Larvae of malacostracan crustaceans represent a large fraction of modern day zooplankton. Plankton is not only a major part of the modern marine ecosystem, but must have played an important role in the ecosystems of the past as well. Unfortunately, our knowledge about plankton composition of the past is still quite limited. As an important part of today's zooplankton, malacostracan larvae are still a rarity in the fossil record; many types of malacostracan larvae dominating the modern plankton have so far not been found as fossils. Here we report a new type of fossil malacostracan larva, found in the 150 million years old lithographic limestones of southern Germany (Solnhofen Lithographic Limestones). The three rather incomplete specimens mainly preserve the telson. A pronounced middle spine on the posterior edge of these specimens indicates that they are either larval forms of a clawed lobster or of an axiidean lobster, or of a closer relative to one of the two groups. The tergo-pleura are drawn out into distinct spines in one specimen, further supporting the interpretation as a larva of a clawed lobster or an early relative. The telson morphology also shows adaptations to a prolonged planktic life style, the latero-posterior edges are drawn out into distinct spines. Similar adaptations are known in larvae of the modern homarid lobster *Nephrops norvegicus*, not necessarily indicating a closer relationship, but convergent life styles. The new finds provide an important new insight into the composition of Mesozoic zooplankton and demonstrate the preservation potential of lithographic limestones.

7 8 **Abstract**

9 Larvae of malacostracan crustaceans represent a large fraction of modern day zooplankton.
10 Plankton is not only a major part of the modern marine ecosystem, but must have played an
11 important role in the ecosystems of the past as well. Unfortunately, our knowledge about
12 plankton composition of the past is still quite limited. As an important part of today's
13 zooplankton, malacostracan larvae are still a rarity in the fossil record; many types of
14 malacostracan larvae dominating the modern plankton have so far not been found as fossils. Here
15 we report a new type of fossil malacostracan larva, found in the 150 million years old
16 lithographic limestones of southern Germany (Solnhofen Lithographic Limestones). The three
17 rather incomplete specimens mainly preserve the telson. A pronounced middle spine on the
18 posterior edge of these specimens indicates that they are either larval forms of a clawed lobster
19 or of an axiidean lobster, or of a close relative to one of the two groups. The tergo-pleura are
20 drawn out into distinct spines in one specimen, further supporting the interpretation as a larva of
21 a clawed lobster or an early relative. The telson morphology also shows adaptations to a
22 prolonged planktic life style, the latero-posterior edges are drawn out into distinct spines. Similar
23 adaptations are known in larvae of the modern homarid lobster *Nephrops norvegicus*, not
24 necessarily indicating a closer relationship, but convergent life styles. The new finds provide an
25 important new insight into the composition of Mesozoic zooplankton and demonstrate the
26 preservation potential of lithographic limestones.

27 28 29 **Introduction**

30
31 Plankton describes the entirety of organisms floating in the water column without the ability to
32 actively swim against the current. Plankton has been recognised as an important basis for marine
33 ecosystems in modern seas. Our understanding of changes in plankton composition are therefore
34 important in modern conservation biology and ecology, but are also of economic importance
35 (e.g., Duffy & Stachowicz 2006; Torres et al. 2013; Sardet 2015).

36 For long-time comparisons of changes in plankton composition, data of fossil plankton is
37 of major interest. Plankton must have been similarly important in the past as it is today.
38 Unfortunately, our knowledge of plankton in the past is often limited to very specific groups of
39 organisms, namely those with strongly sclerotised and/or mineralised morphological structures,
40 or those composed of certain decay-resisting substances such as resting cysts and the like
41 (examples in, e.g. Lipps 1970; Tappan & Loeblich 1973; Leckie 2009), while such groups
42 dominating the modern plankton (often lacking easily preservable structures) have a very scarce
43 or absent fossil record (e.g. Signor & Vermeij 1994; Rigby & Milsom 2000; Perrier et al. 2015).
44 It is nevertheless already possible to recognise that the plankton composition was quite different
45 in the past (e.g. Nützel & Frýda 2003; De Baets et al. 2012; Ritterbush et al. 2014; Servais et al.
46 2015).

47 In modern seas, crustaceans are a major part of the zooplankton. Among these we
48 especially need to mention copepod crustaceans and larval stages of malacostracan crustaceans.
49 Copepods
50 are mainly a part of the microplankton, while decapod larvae additionally include forms of meso-
51 and macroplankton.

52 So what about the fossil record of these groups? Fossil copepods are extremely rare. They
53 are limited to only few instances (Palmer 1960; Cressey & Patterson 1973; Cressey & Boxshall
54 1989; Bennike 1998; Huys et al. 2016), often only very incomplete (Selden et al. 2010) or
55 indirect findings (Radwańska & Radwański 2005; Radwańska & Poirot 2010). Malacostracan
56 larvae are also rare in the fossil record, but new forms have been repetitively identified in
57 recent years (e.g. Haug et al. 2008, 2011a, 2014, 2015a, b, c; Hyžný et al. 2016) and are
58 currently limited to the Mesozoic. Despite their rarity, each of these finds marks another
59 important data point for our understanding of plankton in the past.

60 Due to preservation biases, large larval forms appear to be more commonly found as
61 fossils, not necessarily representing the original composition of the fauna, or the true diversity.
62 The most commonly found fossil malacostracan larvae are consequently the super-sized larvae of
63 spiny lobsters and slipper lobsters (with up to 150 mm in the extant fauna). These are represented
64 by at least a dozen different forms (Polz 1984, 1995, 1996; Haug et al. 2013a; Haug & Haug
65 2016), some known from thousands of individuals (Polz 1971, 1972, 1973) and occurring in at
66 least three Lagerstätten (Polz 1984; Pasini & Garassino 2009; Tanaka et al. 2009; Haug et al.
67 2011a). Other more uncommon fossils are also giant larval forms like those of the raptorial
68 mantis shrimps (Haug et al. 2008, 2009, 2010, 2014, 2015b) or the polychelidan lobsters (today
69 only represented by a relic group, mostly restricted to the deep sea; Haug et al. 2015c; Eiler et al.
70 2016). Groups of larvae dominating the modern plankton, like larvae of true crabs, false crabs
71 and their relatives (Meiura = Brachyura and Anomala, the latter also called Anomura), are very
72 rare on the other hand (Luque 2015; Haug et al. 2015a; Hyžný et al. 2016), as their larvae are
73 significantly smaller and more unlikely to be preserved.

74 Brachyuran and anomalan crustaceans are “still on their way” in the Mesozoic, only
75 diversifying in the later Mesozoic (see discussion in Haug et al. 2015a). It is therefore not to be
76 expected that their larvae were as abundant as in modern oceans. Instead the lobster-like
77 crustaceans, especially polychelidan and clawed lobsters (and their relatives) were dominating
78 parts of the faunas as adults, especially in the mid-Mesozoic, hence the Jurassic. We should
79 therefore expect that larval forms of these groups have represented important parts of the Jurassic
80 plankton. Yet, so far no definite fossils of such planktic larvae have been identified. Possible late
81 larvae of Jurassic polychelidans are late transitory stages, not the truly planktic ones (Eiler &
82 Haug 2016). Some fragmentary specimens have been discussed as possible remains of small
83 malacostracans (Haug et al. 2011a, 2014) and might well be parts of larvae of clawed lobsters,
84 but due to the limitations of preservation this must remain speculative.

85 Here we report the first definite finds of zoea-type larvae of clawed lobsters, hence truly
86 planktic larval forms of this group. We discuss the impact of this new finding on reconstructing
87 the plankton composition in the past and how this finding influences our strategies for detecting
88 further material of fossil malacostracan larvae.

89
90

91 **Material and Methods**

92

93 *Material*

94 Three specimens were available for this study (Fig. 1). All originate from the private collection
95 of Roger Frattigiani, Laichingen, and are now deposited in the Staatliches Museum für
96 Naturkunde Stuttgart (SMNS 70353/1, 70353/2, 70353/3). Specimens were originally found in
97 the Birkhof quarry in the Blumenberg area near Eichstätt (Solnhofen Lithographic Limestones,
98 Upper Jurassic, Tithonian, Hybonotum zone, Riedense subzone; Schweigert 2007). For
99 comparison an extant albuneid zoea from the collections of the Muséum national d'Histoire
100 naturelle Paris was documented (MNHN IU-2014-5527). High-resolution images of the
101 specimens are available at <https://www.morphdbase.de/> (C_Haug_20161213-M-5.1,
102 C_Haug_20161213-M-6.1, C_Haug_20161213-M-7.1, C_Haug_20161213-M-9.1).

104 *Documentation method*

105 All specimens were documented on a Keyence BZ-9000 inverse epifluorescence microscope,
106 exploiting the autofluorescence of the fossils (Haug et al. 2011b). Blue-green fluorescence (GFP)
107 was used instead of the commonly used UV fluorescence (e.g., Tischlinger & Arratia 2013). UV
108 fluorescence is often unfortunate due to dust, which shows a very strong fluorescence and is in
109 many cases not removable from the fossils. This is especially true for the comparably high
110 magnifications as applied here (4x objective lens, resulting in 40x magnification). Due to the
111 magnification, depth of field and field of view were limited. To overcome these limitations,
112 several stacks of images for several adjacent image details were recorded (see details Haug et al.
113 2008). Additionally, in some areas where the fluorescence capabilities differed strongly, two
114 stacks were recorded, each with a different exposure time (Haug et al. 2013b).

116 *Image processing*

117 Stacks of images were fused to sharp images with CombineZP. Fused images were stitched to
118 panoramas using the photomerge function of Adobe Photoshop CS3 or Elements 11. Images of
119 different exposure times were combined into a single evenly illuminated image following the
120 procedure described in Haug et al. (2013b).

121

122

123 **Results**

124

125 *Specimen 1 (SMNS 70353/1)*

126 Specimen 1 is most complete, but still largely represents fragmentary remains (Fig. 2). The
127 overall colour and texture of the surface already clearly indicate that these fragments are the
128 remains of a crustacean (although these characters are hard to quantify, they are significantly
129 different to those in co-occurring groups such as insects, echinoderms or fishes, or also in
130 strongly calcified crustaceans such as isopods). This is also in concordance with the preserved
131 structures.

132 Most anteriorly a shield structure is apparent. It appears to be embedded in a dorso-lateral
133 orientation. The anterior rim is drawn out into a distinct but stout rostrum. Along the edge at
134 least two spines are apparent (Fig. 2A). Close to the shield an elongate structure is preserved
135 composed of five elements. Further distal elements are narrower than proximal ones. The
136 structure most likely represents the flagellum of an antennula or antenna. Close to the posterior
137 part of the shield, a piece of rectangular outline is apparent, most likely representing an isolated
138 element of one of the trunk appendages (posterior thoracopods, "pereiopods").

139 The posterior trunk (pleon) is incompletely preserved and an isolated piece is interpreted
140 as the tergite of pleon segment 3. It is domed and the latero-posterior edges are drawn out into
141 distinct spines. Medially along the posterior rim a posteriorly pointing spine is apparent.

142 The next posterior preserved piece resembles the tergite of pleon segment 3 in overall
143 morphology and is interpreted as the tergite of pleon segment 5. It is slightly larger than the
144 tergite of pleon segment 3, also the spines are more pronounced.

145 Articulated to pleon segment 5 is an elongated part posteriorly extending into a more or
146 less triangular structure. This is interpreted as a compound part of pleon segment 6 and the
147 telson, hence a pleotelson. The posterior part of the pleon segment is partly twisted, and folded
148 onto itself. Still the triangular outline (in dorsal view) of the telson is apparent. The posterior rim
149 bears a prominent median spine (Fig. 2B). Left and right to it numerous hair-like structures are
150 apparent. It remains unclear whether these are jointed (true setae) or not (trichomes). The latero-
151 posterior corners are drawn out into elongate distally tapering spines. Close to the base of each
152 large spine, on its median side, slightly laterally from the hair-like structures is a smaller spine,
153 about the same length as the hair-like structures but more massive.

154

155 *Specimen 2 (SMNS 70353/2)*

156 In comparison to specimen 1, specimen 2 is clearly identified as an isolated telson (Fig. 3A-D). It
157 strongly resembles the posterior part of the pleotelson of specimen 1, but is not twisted and
158 therefore provides additional structural information. The overall size is similar to that of
159 specimen 1. The outline is strongly triangular in dorsal view. The anterior edges, most likely
160 marking the transition to pleon segment 6 are marked by a pair of laterally extending small
161 spines (Fig. 3A).

162 Postero-lateral edges are drawn out into massive spines, forming a shallow angle. The
163 number of hair-like structures along the posterior rim is 13 per side (Fig. 3D). They are all
164 roughly the same length and the distances between them appear evenly distributed.

165 Remains of the uropods appear to be preserved left and right to the telson (Fig. 3B, C).
166 Most likely these remains represent the outer, stronger sclerotised edges of the exopods. One
167 small spine appears to be preserved close to the distal end on the posterior surface of the exopod.

168

169 *Specimen 3 (SMNS 70353/3)*

170 This specimen strongly resembles specimen 2 and is therefore also interpreted as an isolated
171 telson (Fig. 3E-G). Size, general morphology and number of structures are all similar to
172 specimen 2. Yet, it is not as complete; for example, the posterior edge right to the median spine
173 is broken. It differs from specimen 2 only in the angle of the posterior spines. These form a much
174 narrower angle, as they point less far laterally, but more posteriorly.

175

176

177 **Discussion**

178

179 *Systematic interpretation*

180 The specimens are considered conspecific, but differ in the angle between the postero-lateral
181 spines. As all specimens have a similar overall size of the telson region (Fig. 1), it seems unlikely
182 that this difference is an ontogenetic one indicating the presence of several instars. By comparison
183 to modern forms it seems most likely that the spines originally had a certain flexibility and that
184 the difference in angle reflects a preservational difference. We therefore see no possibility to

185 diagnose different forms and see conspecificity as the most parsimonious explanation.

186 The overall morphology of the specimens indicates that they represent larval
187 malacostracans. An important character in this aspect is the pronounced middle spine of the
188 posterior edge of the telson. In adult malacostracans the telson is often elongate triangular in
189 dorsal view, but with the tip pointing posteriorly, or rectangular to square-shaped in dorsal view.
190 In many larval forms, for example, in decapods, the telson appears forked with a pronounced
191 median indent or, similar to the adults, rectangular, with an evenly armed posterior edge (Martin
192 et al. 2014). Forward pointing triangular to trapezoid/trapezium telson shapes with a pronounced
193 median spine occur in modern forms only in larvae of nephropid or axiidean lobsters (Fig. 4).
194 The latter seem to lack tergo-pleura drawn out into posteriorly pointing spines on the pleon (Dos
195 Santos & González-Gordillo 2004; Pohle & Santana 2014). As such spines are present in one of
196 the fossils and in modern nephropid lobsters (Jorgensen 1925; Wear 1976; Smith 1987; Goy
197 2014), the fossil larvae most likely represent larvae of clawed lobsters, i.e., nephropids or now
198 extinct relatives of them.

199

200 The difficulties with 'clawed lobsters'

201 Modern clawed lobsters comprise the true lobsters and the reef lobsters, yet quite a number of
202 fossil forms also resembles clawed lobsters, such as erymid or glypheid lobsters, in general
203 habitus (e.g., Garassino & Schweigert 2006; Charbonnier et al. 2013, 2015; Bracken-Grissom et
204 al. 2014; Hyžný et al. 2015; Schweitzer et al. 2016). The exact relationship of these groups
205 remains still partly unclear (see recent discussions in Charbonnier et al. 2015 and Hyžný et al.
206 2015). As also axiidean lobster larvae possess a pronounced median spine on the posterior edge
207 of the telson it is possible that this feature characterises a larger group including erymid and
208 glypheid lobsters. Therefore, we can currently not be more precise with the systematic
209 interpretation of the larvae described herein. They may represent larval forms of nephropid,
210 erymid or glypheid lobsters or a form closely related to them.

211

212 Functional comparison

213 The telson of the new fossil larvae clearly shows adaptations to a prolonged life in the pelagic
214 realm. Such a life style requires morphological specialisations for staying in the water column
215 without losing much energy, which means that the buoyancy needs to be enhanced (e.g., Perrier
216 et al. 2015). This is especially important if the larvae reach relatively large body sizes such as the
217 specimens investigated here (although they are not as large as those of polychelidan or achelatan
218 lobsters).

219 The investigated specimens bear pronounced latero-posterior spines on the telson, with
220 this distantly resembling the telson of larvae of *Nephrops norvegicus* (scampi). Here also the
221 latero-posterior corners of the telson are strongly drawn out into spines, even more than in the
222 fossils (Fig. 4). As other nephropids, *N. norvegicus* larvae also possess a median spine on the
223 posterior edge. The telson of *N. norvegicus* larvae is also triangular in dorsal view, yet not as
224 pronounced as in other nephropids (Jorgensen 1925; Smith 1987).

225 The overall morphology of the telson of the fossils additionally shows an overall
226 similarity to the larvae of certain false sand crabs (Albuneidae; e.g. Knight 1970; Stuck &
227 Truesdale 1986; Harvey et al. 2014), besides the fact that these lack the median spine (Figs. 4, 5).
228 Still the overall shape is triangular, the corners are drawn out into spines and the posterior edge is
229 armed. We can assume that the specialised telson of the fossil larvae provided additional
230 buoyancy for the rather large larvae, similar to albuneid larvae.

231

232 Significance

233 The fossil record of arthropod zooplankton appears to be very incomplete (Perrier et al. 2015). In
234 general, the overall reconstruction of fossil zooplankton seems based largely on estimations, as
235 especially the microplankton is in focus of different studies, while the mesoplankton is usually
236 less studied. Larvae are in such approaches rarely treated in detail (Rigby & Milsom 2000), and,
237 although the fossil record of malacostracan larvae is growing, it appears to be generally regarded
238 as virtually absent (see recent review of Perrier et al. 2015)

239 Yet, arthropods do play an important role in the modern plankton, especially the larval
240 stages of malacostracans. As pointed out above, clawed lobsters and their relatives, i.e.
241 nephropid, erymid and glypheid lobsters represent an important part of the marine benthic fauna
242 in the Mesozoic. We should therefore expect that their larvae are a major share of the plankton of
243 that time. Finding such larvae is thus important for corroborating this assumption.

244 As discussed above, the newly described specimens show adaptations for prolonged life
245 in the plankton and therefore will represent the upper threshold of size for such larvae. Other
246 larvae of clawed lobsters will be significantly smaller. The larvae furthermore most likely
247 represent only a single specialised form of a wider range of different types of larvae. It has been
248 demonstrated that zoea-type larvae of achelatan lobsters were morphologically more diverse than
249 the larvae of modern forms (Haug et al. 2013a). We can expect that clawed lobster larvae also
250 were morphologically more diverse, possibly similarly diverse to larvae of modern meiruan
251 forms.

252 The fossils demonstrate that it is possible to find such important components of the
253 plankton and also give an important hint what to look for. Haug et al. (2011a) suggested that
254 some incomplete remains represent isolated shields of larvae, as these might have had a higher
255 preservation potential. The fossils described herein show that quite the other end of such a larva,
256 the telson, might also have high preservation potential. Focused search for such remains should
257 provide additional insights into the plankton composition of the past.

258

259

260 **Acknowledgements**

261 We would like to thank Roger Frattigani, Laichingen for providing the specimens. Gideon T.
262 Haug,

263 Neuried photographed the specimens, for which we are very grateful. Laure Corbari, MNHN
264 Paris, kindly provided access to the extant crustacean collections. Kenneth De Baets, Erlangen, is
265 thanked for helpful comments and for editorially handling the manuscript. Vincent Perrier, Lyon,
266 Carrie Schweitzer, Kent, and Matúš Hyžný, Bratislava, are heartily thanked for their comments.
267 J. Matthias Starck, München is thanked for support and discussions. We thank all people
268 providing free and low-cost software.
