The variation in the biomass, abundance and diversity of mobile invertebrates in eelgrass (*Zostera marina*) beds has been examined in relation to various abiotic and biotic factors, such as water temperature, salinity, eelgrass biomass and epiphytic microalgae presence. However, the importance of sessile epibionts, such as macroalgae and calcific spirorbid polychaetes attached to eelgrass blades, has not been the focus of previous studies. In the present study, we examined the effects of three different sessile epibionts, namely, branched red algae, filamentous green algae, and calcific spirorbid polychaetes, on the biomass and diversity of mobile invertebrates in the eelgrass beds of Akkeshi in Northeastern Japan. The relationships of the dominant mobile invertebrate biomass, the total biomass of mobile invertebrates and the species diversity to multiple abiotic and biotic variables were analyzed using a linear mixed model. Our results show that large-sized epibiotic organisms can be good predictors of the variation in the total biomass, species richness and species diversity of mobile invertebrates and the biomass of major dominant species, especially for species that have a relatively high dependency on eelgrass blades. These results suggest that the different functional groups of sessile epibionts have significant roles in determining the biomass and diversity of mobile invertebrates in eelgrass beds.

25 **ABSTRACT**

26

27 The variation in the biomass, abundance and diversity of mobile invertebrates in eelgrass
28 (*Zostera marina*) beds has been examined in relation to various abiotic and biotic factors, such as
29 water temperature, salinity, eelgrass biomass and epiphytic microalgae presence. However, the
30 importance of sessile epibionts, such as macroalgae and calcific spirorbid polychaetes attached to
31 eelgrass blades, has not been the focus of previous studies. In the present study, we examined the
32 effects of three different sessile epibionts, namely, branched red algae, filamentous green algae,
33 and calcific spirorbid polychaetes, on the biomass and diversity of mobile invertebrates in the
34 eelgrass beds of Akkeshi in Northeastern Japan. The relationships of the dominant mobile
35 invertebrate biomass, the total biomass of mobile invertebrates and the species diversity to
36 multiple abiotic and biotic variables were analyzed using a linear mixed model. Our results show
37 that large-sized epibiotic organisms can be good predictors of the variation in the total biomass,
38 species richness and species diversity of mobile invertebrates and the biomass of major dominant
39 species, especially for species that have a relatively high dependency on eelgrass blades. These
40 results suggest that the different functional groups of sessile epibionts have significant roles in
41 determining the biomass and diversity of mobile invertebrates in eelgrass beds.

47 **INTRODUCTION**

48

49 The abundance, biomass and species diversity of marine benthic invertebrate communities vary
50 greatly with multiple abiotic/biotic factors. The effects of temperature and salinity as
51 environmental filters have been known to be critical factors that regulate population/community
52 patterns and processes in coastal habitats, especially in estuaries where strong environmental
53 gradients are generated by tidal fluctuation and freshwater inflow (e.g. Remane & Schlieper,
54 1971; Garrity, 1984; Montagna & Kalke, 1992; Williams & Morritt, 1995; Mannino & Montagna,
55 1997; Ysebaert et al., 1998; Ysebaert et al., 2003; Yamada et al., 2007b; Douglass et al., 2010;
56 Tittersor et al., 2010; Blake & Duffy, 2010). Water temperature can either increase or decrease
57 the abundance and diversity of component species (e.g. Somero, 2002; Harley et al., 2006;
58 Hoegh-Guldberg & Bruno, 2010; Meager, Schlacher & Green, 2011), whereas a decrease in
59 salinity generally leads to a lower species diversity and higher dominance by tolerant species (e.g.
60 Remane & Schlieper, 1971; Montagna & Kalke, 1992; Mannino & Montagna, 1997; Ysebaert et
61 al., 1998; Ysebaert et al., 2003; Yamada et al., 2007b). For the biotic factors, the effect of
62 various macrophytes (e.g. kelps, sargassum, seagrasses) on mobile invertebrates has been
63 investigated. Marine plants act as both a food resource because plant resource utilizers dominate
64 in marine benthic invertebrate communities (e.g. Robertson & Lucas, 1983; Duffy & Hay, 1991;
65 Duffy, Richardson & Canuel, 2003; Valentine & Heck, 1999; Harley, 2006; Aguilera &
66 Navarrete, 2012; Poore et al., 2012) and as habitat-former (e.g. Dean & Connell, 1987; Lee,
67 Fong & Wu, 2001; Attrill, Strong & Rowden, 2000; Thomsen, 2010; Gutow et al., 2012; Gartner
68 et al., 2013).

69 Eelgrass (*Zostera marina*) is an important marine foundation species that is widely

70 distributed along the coast of the northern hemisphere (Hughes et al., 2009). The complex
71 physical structures created by eelgrass provide a habitat for many organisms (Heck & Orth,
72 1980; Orth, Heck & van Monfrans, 1984; Edgar et al., 1994; Jernakoff, Brearley & Nielsen,
73 1996; Heck, Hays & Orth, 2003), which leads to an enhanced biodiversity and secondary
74 production (Hemminga & Duarte, 2000; Duffy, 2006; Valentine & Duffy, 2006). A benthic
75 invertebrate community in the above-ground parts of seagrass beds mainly consists of small
76 crustaceans, gastropod mollusks and polychaetes, most of which are herbivores and detritivores
77 (Valentine & Heck, 1999; Heck et al., 2000). These invertebrates play an important role in
78 mediating the energy flow in the eelgrass bed ecosystem (Duffy & Hay, 2000; Duffy, Richardson
79 & France, 2005). To explore plant-animal interactions in eelgrass bed communities, many
80 studies have investigated the relationship between animal abundance and various eelgrass traits,
81 such as biomass, shoot density, leaf length, habitat patch structure, and epiphytic microalgal
82 biomass of (e.g. diatoms) that serve as food resources (Webster Rowden & Attrill, 1998; Attrill,
83 Strong & Rowden, 2000; Healey & Hovel, 2004; Gartner et al., 2013; Whalen, Duffy & Grace,
84 2013). However, large epibiotic organisms, such as macroalgae and sessile animals (e.g.
85 spirorbid polychaetes, tunicates, bryozoans, hydrozoans), attached to eelgrass blades can also
86 affect the mobile invertebrate community through resource provisioning and/or habitat
87 modification. Despite some studies noting that the role of macroalgae on seagrass blades as food
88 resource and habitat provider can be one of the determinants of the abundance of mobile
89 invertebrates (Hall & Bell, 1988; Bologna & Heck, 1999; Valentine & Duffy, 2006; Gartner et
90 al., 2013; Whalen, Duffy & Grace, 2013), most studies have focused only on the importance of
91 seagrass and/or microalgae (e.g. Orth, 1977; van Montfrans, Wetzel & Orth, 1984; Irlandi &
92 Peterson, 1991; Klumpp, Salita-Espinosa & Fortes, 1992; Jernakoff, Brearley & Nielsen, 1996;

93 Heck & Valentine, 2006). Regarding the effect of sessile animals on mobile invertebrates,
94 although the relevant studies remain few in seagrass systems, the relationships with tunicates and
95 scallops attached to eelgrass blades have been reported (Duffy & Harvilicz, 2001; Duffy,
96 Richardson & Canuel, 2003; Lefcheck et al., 2014; Long & Grosholz, 2015). Interpreting
97 variations in the mobile invertebrate community in relation to various functional groups of
98 epibiotic organisms is thus necessary to deepen our understanding of the organization of animal
99 assemblages in eelgrass beds and of the influences these organisms have on each other and
100 eelgrass.

101 An extensive eelgrass meadow, consisting mostly of *Zostera marina* and partly of *Z.*
102 *japonica* and *Ruppia maritima*, is located in the Akkeshi-ko estuary and the Akkeshi Bay in
103 eastern Hokkaido, Japan (Hasegawa, Hori & Mukai, 2007). From early summer to late fall, a
104 massive variety of algae and sessile animals (epibiotic species), which attach to eelgrass blades,
105 are observed, including microalgae, branched red algae, *Neosiphonia* sp., *Chondria dasyphylla*,
106 filamentous green algae, *Cladophora* sp., calcareous algae, *Circeis spirillum*, and spirorbid
107 polychaetes, such as *Neodexiospira brasiliensis*, bryozoans, hydrozoans, and tunicates. Among
108 them, microalgae, the branched red algae and the spirorbid polychaetes are dominant in eelgrass
109 beds for a long term, between early summer and late fall, with the peak of abundance between
110 August and September (Hamamoto & Mukai, 1999; Kasim & Mukai, 2006; Hasegawa, Hori &
111 Mukai, 2007; Momota, unpublished data). Previous studies on benthic invertebrate assemblages
112 in the Akkeshi-ko estuary and Akkeshi Bay have focused on their variability in relation to the
113 salinity gradient (Yamada et al., 2007a; Yamada et al., 2007b). In addition to salinity, the spatial
114 heterogeneity of other abiotic/biotic factors (e.g. water temperature, microalgal biomass and
115 eelgrass biomass) is also high in estuarine systems, such as the Akkeshi-ko estuary (Iizumi et al.,

116 1996; Kashim & Mukai, 2006; Hasegawa, Hori & Mukai, 2007). Nevertheless, no previous study
117 has investigated the mobile invertebrate community structure using an approach that
118 simultaneously accounts for the details of sessile epibionts and environmental control by abiotic
119 factors in the seagrass beds in Akkeshi.

120 In the present study, we investigated how multiple abiotic and biotic factors are related
121 to the variation in the community structure (total mobile invertebrate biomass, species richness
122 and species diversity) of the mobile invertebrates and the population biomass of the dominant
123 species in the eelgrass beds in Akkeshi. Our specific focus was to test the relationship between
124 various sessile epibionts on eelgrass blades and the mobile invertebrates that live on eelgrass
125 blades. Including these factors in the multivariate model, this analysis expands the classical
126 models that consider only abiotic factors, eelgrass and microalgae as the explanatory variables.

127

128

129 **MATERIALS AND METHODS**

130

131 **Study area**

132

133 The Akkeshi-ko estuary (locally called Akkeshi Lake) and Akkeshi Bay are located in
134 Northeastern Hokkaido, Japan (Fig. 1) and are connected to each other through a narrow channel
135 (width: approximately 500 m, depth: approximately 10 m). The Akkeshi-ko is a brackish estuary,
136 shallow water (depth range in most of the lake: 0.8-1.7 m with the maximum difference in tide
137 levels of up to approximately ± 0.6 m), with an area of approximately 32 km². Most bottom areas
138 of the Akkeshi-ko estuary are muddy and covered with eelgrass (*Z. marina*) except for the

139 aquaculture farms of the clam *Venerupis philippinarum* in the intertidal zone near the channel
140 (Kashim & Mukai, 2006; Hasegawa, Hori & Mukai, 2007; Yamada et al., 2007a, Yamada et al.,
141 2007b). Here, freshwater input from the Bekanbeushi River, which accounts for 98.8% of all of
142 the flow volume (Iizumi et al., 1996), and tidal seawater input from the Akkeshi Bay cause steep
143 physical and chemical environmental gradients (Iizumi et al., 1996; Yamada et al., 2007a).

144 Akkeshi Bay has an area of approximately 110 km² and opens to the Pacific Ocean at the
145 south end. Two seagrass species *Z. marina* and *Zostera asiatica*, are present from the intertidal
146 zone to the subtidal zone (5 m below mean low water); the former occurs at depths shallower
147 than 2 m and the latter dominates in deeper water (Watanabe, Nakaoka & Mukai, 2005). The
148 influence of the freshwater discharge is observed near the channel connecting the bay to the
149 Akkeshi-ko estuary (Yamada et al., 2007a).

150 In this study, we established seven study stations consisting of six stations in the Akkeshi-ko
151 estuary, (BK: river mouth of the Bekanbeushi River, HN: Horonitai, TB: Toubai, SL: the
152 southern lakeside, CL: the central lake and CK: Chikarakotan) and one station in Akkeshi Bay
153 (SR: Shinryu) (Fig. 1). BK (mean sea level, MSL hereafter: 0.9 m) is located at the mouth of the
154 Bekanbeushi River and is strongly affected by freshwater inflow. The vegetation is dense with
155 small-sized *Z. marina* (average shoot length of 1.0 m in August). HN (MSL: 1.1 m) is in a
156 location with a high water temperature and medium salinity relative to the other stations. In
157 addition to *Z. marina*, *Rupia maritima*, a seagrass species that is more tolerant to low-saline
158 water, occurs at HN. The eelgrass beds at HN are mostly continuous but have some gaps, and the
159 average shoot length in August is 1.3 m. TB (MSL: 1.1 m) and SL (MSL: 1.0 m) have a
160 relatively low salinity compared to that of the other stations and are the furthest stations from the
161 Akkeshi Bay. Although these two stations are in a similar environment, the water is often more

162 turbid and the eelgrass bed is patchier at TB than SL. SL has a higher seagrass biomass and shoot
163 density than TB. The average shoot length of eelgrass is approximately 1.3 m in August at both
164 of these stations. CL (MSL: 1.4 m) and CK (MSL: 1.5 m) are deeper stations with a higher
165 salinity and are dominated by longer eelgrass (shoot length: 1.5-3.5 m at the peak season). The
166 eelgrass at SR (MSL: 1.5 m) in the Akkeshi Bay, has a similar shoot size to that in CL and CK.
167 Here, the dominant seagrass species changes from *Z. marina* bed to *Z. asiatica* at a depth of
168 approximately 2 m, as mentioned above.

169 According to Yamada et al. (2007a), salinity varies significantly among stations but does not
170 very greatly among seasons. During the summer (from July to August), eelgrass biomass,
171 microalgal biomass and mobile invertebrates reach their peak (Hasegawa, Hori & Mukai, 2007;
172 Yamada et al., 2007b). Seasonal changes in the mobile invertebrate species richness are not
173 clearly understood (Yamada et al., 2007b).

174

175 **Field sampling**

176

177 We conducted a field survey in August 2012. Sample collection was performed when the tidal
178 current was slow. We collected mobile invertebrates on eelgrass blades when the water level was
179 deeper than the average sheath length of the eelgrass at each station (BK: 20 cm; HN, TB, SL: 30
180 cm; CL, CK, SR: 40 cm). Because the eelgrass at our study stations is tall (> 1 m) compared to
181 the average water depth of each station, the canopy usually reaches the water surface (except for
182 at extremely high tides). All sampling was performed under these conditions. We targeted
183 mobile invertebrates and excluded some species with remarkably higher mobility and less
184 dependency on eelgrass habitat, such as mysids and decapods (Yamada et al., 2007b), which

185 were not quantitatively collected by our method (see below).

186 We measured water temperature and salinity once at each station using a memory sensor
187 (AAQ-175 RINKO, JFE Advantech Co. Ltd., Japan). To obtain the representative values, the
188 sensor was carefully placed approximately 50 cm from the bottom to accurately reflect the
189 environment inside of the seagrass meadow.

190 We collected three replicate samples (a total of 21 samples from all stations) of mobile
191 invertebrates, spirorbid polychaetes and epiphytic macroalgae together with the above-ground
192 parts of the eelgrass using a mesh bag (bore diameter: 20 cm, mesh size: 0.1 mm) based on the
193 mouth area of the mesh bag (314 cm²). Upon collection, we counted the number of eelgrass
194 shoots to determine shoot density. For microalgae, five replicate samples were collected per
195 station together with one eelgrass shoot using a plastic zip bag, because microalgae easily fell off
196 from eelgrass blades when collected with the mesh bag.

197

198 **Laboratory procedures**

199

200 Immediately after being transported to the laboratory, the microalgae were scraped from the
201 eelgrass blades using a glass slide; separated from other organisms such as macroalgae and
202 spirorbid polychaetes; and then filtered using glass fiber filters (Whatman GF/F filter ϕ 47 mm,
203 Whatman International Ltd., Maidstone, UK). If other organisms were present in the microalgal
204 samples, we carefully removed them from the filters with forceps. Other epibiotic organisms
205 collected using mesh bags were separated from the eelgrass by scraping them off with a glass
206 slide; these organisms were classified as red algae, green algae, spirorbid polychaetes and mobile
207 invertebrates. To obtain dry mass, eelgrass shoots, red algae, green algae, spirorbid polychaetes

208 and filtered microalgae were dried at 60°C for 4 days in small aluminum foil bags, and then
209 weighed. We counted and identified the mobile invertebrates after extraction with a sieve (500
210 μm) and fixation with 70% ethanol. Identification of mobile invertebrates was made to the lowest
211 taxonomical unit possible (mostly to species) using detailed guides from the literature
212 (Gammarid amphipod: Nishimura, 1995; Carlton, 2007; Ogawa, 2011; Caprella amphipod,
213 Isopod, Copepod, Cumacea: Nishimura, 1995; Carlton, 2007; Gastropod: Okutani, 2000;
214 Polychaeta: Nishimura, 1992; Imajima, 1996; Imajima, 2001; Turbellaria: Nishimura, 1992;
215 Carlton, 2007; Hirunoidea: Nishimura, 1992) and the World Register of Marine Species online
216 database (WoRMS: <http://www.marinespecies.org>).

217

218 **Statistical analysis**

219

220 We used, as predictors, two abiotic factors (water temperature and salinity) and six biotic factors
221 (eelgrass biomass [g dry weight per unit area: g DW m^{-2}], eelgrass shoot density [shoots m^{-2}],
222 microalgal biomass [g DW m^{-2}], red algal biomass [g DW m^{-2}], green algal biomass [g DW m^{-2}]
223 and spirorbid polychaete biomass of [g DW m^{-2}]). For eelgrass biomass, we used the dry weight
224 data collected using mesh bags. Because microalgal biomass was collected by a different
225 sampling procedure from other biotic variables, we used the mean value of five replicates. All
226 invertebrate biomass (mg ash-free dry weight per unit area, mg AFDW m^{-2}) was estimated from
227 the abundance and the size fraction using the empirical equations in Edgar (1990).

228 To test which of the eight biotic/abiotic factors was a likely predictor of the variation in the
229 mobile invertebrate community, we fit linear mixed models (LMMs) with a Gaussian
230 distribution. The station was used as a random variable. As response variables, we used the

231 biomass of 11 dominant species for the population-level analyses, and total invertebrate biomass,
232 species richness and species diversity (Shannon-Wiener diversity index) for community-level
233 analyses. The 11 most dominant species were selected by a threshold whereby the biomass
234 proportion accounted for more than 1% of the total invertebrate biomass (see Table S1).
235 *Ostreobdella kakibir* (Hirudinoidea) was omitted from the analysis because it occurred only at
236 one station (SR), even though they satisfied the requirement. R software (version 3.1.3) was used
237 for all of the analyses (R Development Core Team, 2015).

238 Prior to the LMM fit, all of the variables excluding species diversity were square root
239 transformed to improve homoscedasticity and meet the assumptions of normality of the LMMs
240 after checking for normality with the Shapiro-Wilk test. To test for collinearity between the eight
241 environmental variables, we calculated Pearson's correlation coefficients for all pairs. If the
242 absolute value of the coefficient (r) was greater than 0.7, the level where collinearity does not
243 affect model predictions (Dormann et al., 2013), we removed the relevant predictor as necessary.
244 Because it followed that water temperature and microalgal biomass were highly correlated
245 (Pearson's $r = -0.82$, $P < 0.01$), we removed microalgal biomass from the models. After this
246 removal, we tested potential multicollinearity among the remaining predictors using the variance
247 inflation factor (VIF) analysis with a cutoff of 10 (e.g. Dormann et al., 2013). VIF values were
248 calculated using the *vif.mer* function developed by Frank
249 (<https://raw.githubusercontent.com/aufrank/R-hacks/master/mer-utils.R>). However, all seven
250 predictors were below the VIF value of 10 and remained. We therefore defined a reduced model
251 with the seven predictors as the full model.

252 We fit the LMMs using the *lmer* function in the lme4 package (Bates et al., 2014). To obtain
253 P -values of the LMMs, we used the *lmerTest* package (Kuznetsova et al., 2014). We selected the

254 optimal model comparing the candidate models on all combinations of the predictors by the
255 Akaike information criterion as corrected for the small sample size (AIC_c ; Burnham & Anderson,
256 2002). We obtained AIC_c based on the maximum likelihood (ML) for comparisons among the
257 LMMs because the restricted maximum likelihood (REML) is inappropriate in the case when the
258 fixed structure is different between the candidate models (Zuur et al., 2009), but the parameters
259 were estimated by REML. We used the *AIC_ctab* function in the *bbmle* library (Bolker & R Core
260 Team, 2013) to compare the AIC_c . After setting the optimal models, we obtained the
261 standardized coefficients as effect sizes by re-fitting using standardized variables that were
262 scaled by the sample standard deviation and centered by sample mean values.

263 Additionally, when the effect of water temperature was detected, we tested the relationship
264 between mobile invertebrates and microalgal biomass which was omitted from the LMM
265 because of the multi-collinearity with water temperature.

266

267

268 **RESULTS**

269

270 **Environmental factors**

271

272 Water temperature was lower at the four stations (BK, CL, CK and SR) near the channel than at
273 the other three stations in the inner parts of the estuary (HN, TB and SL) (Table 1). Salinity was
274 lower at the lakeside stations (BK, HN, TB, SL and CK) that were influenced by freshwater
275 inputs. For these stations, the inter-annual variation was also higher (Table 1).

276 Eelgrass biomass varied between 140 and 278 g DW m⁻² among the stations. It was the

277 lowest at TB, followed by HN and BK (Table 1). Eelgrass shoot density ranged between 85 and
278 234 shoot m⁻². It was highest at BK and second highest at SL. The mean densities were not
279 largely different among other stations. Microalgal biomass varied by more than ten-fold between
280 the lowest station (SL) and the highest station (CL). In the latter, the microalgal biomass
281 exceeded the biomass of the eelgrass. Macroalgae were not present at TB and SR. Red algae
282 were dominated by *Neosiphonia* sp. and *Chondria dasyphylla*, and green algae were dominated
283 by *Cladophora* sp. The mean biomass of red algae was highest at HN and that of green algae was
284 highest at CL, although their biomasses were less than 15 % that of eelgrass. Spirorbid
285 polychaetes were not present at SL and CL. They were highly abundant at SR where their
286 biomass was more than three-fold greater than the eelgrass biomass.

287

288 **Mobile invertebrate community**

289

290 A total of 32 mobile invertebrate species were collected in this study (Table S1). At taxonomic
291 levels, polychaete worms made up 32.2% of the total biomass, followed by gastropods (31.3%),
292 gammarid amphipods (23.0%), and isopods (8.8%). At the species level, a polychaete *Nereis* sp.
293 was most dominant (24.6%), followed by gastropods *Lacuna* spp. (23.4%) and the gammarid
294 amphipod *Ampithoe lacertosa* (18.0%). For an additional eight species including two gammarid
295 amphipod (*Monocorophium* spp. and *Pontogeneia rostrata*), two isopods (*Cymodoce japonica*
296 and *Paranthura japonica*), two gastropods (*Ansola angustata* and *Siphonacmea oblongata*) and
297 two polychaetes (*Exogone naidina* and *Syllis* sp.), their proportions were less than 5% at most.

298 The mean value of the total mobile invertebrate biomass was the highest at CK and
299 much lower at stations along the coastline (HN, TB and SL). Species richness was the highest at

300 CL, followed by CK and was approximately the same level at the other stations (Fig. 2). The
301 mean value of species diversity was the highest at CL and the lowest at SR (Fig. 2).

302

303 **Population level analyses**

304

305 We found that each of the nine invertebrate populations belonging to gammaridae, gastropoda
306 and polychaeta was predicted by a different combination of environmental factors in the optimal
307 models (Table 2). For two isopods, no environmental factor correlated with their biomass.

308 Water temperature was selected as the responsible factor for the variation of *A.*
309 *lacertosa*, *Lacuna* spp. and all three polychaetes. Among them, only *Syllis* sp. showed a
310 significant correlation (positive). The significant effect of the salinity gradient was detected for *A.*
311 *angustata* (negative) and *S. oblongata* (positive).

312 For the two predictors relevant to the characteristics of the eelgrass bed, the above-ground
313 biomass showed a significantly positive relationship only with *Syllis* sp., whereas shoot density
314 was significantly correlated with *Monocorophium* spp. (positive), *P. rostrata* (negative) and *E.*
315 *naidina* (negative).

316 The biomasses of sessile epibionts (red algae, green algae and spirorbid polychaetes) on
317 eelgrass blades were correlated with many invertebrate populations excluding *A. lacertosa*,
318 *Monocorophium* spp., two isopods and *E. naidina* in different manners. Red algal biomass was
319 positively correlated with *P. rostrata*, *Lacuna* spp. and *Nereis* sp., but negatively correlated with
320 *Syllis* sp. and tended to be negatively correlated with *A. angustata*. Green algal biomasses were
321 positively correlated with *P. rostrate* and *Lacuna* spp. The biomass of spirorbid polychaetes was
322 positively correlated with all three species of gastropods and was negatively correlated with

323 *Syllis* sp.

324 Although epiphytic microalgae were removed from our analysis because of the
325 collinearity with water temperature, no significant correlation was found for species that were
326 correlated with water temperature (*A. lacertosa*: Pearson's $r = 4.05$, $P = 0.25$; *Lacuna* spp.: $r = -$
327 3.42 , $P = 0.69$; *E. naidina*: $r = 0.31$, $P = 0.92$; *Nereis* sp.: $r = 10.87$, $P = 0.34$; *Syllis* sp.: $r = 0.21$,
328 $P = 0.86$).

329

330 **Community level analyses**

331

332 The total invertebrate biomass tended to decrease with water temperature, and significantly
333 increased with increasing eelgrass biomass and red algal biomass (Table 2). Species richness
334 showed a negative correlation with water temperature and spirorbid polychaetes. Species
335 diversity was positively correlated with green algal biomass, but was negatively correlated with
336 spirorbid polychaetes (Table 2).

337

338

339 **DISCUSSION**

340

341 The present study demonstrated that the biomass gradient of large-sized epibiotic organisms (e.g.
342 macroalgae and spirorbid polychaetes) was a good predictor of the variation in the mobile
343 invertebrate community in the eelgrass bed and the population biomass of some dominant
344 component species. The effect of the macroalgae is notable because these sessile epibionts have
345 a much lower biomass compared to the biomass of eelgrass and epiphytic microalgae. However,

346 the observed relationships between these functional groups and mobile invertebrate populations
347 varied greatly among the species.

348 In the optimal models, the effects of biomass of epibiotic organisms on the gammarid
349 amphipod *P. rostrata*, all three gastropod species (*A. angustata*, *Lacuna* sp. and *S. oblongata*)
350 and two polychaetes (*Nereis* sp. and *Syllis* sp.) were detected. For those species, the sessile
351 epibionts were positively related to mobile invertebrate biomasses except for *Syllis* sp. and *P.*
352 *rostrata*, which showed a positive correlation with both red and green algae. The algae are
353 considered to be used as a temporal shelter (habitat) rather than as a food resource because these
354 animals do not firmly attach to the eelgrass blades but rather drift among shoots (Suh & Yu,
355 1997; Yamada et al., 2007b; Yu, Jeong & Suh, 2008), and because they have a preference for
356 feeding on phytoplankton and detritus (Yu & Suh, 2011). High predation risk for swimming
357 amphipods with low self-defense abilities, such as *P. rostrata*, has been reported in several
358 studies (Sudo & Azeta, 1992; Beare & Moore, 1998). In fact, gammarid amphipods are a major
359 source of prey for blennoid fish in the eelgrass beds of Northern Japan (Watanabe et al., 1996;
360 Sawamura, 1999; Yamada et al., 2010). Therefore, the complex micro-habitat created by
361 macroalgae allows them to escape these predators.

362 All three gastropods increased in correlation with spirorbid polychaetes, whereas the
363 responses to the other factors were different (Table 2). The positive effect of spirorbid
364 polychaetes appears to result from habitat-formation in terms of our assumption, but should not
365 be oversimplified because of the overlap in the life cycle and because of the functional mismatch.
366 Because the gastropods adhere to flat seagrass blades, the flat (simple) structure created by
367 seagrass blades can be better than the rough structure of spirorbid polychaetes. Therefore,
368 competition for space (negative effect) appears to be more expected than facilitation. Although

369 we do not have a good answer for the positive relationships, one possibility for this unexpected
370 result is that the rough structure acts as a shelter because small-sized individuals (< 3 mm) are
371 frequent in gastropod populations during the summer season (*A. angustata*: Momota, personal
372 observation; *Lacuna* spp.: Kanamori, Goshima & Mukai, 2004; *S. oblongata*: Toyohara,
373 Nakaoka & Tsuchida, 2001).

374 Red algae are considered to positively affect *Nereis* sp. by provisioning habitat because
375 polychaetes build tubes both on eelgrass blades and in red algal canopies in Akkeshi (Momota,
376 unpublished data). The negative effect of red algae and spirorbid polychaetes on *Syllis* sp. may
377 suggest that this mobile polychaete prefers a simple structured habitat without a complex micro-
378 habitat created by eelgrass blades with sessile epibionts.

379 In addition to the effects of sessile epibionts, the significant effects of water temperature,
380 salinity, eelgrass biomass and shoot density were detected for a majority of the dominant species,
381 although the patterns and directions of the effects were different among them. Surprisingly,
382 eelgrass biomass was not correlated with most species except for *Syllis* sp., and the direction
383 (positive/negative) of the effect of eelgrass shoot density was different among the species. The
384 same response of syllid polychaetes was reported in previous studies (e.g. Bone & San Martín,
385 2003). For eelgrass shoot density, the result suggests that it indirectly affects mobile
386 invertebrates through interfering with multiple physical and biological processes (e.g. water
387 current and flux, detritus and drifting algae trapping, recruitment, and predation intensity: Gambi,
388 Nowell & Jumars, 1990; Robbins & Bell, 1994; Attrill, Strong & Rowden 2000; Boström &
389 Bonsdorff, 2000; Lee et al. 2001; Hovel et al., 2002). Notably, the contrasting relationships of *P.*
390 *rostrate* with eelgrass shoot density and macroalgae imply that the shelter effect is different
391 depending on the spatial scale (i.e. blade scale, shoot/patch scale).

392 The isopods *C. japonica* and *P. japonica* were not correlated with any abiotic or biotic
393 factors because of the low dependency on the seagrass habitat; they can utilize other numerous
394 habitats created by both natural and artificial materials (e.g. mussel beds, oyster reefs: Marchini
395 et al., [2014]; Nakamachi, Ishida & Hirohashi, [2015]; gravel, litter layer of macrophytes,
396 *Sargassum* meadow: Momota, personal observation). Additionally, their uniform appearance
397 throughout all of the stations indicates that they have a wide tolerance to a broad range of
398 environmental stress, which leads to a lack of correlation with any of the abiotic factors.
399 Additionally, the gammarid amphipod *A. lacertosa* was not significantly correlated with any
400 factors. This species is widely distributed along the Pacific-rim coast of the northern hemisphere
401 and utilizes a variety of plant habitats by building tubes (Hiebert, 2013), which may explain why
402 it did not show any relationship with the environmental gradients.

403 Although the discussion on underlying drivers that generate apparent correlations (i.e. the
404 causalities) between epibionts and mobile invertebrates is not our main focus, the indirect effects
405 and the top-down control of mobile invertebrates should also be taken into account to interpret
406 present findings. For example, we can give an alternative possibility for the positive relationship
407 between gastropods and spirorbid polychaetes such that high grazing of the gastropods facilitates
408 the recruitment of spirorbid polychaetes through the removal of the microalgal cover.

409 Total biomass, species richness and species diversity were differentially correlated with
410 abiotic/biotic factors, and varied in a complex manner although processes were unclear. The
411 optimal model of the three community variables contains one or two variables of sessile
412 epibionts. The positive correlation of total biomass with red algae reflects a result pulled by the
413 biomass proportions of highly dominant species, such as *Lacuna* spp. and *Nereis* sp. The
414 negative interaction of spirorbid polychaetes with species richness and diversity suggest that

415 spirorbid polychaetes can decrease the homogeneity of the biomasses of component species
416 within a community by allowing some competitive species to dominate. Because no effect on
417 species diversity, total biomass, species richness, or most of the dominant species populations
418 was detected by green algae, it may work on species evenness.

419

420

421 **CONCLUSIONS**

422

423 The present study suggests that macroalgae and sessile animals on eelgrass blades can affect the
424 biomass and diversity of mobile invertebrates and that incorporating these biotic factors can
425 improve the prediction of the variability of the mobile invertebrate community in the eelgrass
426 bed. However, the underlying causal relationships appear to be complex and vary greatly from
427 species to species. Our findings were based on data collected over one sampling period when the
428 eelgrass bed was most productive and when the abundance and/or diversity of algae and mobile
429 invertebrates typically reached their maximum. A more comprehensive investigation of the
430 functional relationships among the various types of organisms and of the temporal changes
431 should be conducted in future studies on eelgrass bed communities.

Table 2. Results of LMMs for explaining responsible environmental factors on variation in mobile invertebrate populations and community components. AIC_c scores and delta AIC_c are also reported. Significant coefficients (*P*-values < 0.05 level) and the lowest AIC_c scores are in **bold face**. Standardized coefficients (*Std.coef*) of the optimal models are reported right below each optimal model in *italic face*. Abbreviations as follows; WT: water temperature, Sal: salinity, ZM.bm: eelgrass biomass, ZM.den: eelgrass shoot density, Red.alg: red algal biomass, Grn.alg: green algal biomass, SP.bm: spirorbid polychaete biomass.
