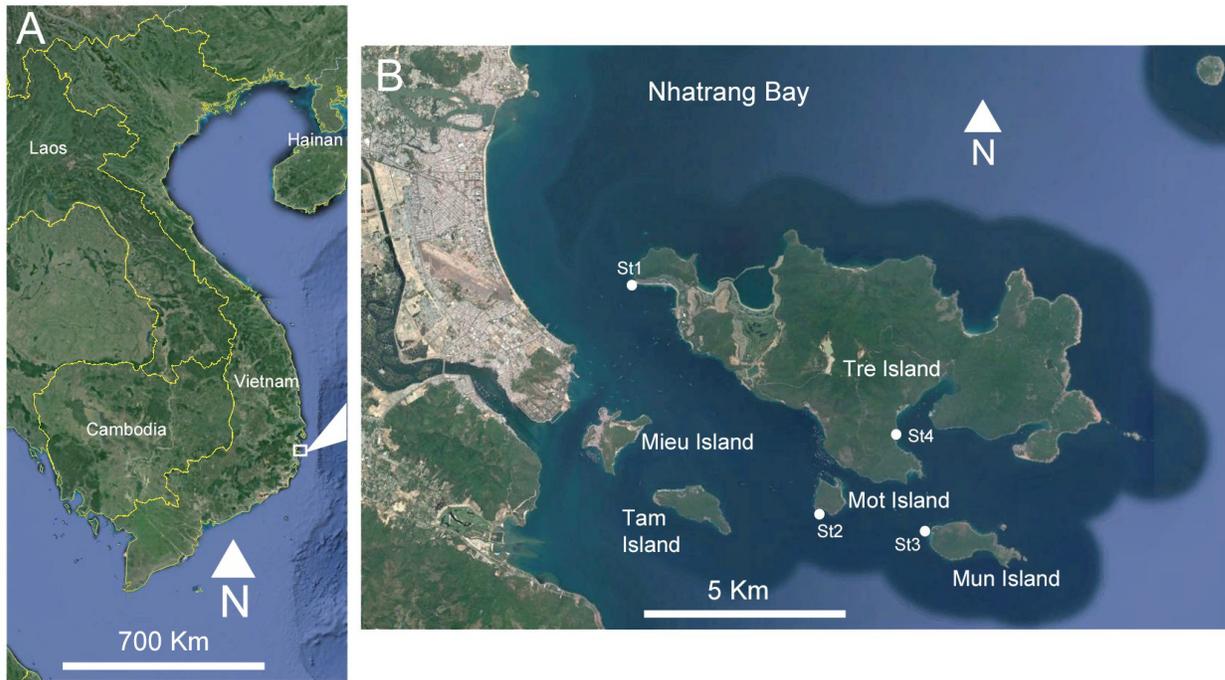

Symbiont species	<i>Chaetopterus</i> sp.	<i>Chaetopterus</i> cf. <i>appendiculatus</i>
<i>Ophthalmonoe pettiboneae</i> (P)	-	64.1 (1.0)
<i>Phestilla</i> sp. (G)	22.2 (2.0)	-
<i>Euleniaios cometes</i> (D)	-	1.3 (2.0)
<i>Polyonyx</i> cf. <i>heox</i> (D)	88.9 (1.7)	-
<i>Polyonyx</i> sp. (D)	66.7 (1.3)	-
<i>Tetrias</i> sp. (D)	11.1 (2.0)	-
<i>Onuxodon fowleri</i> (A)	-	6.4 (1.2)

686 Table 5. Symbiotic community indexes: species richness (mean number of species per one
687 infested host), infestation prevalence (%), and mean intensity (mean number of individuals per
688 infested host).

	Richness	Prevalence	Intensity
<i>Chaetopterus</i> sp.	1.8	100	3.0
<i>Chaetopterus</i> cf. <i>appendiculatus</i>	1.02	67.5	1.05

689 Table 6. Distribution among hosts (as number of host tubes found without and with 1, 2 and 3
 690 individuals) for the five species associated with *Chaetopterus* spp. Cs: *Chaetopterus* sp.; Ca:
 691 *Chaetopterus* cf. *appendiculatus*.

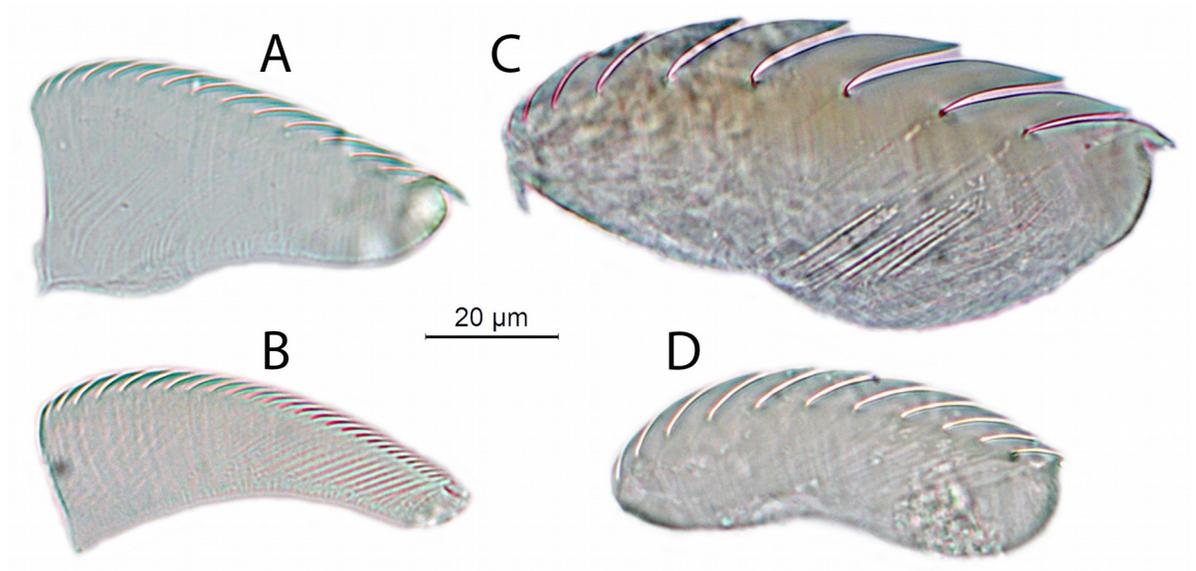

Symbiont	<i>Chaetopterus</i>	0	1	2	3	4
<i>Ophthalmonoe pettiboneae</i>	Ca	21	56	0	0	0
<i>Onuxodon fowleri</i>	Ca	78	5	1	0	0
<i>Euleniaios cometes</i>	Ca	8	0	1	0	0
<i>Polyonyx</i> cf. <i>heox</i>	Cs	1	3	7	0	0
<i>Polyonyx</i> sp.	Cs	3	4	2	0	0
<i>Tetrias</i> sp.	Cs	10	0	1	0	0
<i>Phestilla</i> sp.	Cs	8	1	1	1	0

692 Figure 1. (A) Location of the study area on the Vietnamese coast of the South China Sea. (B)
693 Sampling sites, Nhatrang Bay. Map data from Google Earth Pro, (c) 2016 Google.

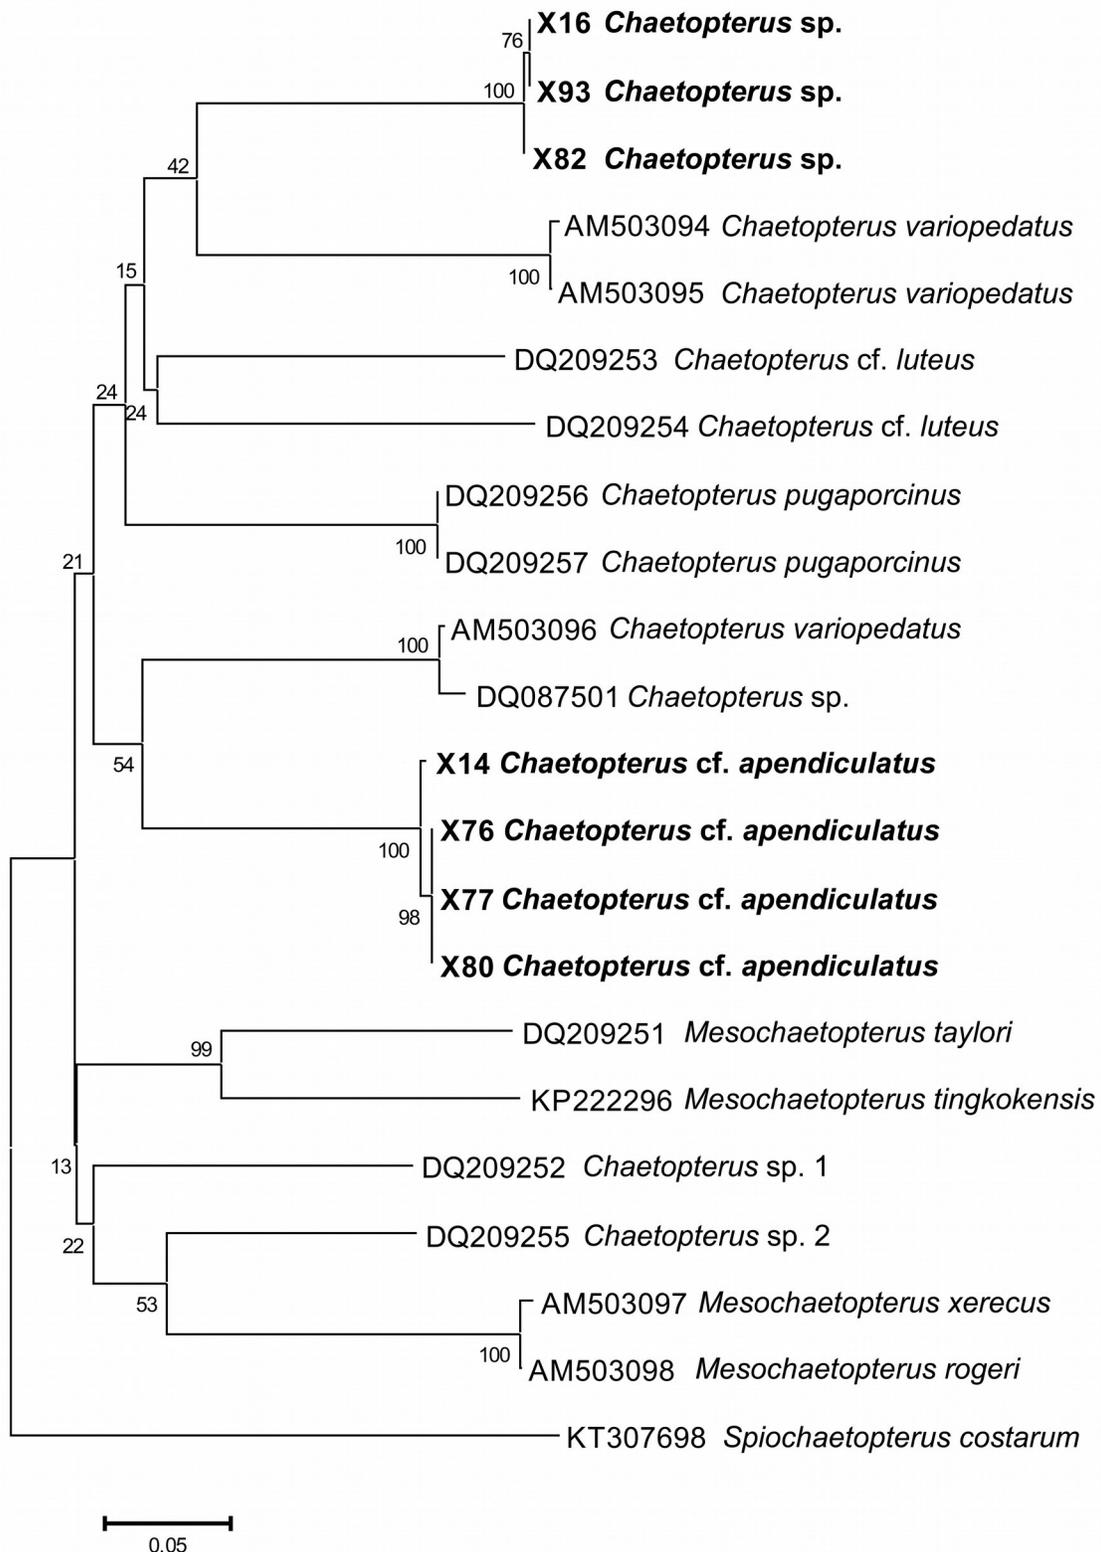

694 Figure 2. *Chaetopterus* cf. *appendiculatus*: (A) whole worm; (B) tube; (C) detail of inner tube
695 surface. *Chaetopterus* sp.: (D) whole worm; (E) tube; (F) detail of inner tube surface. Scale bars
696 are 5 cm.

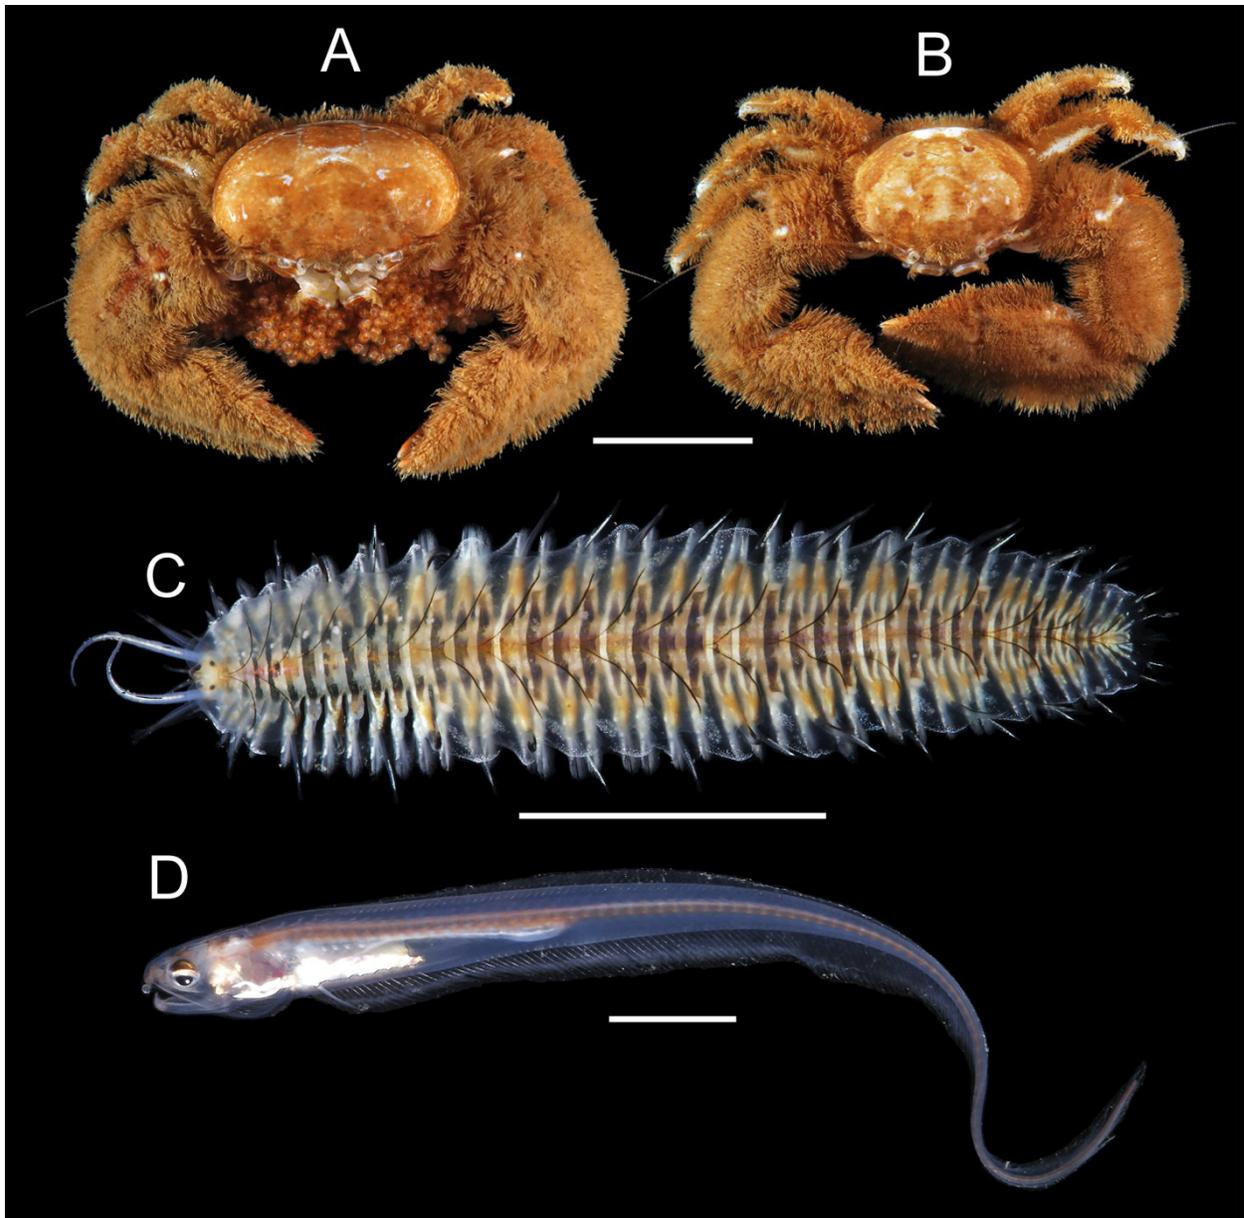

697

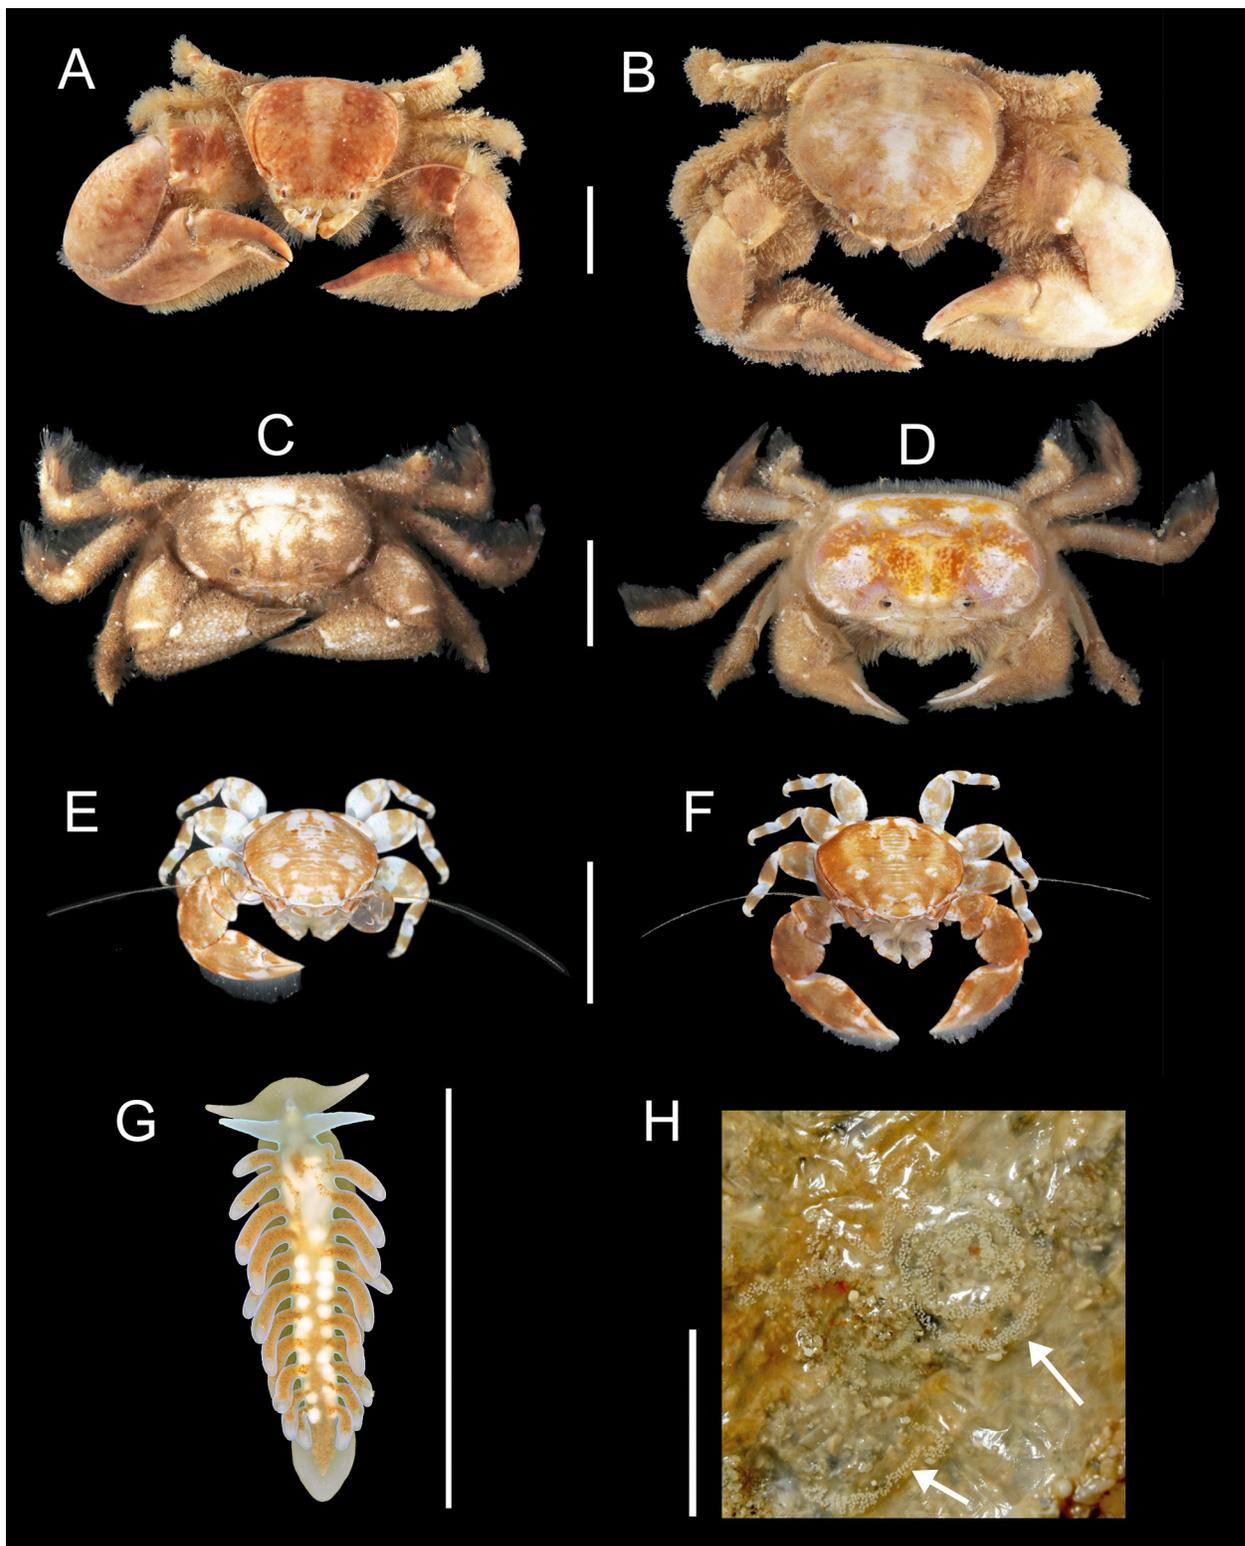

698 Figure 3. Uncini from ventral neuropodial tori of region C. *Chaetopterus* cf. *appendiculatus*: (A)
699 upper tori; (B) lower tori. *Chaetopterus* sp.: (C) upper tori; (D) lower tori.

700 Figure 4. Preliminary phylogenetic tree for species of *Chaetopterus* and *Mesochaetopterus* based
 701 on the COI sequences obtained from NCBI GenBank and our data (in bold). The sequences for
 702 the two Vietnamese species are listed in Table 2.

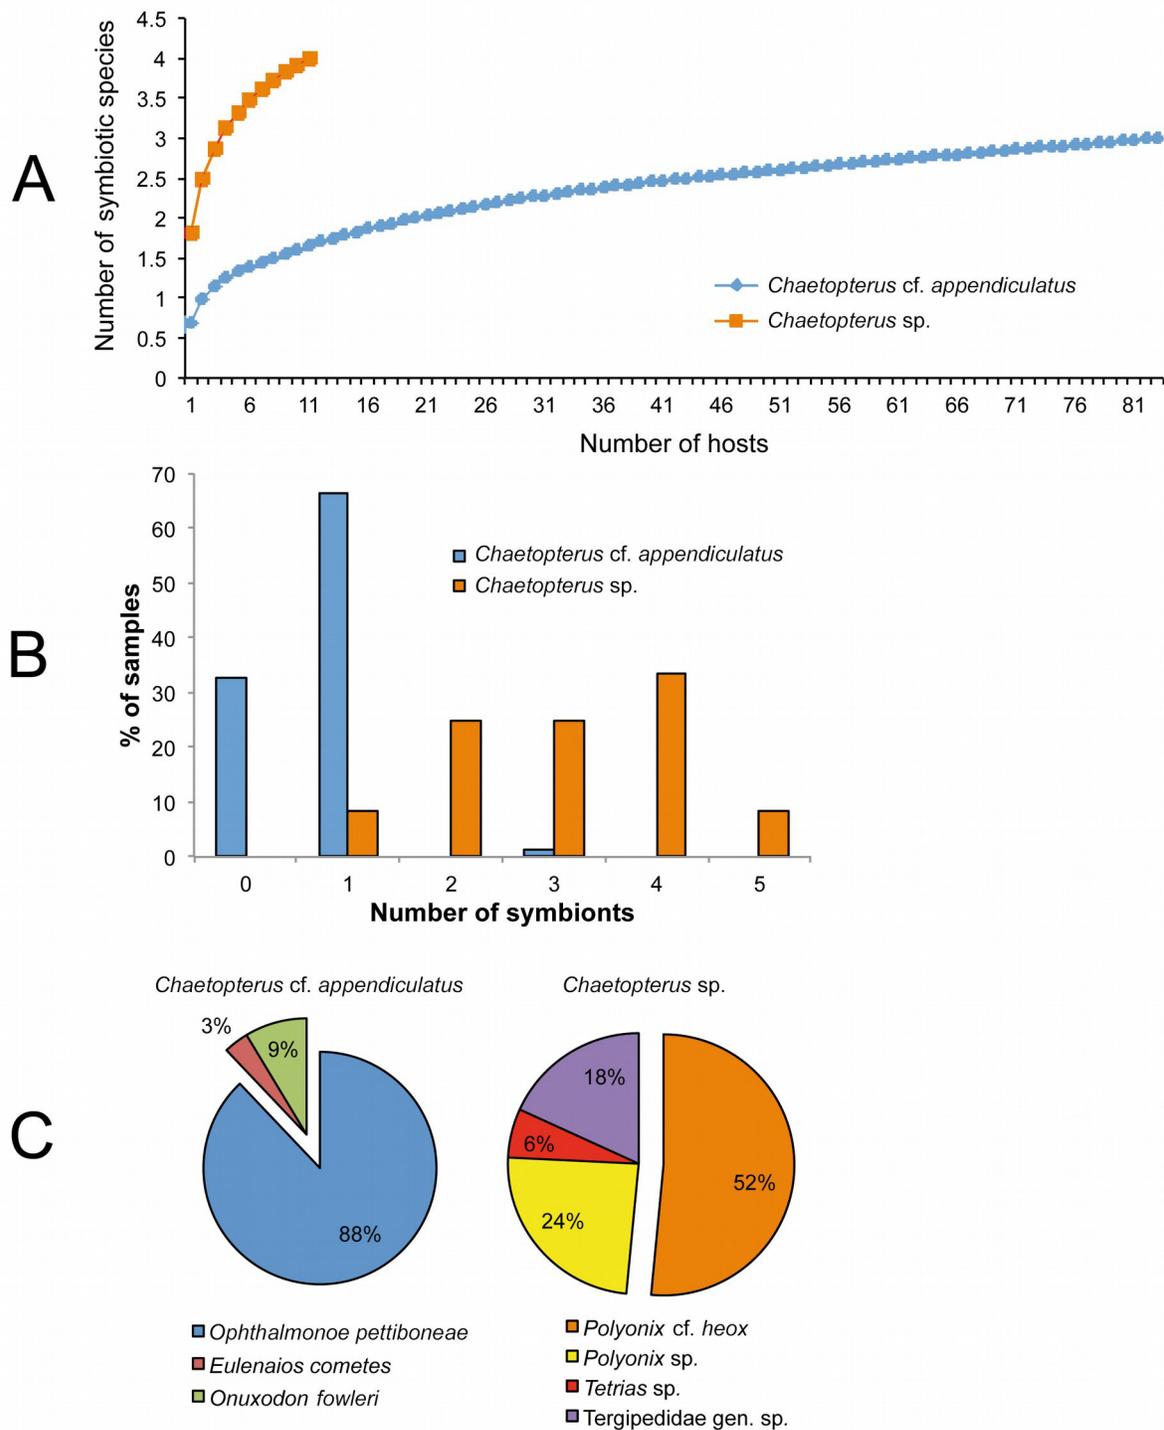

703 Figure 5. Symbiotic community associated with *Chaetopterus* cf. *appendiculatus*: (A, B)
704 *Euleniaios cometes* (female and male, respectively); (C) *Ophthalmonoe pettibonneae*; (D)
705 *Onuxodon fowleri*. Scale bars are 1 cm.

706 Figure 6. Symbiotic community associated with *Chaetopterus* sp.: (A, B) *Polyonyx* cf. *heox* (male
707 and female, respectively); (C, D) *Tetrias* sp. (male and female, respectively); (E, F) *Polyonyx* sp.,

708 (male and female, respectively); (G, F) *Phestilla* sp. (whole body and egg-mass, respectively);
709 egg-mass indicated by arrows. Scale bars are 0.5 cm.

710 Figure 7. Characterization of the symbiotic assemblages associated with the two host species of
 711 *Chaetopterus*: (A) rarefaction curve; (B) distribution of symbionts per host; (C) relative
 712 abundance of the symbiotic species.
