**Background.** Resilience of midsole material and the upper structure of the shoe are conceptual characteristics that can interfere in running biomechanics patterns. Artificial intelligence techniques can capture features from the entire waveform, adding new perspective for biomechanical analysis. This study tested the influence of shoe midsole resilience and upper structure on running kinematics and kinetics of non-professional runners by using feature selection, information gain, and artificial neural network analysis.

**Methods.** Twenty-seven experienced male runners ( $63 \pm 44$  km/week run) ran in four-shoe design that combined two resilience-cushioning materials (low and high) and two uppers (minimalist and structured). Kinematic data was acquired by 6 infrared cameras at 300 Hz, and ground reaction forces were acquired by 2 force plates at 1200 Hz. We conducted a Machine Learning analysis to identify features from the complete kinematic and kinetic time series and from 42 discrete variables that had better discriminate the four shoes studied. And for that, we built an input data matrix of dimensions 1080 (10 trials x 4 shoes x 27 subjects) x 1254 (3 joints x 3 planes of movement x 101 data points + 3 vectors forces x 101 data points + 42 discrete calculated kinetic and kinematic features).

**Results.** The applied feature selection by information gain and artificial neural networks successfully differentiated the two resilience materials using 200(16%) biomechanical variables with an accuracy of 84.8% by detecting alterations of running biomechanics, and the two upper structures with an accuracy of 93.9%.

**Discussion.** The discrimination of midsole resilience resulted in lower accuracy levels than did the discrimination of the shoe uppers. In both cases, the ground reaction forces were among the 25 most relevant features. The resilience of the cushioning material caused significant effects on initial heel impact, while the effects of different uppers were distributed along the stance phase of running. Biomechanical changes due to shoe midsole resilience seemed to be subject-dependent, while those due to upper structure seemed to be subject-independent.

15 **Abstract**

16 **Background.** Resilience of midsole material and the upper structure of the shoe are conceptual  
 17 characteristics that can interfere in running biomechanics patterns. Artificial intelligence  
 18 techniques can capture features from the entire waveform, adding new perspective for  
 19 biomechanical analysis. This study tested the influence of shoe midsole resilience and upper  
 20 structure on running kinematics and kinetics of non-professional runners by using feature  
 21 selection, information gain, and artificial neural network analysis.

22 **Methods.** Twenty-seven experienced male runners ( $63 \pm 44$  km/week run) ran in four-shoe  
 23 design that combined two resilience-cushioning materials (low and high) and two uppers  
 24 (minimalist and structured). Kinematic data was acquired by 6 infrared cameras at 300 Hz, and  
 25 ground reaction forces were acquired by 2 force plates at 1200 Hz. We conducted a Machine  
 26 Learning analysis to identify features from the complete kinematic and kinetic time series and  
 27 from 42 discrete variables that had better discriminate the four shoes studied. And for that, we  
 28 built an input data matrix of dimensions 1080 (10 trials x 4 shoes x 27 subjects) x 1254 (3 joints  
 29 x 3 planes of movement x 101 data points + 3 vectors forces x 101 data points + 42 discrete  
 30 calculated kinetic and kinematic features).

31 **Results.** The applied feature selection by information gain and artificial neural networks  
 32 successfully differentiated the two resilience materials using 200(16%) biomechanical variables  
 33 with an accuracy of 84.8% by detecting alterations of running biomechanics, and the two upper  
 34 structures with an accuracy of 93.9%.

35 **Discussion.** The discrimination of midsole resilience resulted in lower accuracy levels than did  
 36 the discrimination of the shoe uppers. In both cases, the ground reaction forces were among

37 the 25 most relevant features. The resilience of the cushioning material caused significant  
 38 effects on initial heel impact, while the effects of different uppers were distributed along the  
 39 stance phase of running. Biomechanical changes due to shoe midsole resilience seemed to be  
 40 subject-dependent, while those due to upper structure seemed to be subject-independent.

# 41 Introduction

42 Sports shoes have many roles in running; among them, providing adequate impact-force  
 43 absorption [1, 2], stability for foot/ankle movements [3] and comfort [4]. These roles have been  
 44 the most studied in running and shoe biomechanics so far. Running shoes are basically  
 45 constituted by upper, midsole and sole. Among different possible combinations of these three  
 46 elements in the shoe construction, the upper is definitely the one more subject to variations in  
 47 its construction, such as color, model design, added elements and materials, and certainly, the  
 48 last two factors will have a particular influence on running biomechanics. Runners select a  
 49 comfortable running shoe using their own comfort criteria [5] and, because the shoe upper  
 50 maintains a large contact area with the foot, it would have a stronger influence over fit and  
 51 comfort, which in turn would impact in runner's kinematic and kinetic strategies during practice  
 52 and competitions. It has been demonstrated that a firmer foot contact with a shoe resulted in  
 53 lower loading rates due to a better coupling of foot-footwear, which optimizes the use of the  
 54 midsole impact absorption technology by favoring a better foot positioning inside the shoe [6].  
 55 Investigate the isolated influence of upper types in running biomechanics would contribute to a  
 56 more comprehensive and efficient approach in the shoe construction process.

57 Nevertheless, the most manipulated and studied shoe part in biomechanics is still the  
 58 midsole [7-10]. The majority of shoe companies invests a large amount of time, effort and  
 59 money development of damping materials technologies, such as gels, air, and springs for  
 60 supposedly improving sports performance. The midsole hardness is the most explored physical  
 61 characteristic of the midsole in biomechanical studies [1, 7, 10-13]. Running with hard shoes  
 62 resulted in same peak magnitude vertical GRF as running with soft ones [1, 12, 14] and faster

time to achieve the first peak [1]. Therefore, midsole hardness affected the loading rate but not in a proportional rate [7]. Most of running kinematic changes due to the midsole hardness occurs at the ankle joint [1, 10, 15] and some authors state that these different midsole hardness lead to different impact perception by runners [7, 11], which in turn causes distinct alteration on running mechanics [12, 13] and may mislead the real impact damping by shoe midsoles [7, 11].

Apart from midsole hardness, resilience is also an important mechanical property of midsole that has been seldom studied [8, 16, 17]. It represents the energy restored by the cushioning material after an applied force ceases. Managing resilience while maintaining the hardness of a polymeric foam is possible by adding different kinds of compounds to its formula. Ethylene-vinyl acetate (EVA) added to elastomers could have ideal softness and high resilience characteristics, would have a full-recovery capacity for the next foot step after a heel strike, while a less resilient (more viscous) material would have the capacity of attenuating more energies at initial loading cycles, easily achieving compression flattening after some cycles. It is expected that different resilience materials would mainly reflect different initial impact forces, because more resilient materials will quickly restore the cushioning property while less resilient materials will take a little longer to restore the cushioning property [18]. Sinclair et al. [16] have shown that running with shoes with energy return component resulted in greater tibial acceleration peak, calcaneous eversion and internal tibia rotation compared to conventional running shoes. In a later study, they have shown lower oxygen consumption and respiratory exchange ratio with more resilient model of shoes [17]. Worobets et al. [8] manipulated only the midsole materials, maintaining the upper structure, and also reported lower oxygen

consumption when running with a more compliant/resilient midsole condition. However, the isolated effect of resilience changing in shoe midsole is still unknown in running biomechanics.

The majority of biomechanics studies vary the shoe model as a whole to investigate the effects of various structural shoe properties and elements while running [19-22]. Such an approach deeply interferes with an appropriate differentiation and interpretation of which shoe characteristics most influence the kinetic and kinematic changes during running. Identifying more precisely which shoe characteristics really matter for impact attenuation and kinematic adaptation would facilitate the development of more effective products for athletes.

Nonetheless, individual's mechanical and neuromuscular adaptations to changes in shoes are influenced by mechanical, neurophysiological, anatomical and even psychological factors and, therefore, is likely to observed different individuals using different strategies in response to changes in running shoes [9, 12]. Thereby, one may conclude that regardless the type of shoe modification, the biomechanical responses observed may be subject-dependent.

We proposed to identify the most relevant biomechanical features to differentiate two different midsole resiliencies and upper structures of shoes during running using an entirely supervised approach based on machine learning (ML). This approach has been used to identify crucial features and relevant patterns for classifying and predicting locomotor patterns in a given condition [23-25]. Our strategy consisted of using Information Gain (IG) to select important features and Artificial Neural Networks (ANN) to classify and predict the different shoe resiliencies and upper types. Our assumptions were: (h1) low versus high resilient cushioning effects on running kinematics and ground reaction forces are classifiable by using a ML approach, (h2) structured versus minimalist upper effects on running kinematics and

ground reaction forces are classifiable by using a ML approach, and (h3) there are biomechanical changes due to shoe midsole resilience or upper structure that are subject-independent.

## Methods

### *Subjects*

Twenty-seven experienced non-professional male runners ( $36.0 \pm 7.3$  years old,  $1.72 \pm 0.05$  m,  $73.9 \pm 6.2$  kg,  $62.9 \pm 43.8$  km/week run,  $7.5 \pm 7.1$  years of practice) with a rearfoot strike pattern and with no experience in minimalist shoe participated in this study. All runners were free of injury or musculoskeletal pain according to the definition of Macera et al. [26]; had no major foot or ankle postural alterations or deformities, excessive static pronation or supination of the foot and ankle complex according to the Foot Posture Index [27]; and did not present leg length discrepancy greater than 1cm. All subjects agreed to participate in the study approved by the Ethics Committee of the School of Medicine of the University of Sao Paulo (Ethical Application CEP-FMUSP: Protocol #054/14) and signed a written consent form.

### *Tested running shoes*

Four running shoes were especially developed by a local sportive shoe manufacturer. The final masses of the 4 constructions were equivalent to avoid negative effects due to mass differences [28]. All shoes were constructed using the same last, the same design of upper pieces, midsole geometry, and outsole. The hardness of cushioning materials was fixed at 40

Asker C, measured by a durometer (GoTechAskerC, Taichung, Taiwan). The two shoe uppers had the same design and shape, but the different structure and materials:

(1) **SU - structured upper**: 15 mm of soft foam in the heel collar and tongue, hard heel cup involving the medial, lateral and posterior parts of the heel, synthetic pieces sewed in the vamp and doubled fabric over the whole shoe (Figure 1A).

(2) **MU - minimalist upper**: light-weight mesh, tongue without foam, without heel cup, and almost all pieces of the upper were connected by means of heat fusion (Figure 1B).

Both cushioning materials were made of ethylene-vinyl acetate (EVA); were inserted in the same rearfoot area within the midsole; and had an oval shape of 10mm thickness, 50mm width, and 70mm length. Resilience was assessed by vertical resiliometer (GoTech GT7042-V1, Taichung, Taiwan). The midsoles were: (1) **LR - low resilience** - 5% of resilience (+/- 3%) (Figure 1C), and (2) **HR - high resilience** - 55% of resilience (+/- 3%) (Figure 1D).

# Figure 1

The first tested condition (condition 1 - upper SU and cushioning material LR) was the same for all runners; the other three testing conditions were randomized for each subject using simple draw. The other three conditions were: condition 2 - upper SU and cushioning material HR, condition 3 - upper MU and cushioning material LR, and condition 4 - upper MU and cushioning material HR. The subjects were asked to lace their shoes tightly and comfortably, in the same way they typically lace during their running practice.

## Experimental protocol

Kinematic data were acquired by six infrared cameras (VICON T-40, Oxford, UK). Sixteen passive-reflexive markers (14 mm diameter) were fixed on both lower limbs (two anterior superior iliac spines; two posterior iliac spines; two lateral epicondyles of the knees; two markers over the lower lateral 1/3 surface of the thighs; two lateral malleolus; two markers over the lower 1/3 of the shank; two second metatarsal heads; two posterior surface of calcaneus at the same height above the plantar surface of the foot as the toes markers) according to Plug'n Gait marker set, [29]. The two foot markers were fixed on the shoes (second metatarsal heads and calcaneus) after deep palpation of bone prominences. The laboratory coordinate system was established at one corner of one force plate, and all initial calculations were based on this global coordinate system. In Nexus software (Vicon Nexus 1.7, Oxford, UK), each data sample from each lower limb segment (foot, shank, and thigh) was modeled as a rigid body with a local coordinate system that coincided with anatomical axes. Translations and rotations of each segment were reported relative to neutral positions defined during the static standing trial.

The program calculates the joint angles by means of a decomposition matrix based on Cardan sequences and six degrees of freedom model. The decomposition matrix describes the relationship between two local coordinate systems, one for each segment between which the relative angle is determined. The joint kinematics was considered as the movement of the distal segment in relation to the proximal; e.g. for determining the knee angle, the thigh was the proximal segment and the shank the distal one. The movements occur around 3 different axes which describe two definition of movement each: flexion/extension, abduction/adduction, and internal/external rotation [30].

Ground reaction forces were acquired at 1200 Hz by two force plates (AMTI BP600600, Watertown, USA) embedded in the center of a 25 m walkway. Acquisitions of kinematic and force data were synchronized by a 64 multichannel Vicon MX Giganet Lab and A/D converter.

Running velocity was kept between 9.5 to 10.5 km/h (mean  $10.1 \pm 0.5$  km/h), monitored by 2 photoelectrical sensors (Tecsistel Speed View, Novo Hamburgo, Brazil). Ten trials per subject for each shoe condition were collected, resulting in 40 trials on the dominant limb. The limb dominance was defined as the leg used to kick a soccer ball [31].

### ***Biomechanical data analysis***

The marker coordinates were filtered using a 12 Hz zero-lag fourth-order low-pass Butterworth filter. Force data was filtered with a 300 Hz zero-lag fourth-order low-pass Butterworth filter. The angular and force data from initial contact to take-off were normalized in stance time (interpolated 0-100%) and in magnitude by the body weight.

The 30 discrete kinematic features analyzed were: peak angles (degrees), angles at the beginning of stance phase (degrees), instant of peak angle (seconds), range of motion from the beginning of stance phase to peak angle (degrees), and final angle of stance phase (degrees); for ankle, knee and hip joints; for sagittal and frontal planes of movement (5x3x2).

For vertical and antero-posterior forces, the magnitude of first vertical force peak (1VFP) (body weight), time of 1VFP (milliseconds), magnitude of second vertical force peak (2VFP)(body weight), time of 2VFP (milliseconds), loading rate (slope of 20% to 80% of 1VFP) (body weight/ second), time of minimal vertical force in midstance (milliseconds), propulsion rate (slope of curve between minimal vertical force in midstance and the 2VFP) (body weight/

second), minimum breaking antero-posterior force (body weight), breaking antero-posterior impulse, median frequency of 1VFP (Hz), time of stance phase (milliseconds), and decay rate (slope of curve from 2VFP to the end of stance phase) (body weight/ second) were calculated.

The whole interpolated time-series of all three planes of motion (sagittal, frontal and transversal) and forces (vertical, antero-posterior and medio-lateral) were also analyzed. Usually, there are high-dimensional and redundant datasets in cross-sectional studies that investigated shoe effects in running biomechanics [13, 32], and therefore a careful feature selection must be conducted to minimize bias and help identifying the biomechanical parameters that is most influenced by shoe characteristics [13, 23, 32]. This was the main reason why we chose to include both discrete and whole time-series points in the analysis. As explained in the next sections, we adopted an approach based on ANN, which can receive large numbers of data simultaneously and the pieces of data do not have to be isolated from each other [33].

### ***Machine learning approach***

IG and Artificial Neural Networks (ANN) are ML techniques that have been successfully used for feature selection and classification in many areas. Whereas ANN have been used to classify patterns in biomechanics studies [24, 34-36], IG has not been explored in biomechanics. The IG is a supervised method that ranks variables individually without applying data transformations, and it has the potential to facilitate the interpretation of the influence of a single variable on the underlying discrimination process [37, 38]. IG is a methodology to select the most relevant variables in a big and redundant set of variables.

215

# 216 Input variables and feature selection by IG

217       The 3D joint angular displacement time series was vectorized to a 1254 dimensional  
218 vector (3 lower limb joints x 3 planes of angular displacement x 101 interpolated data points + 3  
219 vectors of ground reaction forces x 101 interpolated data points + 42 discrete calculated kinetic  
220 and kinematic features). An input data matrix M was then created (10 trials x 4 shoe condition x  
221 27 subjects), resulting in a matrix dimension of 1080 x 1254. The lines of M represented each  
222 subject trial in terms of 1254 variables, some of which may be more affected by specific  
223 characteristics of shoe design. In this context, finding a small subset of variables is a desired  
224 result [36], because that may indicate a more discriminative and less redundant subset of  
225 features that would improve the results of the classification.

226       To assess the effects of shoe interventions, many studies have generated high-  
227 dimensional and redundant datasets [13, 32], therefore, a variable selection stage must be  
228 carefully conducted because it plays a critical role in minimizing bias and the influence of  
229 intrinsic factors such as individual characteristics [13, 23, 32]. Frequently, redundant data  
230 imposes challenges for understanding the phenomena of interest. To overcome these  
231 challenges, approaches that capture features of the entire waveform instead of isolated  
232 parameters add new perspectives to the analysis of the complex effects that a shoe may have  
233 on a movement pattern [39]. The feature selection was conducted by analyzing the accuracy  
234 levels of variables subsets. It was not practical to test all subsets of the 1254 variables/columns  
235 available in M matrixes. We used IG to rank the variables in decreasing order of relevance. As a  
236 supervised method, IG ranks the variables according to their discriminative power in separating

subjects' trials in terms of the two target variables, i.e., low vs high resilience and minimalist versus structured upper. Diverse variables subsets were tested; they contained an increasing number of variables (25, 50, 100, 150 and 200) and bigger subsets were systematically formed by aggregating less relevant variables according to the IG criteria. This step was crucial to determine the smallest number of variables that achieved accurate discrimination of the resiliencies and upper structures. In this context, the greatest subset of variables involved in our experiments included 200 variables, since our analysis indicated that 200 variables were enough to evaluate the hypotheses of this study.

#### Classification Procedure

As a supervised classification approach, we adopted the standard k-fold-cross-validation, which divides the subject trials into folds:  $k-1$  folds for training and the remaining fold for testing. In the training set, a subset of variables was selected by using IG, their values were scaled from -1 to 1, and then an ANN learning model was trained. The classification accuracy of the resulting ANN model was then computed on the test fold. We reported results when the ANN method achieved the best classification accuracy. We used a traditional feed-forward network with a single hidden layer [40]. As it requires a parameter setting, which is still a research issue, we perform an exhaustive searching through a subset of parameters values: the number of neurons in the hidden layer was selected from the set  $\{10, \dots, 75\}$ ; the learning rate  $\in \{0.05, \dots, 0.25\}$  and the number of training cycles  $\in \{300, \dots, 1500\}$ . To reduce the risk of overfitting, we adopted the decay procedure [40], as implemented in the RapidMiner software.

We conducted the classification in two contexts:

I. a 4-fold-cross-validation for *each subject* (40 trials) to assess the existence of effects from shoes conditions, finding one accuracy value to discriminate the shoe condition for each subject and for each subset of features;

II. a standard 10-fold-cross-validation involving *all subjects'* trials to assess the existence of subject-independent changes induced by the shoes interventions, finding one accuracy value for each subset of features.

By comparing classification accuracies between the contexts I and II, it was possible to analyze the subject-dependency of the results and provisionally evaluate a pattern induced by different resilience and upper conditions. Classification accuracy of higher than 80% was considered good [23]. The machine learning procedures were conducted in the software RapidMiner (v.5.3.015, Dortmund, Germany).

## Results

All 1254 variables were involved in the experiments of resiliencies and uppers. In both cases, the accuracy of discriminating the effect of shoe conditions indicated that context I outperformed context II.

The composition of the most relevant features subsets according to IG are detailed in Tables 1 and 2 for the midsole resilience and upper structures comparisons, respectively. Although forces have been the most discriminative variables for both midsole and upper, the top 5 features for upper and resilience came from different components, respectively vertical and medio-lateral forces.

# Table 1 and 2

## *Resilience effect*

In context II, 200 variables were sufficient to distinguish midsole resiliencies with an accuracy of 84.8% (Figure 2, red line). The accuracies indicated that context I, which considers only trials of a single subject, outperformed context II for all subsets of features (Figure 2, blue line). A mean accuracy of 89.4% ( $\pm 8.3\%$ ) to classify the two resiliencies was reached by considering only the 25 most relevant features, while the best accuracy of 93.9% ( $\pm 5.0$ ) to classify the two resiliencies was reached with the 150 most relevant features.

## Figure 2

Among the 200 most relevant variables to discriminate between low and high resilience cushioning materials, six of them were discrete biomechanical variables (4 ground-reaction force variables and 2 kinematic variables) (Figure 3). The 5 most relevant variables came from medio-lateral force, between 6% and 10% of stance phase.

## Figure 3

## *Upper structure effect*

The results indicated that the upper structures effects were less complex than the cushioning materials ones. In the context II, accuracy higher than 85% was achieved by considering only 25 variables to differentiate upper structures (Figure 4, red line). As in the case of resiliencies, results on uppers shown that context I outperformed context II; it was possible

301 to obtain a mean accuracy of 93.4% ( $\pm 4.8\%$ ) with 25 variables, and 95.6% ( $\pm 3.8$ ) with 150  
302 variables (Figure 4, blue line).

303 **Figure 4**

304 Among the 200 most relevant variables to discriminate structured and minimalist  
305 uppers 11 of them came from the discrete biomechanical variables (9 force variables and 2  
306 kinematic variables) (Figure 5). The 5 most relevant variables to discriminate between uppers  
307 were vertical forces from 11% to 14% of stance phase and the first peak.

308 **Figure 5**

## 309 Discussion

310 We proposed an entirely supervised approach based on ANN to distinguish the effects  
311 of different midsole resiliencies and upper structures of shoes on running biomechanics. The  
312 results confirmed our first and second hypotheses because the effects on running kinematics  
313 and kinetics caused by low and high resilient cushioning midsoles and structured and minimalist  
314 uppers were separable and classifiable by the adopted ML approach. IG was efficient in  
315 selecting important features, as was confirmed by the proportionally slower increase in  
316 classification accuracy with respect to increasing numbers of input features (Figure 4). The top  
317 features in the IG rank may be considered the most responsible for distinguishing the effects of  
318 the upper structures and midsole resiliencies.

319 When analyzing all subjects together, the methodology successfully differentiated the  
320 two resiliencies with 84.8% accuracy using 200 variables and the two shoe uppers with 85.3%

accuracy using 25 variables, which is higher than the classification rate threshold of 80% chosen by Hoerzer et al. [23]. Intra-subject analysis increased the classification accuracy for resiliencies to a mean of 89.4% and for uppers using just 25 variables to a mean of 93.4%. This indicated that the adopted ML analysis achieved more accuracy to identify different conditions (cushioning materials and shoe uppers) within a given subject than within the set of all subjects, which is consistent with the higher inter-subject variability.

Among the variables in the interpolated time series, the 25 most relevant features for discriminating midsole resilience were mainly forces, ankle flexion-extension, and hip rotation variables. Considering the discrete variables that differentiated the resiliencies, 4 were related to vertical force (first peak and minimal force) and 2 were related to ankle kinematics (dorsiflexion and eversion). Resilience causes significant effects on the initial impact of the heel with the ground while running. The cushioning materials were inserted only under the heel part of the shoe; considering we focused our study on rearfoot strikers, it was acceptable that the resilience especially influenced the variables related to this first part of the stance phase. However, resilience probably did not affect only this part of the stance for all runners.

The 200 most relevant features that discriminated the two resiliencies were distributed in short time windows spread over all cycle periods of the kinematic and kinetic time series. This does not mean, however, that these 200 features were equally relevant for all 27 subjects. These short and sparse windows corresponded to individual patterns of biomechanical responses, or a group of individuals with the same biomechanical responses, which leads us to refute part of the third hypothesis and conclude that changes due to shoe midsole resilience seemed to be subject-dependent. This means that is possible to discriminate the two

resiliencies with a fewer number of variables and with a higher accuracy if we analyze individualized biomechanical data. In summary, each runner responded differently to resilience in the cushioning materials, changing a different pool of biomechanical variables that represent distinct motor strategies. Additionally, the most discriminative kinematic features were not found at the same time periods as the most discriminative kinetic features in the stance phase, suggesting that kinematics adjustments in the lower limbs caused by shoe changes might not be influencing impact attenuation. This differs from what Hennig et al. [11] and Milani et al. [7] suggested in their studies.

The upper structures classification had higher discriminative power than midsole resiliencies, as was reflected in the higher accuracy levels of upper structure classification. The 25 most relevant features for discriminating upper structures were composed mainly of force variables (both discrete variables and time series features) and sagittal ankle variables. From the 200 features, we found that the most relevant biomechanical variables for the classification of uppers were concentrated in the first and last third of the stance phase for all three-force components, sagittal plane of ankle, and for all planes of knee. The exceptions were for the frontal and transverse planes of the ankle, which had the central third as the most relevant part for classification. Therefore, changes in shoe uppers seem to be more subject-independent.

Eleven discrete biomechanical features were among the most relevant for classifying upper structures. Nine were force variables related to first and second vertical peaks, minimal vertical force, and breaking antero-posterior force; two were from ankle kinematics. According to the relevant discrete parameters, it seemed that force features had highest discriminative power, so were more relevant for differentiating upper structures than kinematic variables and

they were temporally distributed across the stance phase. The flexibility of the upper (due to different applied materials) could affect the flexibility of the foot inside the shoe, its own capability to absorb impact by stretching the foot arches and generate the propulsion force, so it is reasonable to assume that the force features across the entire stance phase are relevant variables for distinguishing upper differences. The differences in structure probably affect sensitivity to the ground, and consequently how runners modulate applied force to the ground. As seen by Hagen and Hennig [6], firmer foot contact with a shoe could result in lower loading rates due to a better coupling between the foot and shoe, which in turn facilitates the use of the impact-absorbing technology of the midsole.

In a training context, it would be ideal if each runner performed a biomechanical assessment of his or her running shoes. Then it would be possible to understand how this external factor (running shoe) changes (or not) each runner's particular running mechanics. Moreover, only few variables among the 1254 available (about 12% for different cushioning materials and 4% for different shoe uppers) are evidently necessary to detect alterations of running biomechanics with high accuracy ( $93.9\% \pm 5.0\%$  and  $94.3\% \pm 4.5\%$ , respectively). This result is plausible with the theory of "functional groups" [9, 23] and it is appropriate to understand particular cases. Our results showed that runners have different responses to the materials used in the shoes and a general conclusion arising from a heterogeneous sample may lead to wrong outcomes. Further studies could analyze the influence of smaller sub-groups with similar biomechanical responses to shoe characteristics. This procedure would be useful for understanding how different resilience of cushioning material affects the running mechanics for specific "types" of athletes. It was also possible to demonstrate that a biomechanical study of

sports shoes isolating characteristics to be tested provided more specificity in the comprehension of the influence each part on running biomechanics.

## Conclusion

The applied methodology based on feature selection by IG and classification by ANN successfully differentiated the high and low resilience materials and the structured and minimalist uppers with accuracies of higher than 85% using 200 features (16% of 1254 available features). The classification of upper structures presented higher accuracy levels than that of midsole resilience probably due to higher inter-individual variability, but in both cases, the forces are among the 25 most relevant features subset. The ground reaction forces are the most important features to differentiate midsole resilience and the resilience caused valuable effects on initial heel impact while running. The different patterns of biomechanical response chosen by runners to adapt to different resilience probably led to lower accuracy levels for this classification. We can therefore conclude that biomechanical changes due to shoe midsole resilience seem to be subject-dependent and changes due to upper structure seem to be subject-independent.

## Acknowledgements

We would like to thank Dass Nordeste Calçados e Artigos Esportivos Inc. for supplying the shoes prototypes and the laboratory used in this study, and Alexandro Rodrigo da Rosa and Jonas Schneider for designing and developing the shoes used in this study.
