Body size sexual dimorphism (SSD) is widespread among animals, with larger females usually attributed to an optimization of resources in reproduction and larger males to sexual selection. A general pattern in the evolution of SSD is Rensch's rule, which states that SSD increases with body size in species with larger males but decreases when females are larger. We studied the evolution of SSD in the genus *Limnebius* (Coleoptera, Hydraenidae), measuring SSD and male genital size and complexity of ca. 80% of its 150 species and reconstructing its evolution in a molecular phylogeny with 71 species. We found strong support for a higher evolutionary lability of male body size, which had an overall positive allometry with respect to females and higher evolutionary rates measured over the individual branches of the phylogeny. Increases in SSD were associated to increases in body size, but there were some exceptions with an increase associated to changes in only one sex. Male secondary sexual characters appeared several times independently, generally on species that had already increased their size. There was an overall significant correlation between SSD and male genital size and complexity, although some lineages with complex genitalia had low SSD, and some small species with complex genitalia had no SSD. Our results suggest that the origin of the higher evolutionary variance of male body size may be due to lack of constraints rather than to sexual selection, that may start to act in species with already larger males due to random variation.

16

17

18 **Abstract**

19 Body size sexual dimorphism (SSD) is widespread among animals, with larger females usually  
20 attributed to an optimization of resources in reproduction and larger males to sexual selection. A  
21 general pattern in the evolution of SSD is Rensch's rule, which states that SSD increases with  
22 body size in species with larger males but decreases when females are larger. We studied the  
23 evolution of SSD in the genus *Limnebius* (Coleoptera, Hydraenidae), measuring SSD and male  
24 genital size and complexity of ca. 80% of its 150 species and reconstructing its evolution in a  
25 molecular phylogeny with 71 species. We found strong support for a higher evolutionary lability  
26 of male body size, which had an overall positive allometry with respect to females and higher  
27 evolutionary rates measured over the individual branches of the phylogeny. Increases in SSD  
28 were associated to increases in body size, but there were some exceptions with an increase  
29 associated to changes in only one sex. Male secondary sexual characters appeared several times  
30 independently, generally on species that had already increased their size. There was an overall  
31 significant correlation between SSD and male genital size and complexity, although some  
32 lineages with complex genitalia had low SSD, and some small species with complex genitalia  
33 had no SSD. Our results suggest that the origin of the higher evolutionary variance of male body  
34 size may be due to lack of constraints rather than to sexual selection, that may start to act in  
35 species with already larger males due to random variation.

## 41 INTRODUCTION

42 Sexual size dimorphism (SSD) is highly variable among animal species, from minuscule males  
43 with comparatively giant females to males much larger than females (Darwin, 1871; Hedrick &  
44 Temeles, 1989; Fairbairn, 1997; Vollrath, 1998). In most insect species females are larger than  
45 males (Darwin, 1871; Arak, 1988; Shine, 1988; Fairbairn, 1997), a fact usually explained  
46 because the energetic investment in the progeny is larger in females than in males, which mostly  
47 provide just genetic information. For this reason, population fertility depends more on females  
48 than on males, so females should be as big and males as small as possible, to minimise resources  
49 spend on their maintenance (Darwin, 1871; Thornhill & Alcock 1983; but see Shine, 1988 for  
50 some alternative views).

51         Although some species have reached this "optimum" state of minimised males, in the  
52 absence of selection both sexes will tend to have the same size, given the strong genetic  
53 correlation between sexes for most traits (Lande, 1980). However, rapid changes in SSD can  
54 occur even when selection pressure is small (Reeve & Fairbairn, 2001), which begs the question  
55 not why sexual dimorphism exist, but why are there so many species in which males are about  
56 the same size or bigger than females. One reason could be ecological (Slatkin, 1984; Shine,  
57 1989; Musterud, 2000): when sexes have widely different sizes, they may not be able to share the  
58 same ecological niche. This may be an advantage in avoiding intraspecific competition, but there  
59 is little evidence that SSD may have originated primarily through ecological divergence in any  
60 group (Fairbairn, 1997). There could also be social reasons, if males contribute to raising the  
61 progeny either by protecting females or providing resources, thus equalizing the investment of  
62 the two sexes. An alternative explanation is sexual selection: larger males may have an  
63 advantage, either because they can gain better access to females (male-male competition), or  
64 because females prefer them (female choice). In the first case, differences may affect the size of  
65 the body or other structures used for male-male competition; in the second there may be other  
66 characters involved, especially genital characters when there is cryptic female choice (Eberhard,  
67 1985; Kuijper et al., 2012).

68         Despite the large body of work on sexual dimorphism, there is still a lack of  
69 understanding of its long-term evolution in diverse lineages, particularly among invertebrates  
70 (Fairbairn, 1997). There are a number of unresolved questions on the origin and evolution of  
71 sexual dimorphism that can be addressed with a phylogenetic reconstruction in speciose lineages

72 with a diversity of male genital and body sizes. One of the few recognised general trends in the  
73 evolution of SSD is the so-called Rensch's rule (Abouheif & Fairbairn, 1997; Fairbairn, 1997;  
74 Székely et al., 2004). Rensch (1950) observed that sexual differences increased with body size in  
75 species where males were larger, but decreased in species where females were larger. This  
76 implies that male body size varies more over evolutionary time than female body size,  
77 irrespective of which sex is larger (Fairbairn, 1997). Fairbairn & Preziosi (1994) hypothesized  
78 that sexual selection for large male size may be the primary force driving Rensch's rule, a  
79 hypothesis supported by the observation of Rensch's rule in sexually selected characters other  
80 than size, such as male pigmentation (Santos & Machado, 2016). An alternative possibility is  
81 that males have a larger evolutionary plasticity, somehow equivalent to a larger intraspecific  
82 phenotypic plasticity (Fairbairn, 2005; Gómez-Mestre & Jovani, 2013).

83 Data supporting Rensch's rule is mostly intraspecific or from closely related small species  
84 groups (Abouheif & Fairbairn, 1997; Fairbairn, 1997; Székely et al. 2000; Kraushaar &  
85 Blanckenhorn, 2002), with only few global studies of diverse lineages, and mostly among  
86 vertebrates (e.g. Lindenfors et al., 2003; Székely et al., 2004). In two reviews of Rensch's rule  
87 support in some groups of arthropods, Blanckenhorn et al. (2007a,b) found strong support in  
88 some groups (some Diptera and Hemiptera Gerridae), which show negative allometry in plots of  
89 females vs. males; while in others there was isometry (e.g. some beetles and hymenopterans) or  
90 only weak tendencies (butterflies and spiders). Rensch's rule was mostly supported in groups  
91 with males larger than females, something unusual in ectotherms (contrary to mammals and  
92 birds, Fairbairn, 1997), and there was little evidence to support its prevalence at the intraspecific  
93 level (see also Martin et al., 2016).

94 In this work we reconstruct the macroevolutionary patterns of SSD evolution in a diverse  
95 lineage of insects with the aim to investigate the origin and evolution of body size differences,  
96 and to determine the underlying causes of Rensch's rule over long evolutionary periods. We  
97 particularly focus on the relationship between SSD and evolutionary changes in body size of  
98 males and females, and whether SSD is linked to size variation in both sexes or can appear  
99 through changes in one sex only (Fairbairn, 1997). We also study the correlation of SSD with  
100 other characters of the male genitalia, such as size and complexity.

101 As a study group we use a diverse and ancient lineage of beetles, the genus *Limnebius*  
102 (family Hydraenidae). *Limnebius* includes ca. 150 species with an almost cosmopolitan

103 distribution, all of them aquatic, living in all types of continental waters with the only exception  
104 of saline habitats (Perkins, 1980; Jäch, 1993; Hansen, 1998; Rudoy et al., 2016). In a recent  
105 work, *Limnebius* was shown to be divided in two sister lineages with an estimated Oligocene  
106 origin, the subgenera *Bilimneus* and *Limnebius* s.str., with ca. 60 and 90 described species  
107 respectively (Rudoy et al., 2016). The two subgenera differ in a number of traits, including  
108 variation in body size and in the size and complexity of the male genitalia, much larger in  
109 *Limnebius* s.str. (Rudoy et al., 2016; Rudoy & Ribera, 2016). They also differ in sexual  
110 dimorphism and the presence of secondary sexual characters (SSC). In *Bilimneus* females are  
111 slightly larger than males, which do not have strongly developed SSC; on the contrary, within  
112 *Limnebius* s.str. there are a wide range of different situations, including males much larger than  
113 females and with well developed SSC (Jäch, 1993; Rudoy & Ribera, 2016), providing thus a  
114 suitable system for the study of the origin and evolution of SSD.

115

## 116 MATERIAL AND METHODS

### 117 Taxon sampling

118 We obtained morphological data of the males of 120 and the females of 86 of the ca. 150  
119 described species of *Limnebius*, among them four undescribed species (Table S1). Females were  
120 identified mostly by association with males, as there are few characters that could identify them  
121 unequivocally (Perkins, 1980; Jäch, 1993), but in some species this was not possible as several  
122 species of similar size could coexist in the same locality. In some cases very few specimens of  
123 some of the sexes could be studied (Table S1). In some species with a low number of specimens  
124 (e.g. *L. paranuristanus*, *L. angustulus* or *L. fontinalis*; see Table S1 for the taxonomic  
125 classification of the genus) the SSD was very similar to that of the most closely related species  
126 with enough data, but in other cases (e.g. *L. canariensis*) the few specimens that could be  
127 obtained differ in SSD from related species, but there is the possibility that the measured  
128 specimens were not representative.

129

### 130 Morphometric measurements

131 We measured body length of adults (males, *lm* and females, *lf*) as the sum of the individual  
132 maximum lengths of pronotum and elytra, as the different position of the articulation between  
133 the two could alter the total length when measured together. Similarly, the head was not

134 measured, as in many specimens it was partly concealed below the pronotum. Measures were  
135 obtained with stereoscope microscopes equipped with an ocular micrometer.

136 Measures of the genitalia were obtained from Rudoy & Ribera (2016). Briefly, male  
137 genitalia (aedeagi) were dissected and mounted on transparent labels with dimethyl hydantoin  
138 formaldehyde (DMHF). For size measurements we used as a single value the average of each  
139 measure in all studied specimens of the same species (Table S1). For shape characterisation a  
140 single specimen was used as species show in general a very constant shape of the aedeagus, with  
141 very low intraspecific variability as compared with the marked differences between species  
142 (Jäch, 1993; Rudoy et al., 2016). We measured the maximum length of the male genitalia (*lg*)  
143 orientated in ventral view according to the foramen. We did not include setae or apical  
144 membranous structures but included appendages when they were longer than the median lobe (as  
145 in e.g. some species of the *L. nitidus* group, Rudoy et al., 2016). Measurements were directly  
146 obtained from the digital images using ImageJ v.1.49 (National Institutes of Health, US,  
147 <http://imagej.nih.gov/ij/>) (Fig. S1).

148 We used two different measures to characterise the complexity of the aedeagus, following  
149 Ribera & Rudoy (2016): (1) Perimeter (*per*) of the aedeagus in ventral view, including the  
150 median lobe and the main appendages. We obtained an outline of the genitalia from digital  
151 images using ImageJ. The total perimeter was the sum of the values of the different parts of the  
152 genitalia (median lobe and left parameter, plus main appendages if present, see Rudoy et al.,  
153 2016). We standardised the values by dividing the perimeter by the length of the aedeagus, to  
154 obtain a measure of complexity by unit of length (Fig. S1; Table S1).

155 (2) Fractal dimension (*fd*). We estimated the fractal dimension of the outline of the  
156 aedeagus in ventral view on images of standard size (2100x2100 pixels, 2000 pixels from base to  
157 apex of the aedeagus) with the software Fractal Dimension Estimator ([http://www.fractal-](http://www.fractal-lab.org/index.html)  
158 [lab.org/index.html](http://www.fractal-lab.org/index.html)). This software estimates the Minkowski fractal dimension of bidimensional  
159 images using the box-counting method (Falconer, 1990). The software converts the image to  
160 binary data, selects the scaling window of the box, and counts how many boxes are necessary to  
161 cover the image. The absolute value of the slope of a log-log graph of the scale with the number  
162 of boxes is the fractal dimension of the image (Fig. S1; Table S1).

163

## 164 **Phylogenetic analyses**

165 For our analyses we use two phylogenetic reconstructions, one with the species for which there  
166 were molecular data available and a second one with all species for which there were  
167 morphological data, added to the molecular phylogeny according to their morphological  
168 similarities.

169 The molecular phylogeny was based on that obtained in Rudoy et al. (2016) and Rudoy &  
170 Ribera (2016), including 71 species of *Limnebius* (Table S2). Taxon sampling was denser for the  
171 Palearctic lineages in subgenus *Limnebius* s.str., including the full range of body sizes and  
172 structural variation of the aedeagus. We used as outgroup and to root the tree the genus  
173 *Laeliaena*, considered to be sister to *Limnebius* based on multiple morphological  
174 synapomorphies (Hansen, 1991; Jäch, 1995; Perkins, 1997; Beutel et al., 2003).

175 The phylogeny was constructed with Bayesian methods in BEAST 1.8 (Drummond et al.,  
176 2012) using a combined data matrix with three partitions, (1) mitochondrial protein coding genes  
177 (two *cox1* fragments plus *nad1*); (2) mitochondrial ribosomal genes (*rrnL* plus *trnL*) and (3)  
178 nuclear ribosomal genes (*SSU* plus *LSU*) (Table S2; Rudoy & Ribera, 2016), with a Yule  
179 speciation process as the tree prior and an uncorrelated relaxed clock.

180 Trees were calibrated with the rates estimated in Cieslak et al. (2014) for family  
181 Leiodidae, within the same superfamily Staphylinoidea (Beutel & Leschen, 2005) and the same  
182 gene combination based on the tectonic separation of the Sardinian plate 33 Ma. It must be noted  
183 that for our objectives only relative rates are needed. An absolute calibration would only be  
184 necessary to obtain absolute estimates of character change, which is not our main objective and  
185 does not affect our conclusions.

186 We reconstructed the ancestral values of the morphological variables using the values of  
187 the terminals (extant species) in BEAST 1.8. We implemented a Brownian movement model of  
188 evolution (BM), a null model of homogeneous evolution in which variation accumulates  
189 proportionally with time, with incremental changes drawn from a random distribution with zero  
190 mean and finite constant variance (Hunt & Raboski, 2012; Adams, 2014). The reconstruction of  
191 ancestral values using a BM model of evolution is biased toward average or intermediate values  
192 (Pagel, 1999; Finarely & Goswami, 2013), which may result in an underestimation of the rates  
193 of evolution of some characters. Due to these limitations our reconstruction needs to be  
194 understood as the simplest null model explaining the evolutionary change in the studied  
195 characters.

196 We reconstructed the origin and secondary lost of some SSC with MESQUITE v.3  
197 (Midfort et al., 2011) using parsimony. Secondary male sexual characters in the genus *Limnebius*  
198 affect mostly the tibiae and the last abdominal sternites (Jäch, 1993). In many species of  
199 *Limnebius* (but mostly in *Limnebius* s.str.) males have slightly curved and apically wider tibiae,  
200 especially in the anterior and medial legs, which also have suction setae (Jäch, 1993). However,  
201 these characters are difficult to quantify precisely and more observations are needed to establish  
202 their prevalence. The hind tibiae of males are also modified in some species of *Limnebius* s.str  
203 (Fig. S2). There are three different types of SSC in the abdominal sternites of males: (1) a more  
204 or less developed medial protuberance; (2) two parallel tufts of setae; and (3) a medial  
205 impression delimited by ridges (Jäch, 1993; Fig. S2). All of them occur mostly in large species.

206 We studied the evolution of the morphological characters through the full evolutionary  
207 path of species (i.e. from root to tips) and in the individual branches, using phylogenetic  
208 ancestor-descendant comparisons (PAD; Baker et al., 2015; Rudoy & Ribera, 2016). We  
209 measured three values for each of the individual branches (including terminals): (1) amount of  
210 phenotypic change, equal to the arithmetic difference between the final and initial values of the  
211 branch; (2) absolute amount of phenotypic change, equal to the absolute value of the amount of  
212 phenotypic change; (3) phenotypic change measured in darwins (Haldane, 1949), computed as  
213 the absolute value of the natural logarithm of the ratio between the final and initial values  
214 divided by the length of the branch in million years (Myr) (Table S3). The use of the natural  
215 logarithm standardises the change so it is proportional and directly comparable among species  
216 with different sizes (Haldane, 1949; Gingerich, 2009). To qualitatively characterise phenotypic  
217 change in the individual branches, we coded as positive or negative the increase or decrease of  
218 body size in each sex, as well as the SSD measured as the absolute difference between male and  
219 female body size. An estimated change lower than 5% in body size of males or females was  
220 considered within experimental error (i.e. "without change"). For SSD, we considered as  
221 "without change" branches with a change lower than 5% of the total range of observed  
222 differences. As individual branches are in principle independent from each other we analysed  
223 these variables with standard statistical procedures (see e.g. Baker et al., 2015).

224 We estimated the phylogenetic signal of the morphological variables in the whole tree  
225 using the  $K$  metric (Blomberg et al., 2003), which tests whether the topology and branch lengths  
226 of a given tree better fits a set of tip data compared with the fit obtained when the data have been

227 randomly permuted. The higher the  $K$  statistic, the more phylogenetic signal in a trait.  $K$  values  
228 of 1 correspond to a BM model, which implies some degree of phylogenetic signal.  $K$  values  
229 closer to zero correspond to a random or convergent pattern of evolution, while  $K$  values greater  
230 than 1 indicate strong phylogenetic signal. We used the R package ‘Picante’ (Kembel et al.,  
231 2010) to compute  $K$  and the significance test. We also measured the correlation between some  
232 variables across the whole tree with a regression of phylogenetic independent contrasts with the  
233 PDAP package in MESQUITE v.3. We use a type II regression with reduced major axis (RMA)  
234 to relate the independent contrasts obtained in PDAP of log<sub>10</sub> male and female size (Fairbairn,  
235 1997; Blanckenhorn et al., 2007b) using the package PAST v.3 (Hammer et al., 2001).

236 To test for the possible effect of the incomplete taxon sampling, in some analyses we also  
237 used a phylogeny including species with only morphological data. We used the tree provided in  
238 Rudoy et al. (2016), in which species without molecular data were placed mostly according to  
239 the similarities of the male aedeagus (Fig. S3). When relationships were uncertain, a polytomy  
240 was formed with all the species sharing a similar structure of the aedeagus, and whenever  
241 necessary for the analyses these polytomies were randomly resolved in MESQUITE v.3. For  
242 comparison, some of the correlations were also repeated using the species values directly,  
243 without phylogenetic correction.

244

## 245 RESULTS

### 246 Overall interspecific allometry in SSD

247 Both for the whole genus *Limnebius* and subgenus *Limnebius* s.str. the slope of the regression  
248 between the size of females and the size of males was significantly larger than one (Fig. 1; Table  
249 1), i.e. there was a positive allometry in the size of males with respect to females. Although the  
250 estimate of the slope of the regression for subgenus *Bilimneus* was also larger than one, the 95%  
251 confidence interval could not reject isometry between both sexes (Table 1). Results were similar  
252 for both phylogenies (only with species with molecular data and with all species), or when data  
253 were compared without phylogenetic correction (Table 1).

254 The phylogenetic signal  $K$  of the SSD, as measured with the ratio male/female body size  
255 (rSSD), was lower than one, suggesting lack of phylogenetic signal ( $K = 0.56$ ;  
256  $p < 0.001$ ). The  $K$  values for body size of males and females were, on the contrary, clearly larger  
257 than one, suggesting a strong phylogenetic signal (1.35 and 1.65 respectively, both  $p < 0.01$ ).

258 In the whole genus *Limnebius*, rSSD was significantly correlated with male and female  
259 body size (*lm* and *lf*), but correlation values were much larger for males than for females (Table  
260 2). When the two subgenera were considered separately, the correlation with *lf* was not  
261 significant in subgenus *Limnebius* s.str. when using the phylogeny with all species included, and  
262 never in *Bilimneus* (Table 2).

263 The correlations of rSSD with the measures of aedeagus size and complexity were also  
264 highly significant, although weaker when using the phylogenetic tree with all species than when  
265 using the phylogeny with only species with molecular data, or when using raw data without  
266 phylogenetic correction (Table 3). Correlations were also weaker within the species of  
267 *Bilimneus*, and significant only for the perimeter.

268

### 269 **Evolution of SSD**

270 According to our reconstruction, the ancestral condition of *Limnebius* was a SSD close to a 1:1  
271 ratio; Fig. 2, Table S3). The general evolution in *Bilimneus* was to a slight decrease in size, with  
272 females larger than males, while in *Limnebius* s.str. the general trend was an increase in size  
273 (although some lineages maintained the ancestral small size), with males larger than females  
274 (Fig. 2; Table S3). This increase in size and SSD was continuous for the extant species with the  
275 largest SSD.

276 Of all 130 individual branches of the phylogenetic molecular tree, only in 32 female body  
277 size had a faster evolutionary rate than male body size, as measured in darwins (average  
278 difference of male minus female darwins = 0.006, std = 0.017; Fig. 3). Many of the branches in  
279 which females evolved faster than males were in the *L. nitidus* subgroup, with an uncertain basal  
280 topology but reconstructed as having an overall decrease in SSD (Figs 2, 4F and S5). Differences  
281 were similar when measured with absolute phenotypic change, with only 33 branches out of 130  
282 in which female body size changed more than male body size (average difference of male minus  
283 female absolute body size = 0.029 mm, std = 0.045) (Figs 4D and S5; Table S3).

284 The reconstructed changes in SSD in the individual branches of the phylogenetic tree  
285 were clearly associated to changes in body size. In almost 50% of the branches (63 out of 130)  
286 SSD increased when the body size of males and females also increased, and decreased when  
287 body sizes decreased (Table 4; Fig. 4B,E). There were, however, a number of possible  
288 alternative situations, the most common of them that SSD increased when body size of both

289 sexes decreased (Fig. 4A,C; Table 4). In all individual branches in which this happened females  
290 were larger than males, so the increase in SSD was due to a relative larger reduction in male size  
291 (Table 4). The inverse situation, i.e. a decrease in SSD when body size of both sexes increased,  
292 was much less frequent (Fig. 4C,F; Table 4). But again, in the single branch with a SSD decrease  
293 larger than 5% when both sexes increased in size females were larger than males, so the  
294 reduction in SSD was due to a relative larger increase of the male body size (Tables 4 and S3).  
295 When only change above 5% was considered, the most common situation was no change in  
296 either males or females (Table 4), but the general pattern did not change.

297         There were branches in which there was a significant change in SSD with an increase in  
298 body size of only one of the sexes. When males were the sex that changed there was generally an  
299 increase in SSD (17 out of 24 branches, Table 4). When females were the only sex to  
300 significantly increase their size, SSD increased when female size decreased (3 branches), or  
301 decreased when female body size increased (also 3 branches, Table 4). There was only one case  
302 in which SSD decreased when only female body size decreased (4 for the males), and none in  
303 which SSD increased only due to an increase in female body size (against 10 branches for males,  
304 Table 4). In all these cases it can be considered that changes in SSD were not associated with an  
305 overall size increase. Overall, there were 24 branches in which SSD significantly changed only  
306 due to male change, while change was only due to females in seven branches (Table 4;  $p < 0.005$   
307 of equal probabilities assuming a binomial distribution). For all studied species, the reconstructed  
308 average size change along the evolutionary path was larger for males than females.

309         Differences in the rate of phenotypic evolution of male and female body size in the  
310 individual branches, as measured in darwins, were positively correlated to the change in males,  
311 but negatively (albeit not significantly) with that of females (Table 5). When measured in  
312 absolute phenotypic change, differences between male and female body size were positively  
313 correlated with the change of both sexes, but with a stronger correlation and a steeper slope for  
314 males (Table 5).

315

### 316 **Evolution of secondary sexual characters**

317 According to our reconstruction, modifications in the hind tibiae appeared three times  
318 independently in the phylogeny (Fig. 5). Within the *L. nitidus* group, species in the *L.*  
319 *nitiduloides* subgroup have a row of setae (Figs 4E and S3), and two species, *L. truncatellus* and

320 *L. mesatlanticus*, have the distal part of the male hind tibia strongly widened (Fig. S2; Jäch,  
321 1993). In addition to these, in three closely related species within the *L. parvulus* group males  
322 have wider hind tibiae (*L. doderoi*, *L. furcatus* and *L. gridellii*, Fig. 5).

323         According to our reconstruction, the protuberance in the male abdomen appeared  
324 independently in the *L. gracilipes* group (in the clade excluded *L. cordobanus*, Rudoy et al.,  
325 2016) (Figs 4D and S3 ) and in the *L. nitidus* group. Within the later, it was secondarily lost in  
326 the *L. nitidus* subgroup, with the exception of *L. kocheri* (Fig. 4F,S3). The other modifications of  
327 the abdomen of males occur in two of the subgroups of the *L. parvulus* group (Fig. 5). The two  
328 species of the *L. setifer* subgroup have a medial impression, and the species of the *L. parvulus*  
329 subgroup a tuft of setae, with the exception of *L. glabriventris*, very close to *L. parvulus*, which  
330 likely lost it secondarily (Jäch, 1993). There was no molecular data for the species of the *L.*  
331 *setifer* subgroup (Fig. S3), so it remains uncertain whether there may have been a single origin  
332 for the secondary modifications of the abdomen, which subsequently diverged in the two  
333 subgroups, or they appeared independently.

334

## 335 **DISCUSSION**

### 336 **Rensch's rule**

337 Our results confirm the general validity of Rensch's rule in the genus *Limnebius*, that is, that  
338 body size of males is evolutionary more labile than that of females (Rensch, 1950; Fairbairn,  
339 1997). There are several lines of evidence supporting this conclusion: (1) the correlation between  
340 male (y-axis) and female (x-axis) body size had a slope larger than one (i.e. a positive allometry)  
341 both for the genus and the subgenera, although for *Bilimneus* (with small species and females  
342 larger than males) when considered separately the regression was not significant. (2) The ratio  
343 male/female body size (rSSD) was correlated mostly with male body size, while the correlation  
344 with female body size was lower and in some cases not significant, indicating that males drive  
345 the evolution of SSD. And (3) when the evolution of SSD was reconstructed in the individual  
346 branches of the phylogeny evolutionary rates of male body size were generally higher than in  
347 females, and when females had higher rates there was a secondary reduction in SSD. When the  
348 change in SSD was measured in darwins (a compound measure including rate) it was also  
349 correlated to absolute changes in male, but not female body size, for which the correlations were  
350 negative but not significant. Results were very similar when regressions were obtained using raw

351 data or phylogenetic independent contrasts, and for the later, when using the molecular  
352 phylogeny (with a subset of the species) or the estimated phylogeny with all species.

353         The most commonly accepted cause for Rensch's rule is the continued action of  
354 directional sexual selection on the body size of males (Abouheif & Fairbairn, 1997; Székely et  
355 al., 2004). The increase in male body size results in an increase in SSD when males are larger,  
356 but a decrease in SSD if females are larger. This model assumes a correlated evolution between  
357 male and female body size, so that when males increase in size females also increase, although at  
358 a lower rate (i.e. the correlation is  $<1$ ) (Maynard Smith, 1977; Fairbairn & Preziosi, 1994). Our  
359 results are in general agreement with this model, as changes in SSD were most frequently  
360 associated to changes in body size of both sexes (although larger in males). However, there were  
361 a variety of particular cases, the most common being an increase in SSD while both sexes  
362 decrease in size. The contrary situation, with an increase in body size of both sexes leading to a  
363 decrease in SSD, was more infrequent, being found only in one branch within *Bilimneus*, the  
364 subgenus with females generally larger than males. Both cases contradict the association of SSD  
365 with an overall increase in size, but still show larger changes in males than in females, in  
366 agreement with Rensch's rule.

367         There are two other possible cases in which SSD is not associated with changes in body  
368 size of both sexes. One is isometry, defined in our case as a change larger than 5% in body size  
369 of both sexes in parallel, but with a change in SSD of less than 5% (i.e., considered to be not  
370 significant). The reconstructed branches with isometric change in the *Limnebius* phylogeny  
371 occurred in lineages with small species with low SSD. The second case is an increase in SSD due  
372 only to an increase in male body size, with no change (or a change lower than 5%) in the  
373 females. This situation was more frequent in the phylogeny, suggesting that in some  
374 circumstances there may be a decoupling of the evolution of the male and female body size. It  
375 has been suggested that when body size is subjected to other selective forces females should  
376 approach their optimal size independently of the size of males, which may be mostly driven by  
377 sexual selection (Lande, 1980). There were also cases in which changes in SSD were associated  
378 to changes in only one sex, challenging the assumption that selection on body size of one sex  
379 will always drive the evolution of the other due to their overall genetic correlation. Our results  
380 are in agreement with simulation studies showing that in species with large populations genetic

381 correlations between the sexes do not pose strong constraints to the evolution of SSD (Reeve &  
382 Fairbairn, 2001).

383 In general, although the overall evolution of SSD in *Limnebius* seems to conform to a  
384 standard model with sexual selection favouring an increase in male body size with female body  
385 size also increasing due to genetic correlation, there was considerable variation, and some  
386 lineages show deviating patterns. The high evolutionary lability of SSD was confirmed by its  
387 low phylogenetic signal as measured with the K statistic, lower than for male and -especially-  
388 female body size.

389

### 390 **Relationship between SSD and aedeagus size and complexity**

391 We found a general positive correlation between SSD and size and complexity of male genitalia,  
392 which would suggest that genital characters are also subjected to sexual selection, in parallel to  
393 male body size. However, in a previous study Rudoy & Ribera (2016) did not found clear  
394 evidence for the presence of directional selection in the evolution of the complexity and size of  
395 the male genitalia in the genus *Limnebius*. Although the most complex genitalia are always  
396 present in the larger species, small species may also have complex genitalia. The size of the male  
397 genitalia was also evolutionary very labile, with no clear trends and a large variance, specially in  
398 *Limnebius* s.str., with the larger species and the more complex genitalia (Rudoy & Ribera, 2016).  
399 Similarly, there are lineages with uniformly complex genitalia, but with a wide variation in SSD  
400 (as in e.g. the species of the *Limnebius punctatus* subgroup, Table S1), contrary to hypotheses  
401 linking Rensch's rule with the evolution of genital characters (Bonduriansky & Day, 2003). In  
402 other insects (e.g. water striders) a positive correlated evolution between non-intromittent  
403 genitalia and sexual size dimorphism has been reported, but there was no correlation between the  
404 shape of intromittent genital traits and sexual size dimorphism (Arnqvist & Rowe, 2002).

405

### 406 **Secondary sexual characters**

407 Secondary sexual characters (SSC) appeared several times independently in *Limnebius*, but  
408 generally in large species with high SSD. Male secondary sexual traits are often linked to  
409 directional sexual selection (Petrie, 1988; Wilkinson, 1993; Simmons & Tomkins, 1996;  
410 Wilkinson & Taper, 1999; Simmons, 2013; Santos & Machado, 2016), which will be supported  
411 by their association with species with high SSD. It is also interesting to note that the only loss of

412 SSC affecting a relatively diverse lineage (within the *Limnebius nitidus* subgroup) occurred in a  
413 lineage that also secondarily reduced the SSD and the complexity of the male genitalia in some  
414 of the species, although other still have relatively complex aedeagus (Rudoy et al., 2016). Due to  
415 the uncertainty in the topology of the *L. nitidus* subgroup (Rudoy et al., 2016) it is not possible to  
416 assess if the presence of protuberance in *L. kocheri* is homologous to that of the other species of  
417 the group (i.e., it is sister to the rest of the species within the subgroup) or if it acquired the  
418 character independently, although the different conformation (short and acute in *L. kocheri*, long,  
419 oblique and medially impressed in other species) suggest the later possibility (Jäch, 1993). This  
420 would also agree with an alternative topology grouping in a monophyletic clade all lineages  
421 within the *L. nitidus* group with SSC in the abdomen, in which case the absence of SSC in the *L.*  
422 *nitidus* subgroup (with the exception of *L. kocheri*) could be ancestral and not secondary (Rudoy  
423 et al., 2016).

424         The presence of SSC seems to be more linked to the complexity of the genitalia, both for  
425 the characters present in the terminal segments of the abdomen and the extreme modifications of  
426 the legs. According to our reconstruction, the modification of the posterior legs appeared after  
427 the development of SSC in the abdomen, and they are also not linked to SSD. Thus, they are  
428 conserved in species with a secondarily rSSD close to 1, as for example in some species of the *L.*  
429 *nitiduloides* group, which has a strong variation in SSD despite having uniformly complex  
430 genitalia (Rudoy & Ribera, 2016). As already noted, the relationship between SSC and complex  
431 genitalia is, however, not reciprocal, as there are groups with a complex genitalia but without  
432 SSC (as in e.g. the *L. nitidus* complex or the *L. punctatus* subgroup, Table S1).

433

#### 434 **Concluding remarks**

435 Our results demonstrate that the evolution of SSD dimorphism in the genus *Limnebius* was  
436 largely driven by changes in males, thus providing strong support for the prevalence of Rensch's  
437 rule. However, the increase in SSD was not always linked to an overall size increase in both  
438 sexes, and was not always associated to the presence of male secondary sexual characters (SSC),  
439 contrary to the expectations under the hypothesis of sexual selection as the primary cause of  
440 Rensch's rule. Although most species with SSC had a strong SSD, with males larger than  
441 females, SSC are evolutionary more derived, appearing generally when species had already  
442 increased their size. In Rudoy & Ribera (2016) it was shown that differences in the evolution of

443 the male genitalia between *Bilimneus* and *Limnebius* s.str. were largely due to an increase in the  
444 variance of the change in the later, in which males are generally larger than females and which  
445 includes the larger species and the species with the stronger SSD and the more complex  
446 genitalia. This raises the possibility that the primary driver for the evolution of male body size is  
447 simply their larger evolutionary variance, maybe related to the lack of constraints associated with  
448 egg development and reproduction acting on females. In *Limnebius* s.str. sexual selection, with  
449 the subsequent development of SSC, may have been triggered in lineages that already had larger  
450 males and complex genitalias, reinforcing these pre-existing traits. The stronger constraints in the  
451 variability of males in subgenus *Bilimneus* remains to be explained, but it may be related to  
452 unknown differences in mating behaviour or other traits related to reproduction.

453

#### 454 **ACKNOWLEDGEMENTS**

455 We are grateful to M.A. Jäch (NMW, Wien) and P. Perkins (MCZ, Harvard) for allowing us to  
456 study the collections of their institutions and for supporting this work in many ways. A.R. thanks  
457 M.A. Jäch for his help during his stay in the NMW. We also thank the comments and advice of  
458 F. García-González (EBD, Seville) and A. Cordero-Rivera (University of Vigo). This work was  
459 partly funded by a JAE PhD studentship (CSIC) to A.R., the Spanish Ministerio de Economía y  
460 Competitividad (projects CGL2010-15755 and CGL2013-48950-C2-1-P), a Salvador de  
461 Madariaga grant in the Phyletisches Museum in Jena (PRX14/00583) to I.R. and the "Secretaria  
462 d'Universitats i Recerca del Departament d'Economia i Coneixement de la Generalitat de  
463 Catalunya" (project SGR1532).

598 **Figures**

599

600 **Fig. 1.** Regression between male (y-axis) and female (x-axis) body size. A, phylogenetic  
601 independent contrasts of species in the molecular phylogeny (Figs 2 and 5); B, phylogenetic  
602 independent contrasts of the estimated phylogeny with all species (Fig. S3); C, regression with  
603 the raw data (without phylogenetic correction). Dotted lines, isometric relationship (slope = 1).  
604 See Table 1 for the numerical values of the regressions.

605

606 **Fig. 2.** Evolution of the sexual dimorphism (rSSD) in the phylogeny of *Limnebius*, reconstructed  
607 in BEAST using a Brownian model of evolution. Numbers in nodes, reconstructed value of rSSD  
608 with 95% confidence interval in square brackets (see Fig. S4 for node support values).

609

610 **Fig. 3.** Histogram of the differences in darwins of the phenotypic change in males and females in  
611 the individual branches of the phylogeny (see Table S3 for the values of the individual branches).

612

613 **Fig. 4.** Evolutionary trajectories of SSD in selected species of *Limnebius*. In the y-axis,  
614 reconstructed values of male (filled circles) and female (white circle) body sizes (mm); in the x-  
615 axis, nodes in the reconstructed evolution of the species (Figs 2 and 5). Distances in the x-axis  
616 are proportional to time (Ma, note that the scale is reversed, i.e. the root of the Limnebiini tree is  
617 dated with time 0). Filled arrows, apparition of abdominal secondary sexual characters (SSC);  
618 empty arrows, apparition of SSC in the posterior tibiae; crosses, secondary lost of SSC, all  
619 according to the reconstruction in Fig. 5. The trajectory represented in F (*L. nitidus* complex) is  
620 the same for all the species in this complex, due to the short terminal branches and the uncertain  
621 relationships among the species.

622

623 **Fig. 5.** Evolution of the male body size (*lm*, mm) in the phylogeny of *Limnebius* reconstructed in  
624 BEAST using a Brownian model of evolution, with the reconstructed origin and lost of  
625 secondary sexual characters (SSC) in MESQUITE using parsimony. Numbers in nodes,  
626 reconstructed value of *lm*. Arrows mark the appearance of SSCs, crosses mark their loss.

627 **Tables**

628

629 **Table 1.** Type II regression (MRA) between male and female body size. Regressions using a  
 630 phylogenetic correction (molecular and including all species, Figs 2, 5 and S3) were done using  
 631 PDAP contrasts.

## Figures

**Fig. 1.** Regression between male (y-axis) and female (x-axis) body size. A, phylogenetic independent contrasts of species in the molecular phylogeny (Figs 2 and 5); B, phylogenetic independent contrasts of the estimated phylogeny with all species (Fig. S3); C, regression with the raw data (without phylogenetic correction). Dotted lines, isometric relationship (slope = 1). See Table 1 for the numerical values of the regressions.

**Fig. 2.** Evolution of the sexual dimorphism (rSSD) in the phylogeny of *Limnebius*, reconstructed in BEAST using a Brownian model of evolution. Numbers in nodes, reconstructed value of rSSD with 95% confidence interval in square brackets (see Fig. S4 for node support values).

**Fig. 3.** Histogram of the differences in darwins of the phenotypic change in males and females in the individual branches of the phylogeny (see Table S3 for the values of the individual branches).

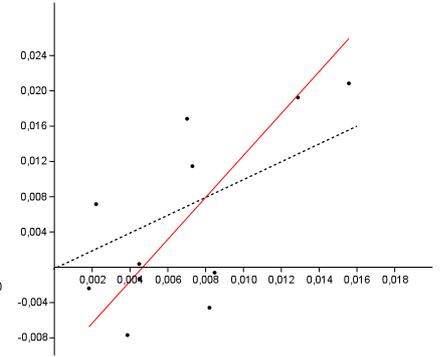

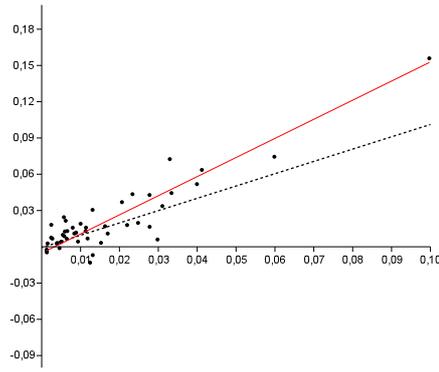

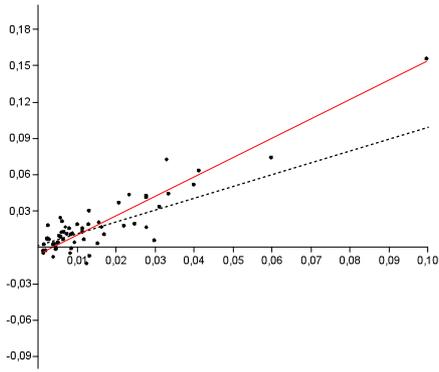

**Fig. 4.** Evolutionary trajectories of SSD in selected species of *Limnebius*. In the y-axis, reconstructed values of male (filled circles) and female (white circle) body sizes (mm); in the x-axis, nodes in the reconstructed evolution of the species (Figs 2 and 5). Distances in the x-axis are proportional to time (Ma, note that the scale is reversed, i.e. the root of the Limnebiini tree is dated with time 0). Filled arrows, apparition of abdominal secondary sexual characters (SSC); empty arrows, apparition of SSC in the posterior tibiae; crosses, secondary lost of SSC, all according to the reconstruction in Fig. 5. The trajectory represented in F (*L. nitidus* complex) is the same for all the species in this complex, due to the short terminal branches and the uncertain relationships among the species.

**Fig. 5.** Evolution of the male body size (*Im*, mm) in the phylogeny of *Limnebius* reconstructed in BEAST using a Brownian model of evolution, with the reconstructed origin and lost of secondary sexual characters (SSC) in MESQUITE using parsimony. Numbers in nodes, reconstructed value of *Im*. Arrows mark the appearance of SSCs, crosses mark their loss.
