Background. The primary aim of the study reported here was to determine the effectiveness of utilizing local spatial variations in environmental data to uncover the statistical relationships between West Nile Virus (WNV) risk and environmental factors. Because least squares regression methods do not account for spatial autocorrelation and non-stationarity of the type of spatial data analyzed for studies that explore the relationship between WNV and environmental determinants, we hypothesized that a geographically weighted regression model would help us better understand how environmental factors are related to WNV risk patterns without the confounding effects of spatial non-stationarity.

Methods. We examined commonly mapped environmental factors using both ordinary least squares regression (LSR) and geographically weighted regression (GWR). Both types of models were applied to examine the relationship between WNV-infected dead bird counts and various environmental factors for those locations. The goal was to determine which approach yielded a better predictive model.

Results. LSR efforts lead to identifying three environmental variables that were statistically significantly related to WNV infected dead birds (adjusted $R^2=0.61$): stream density, road density, and land surface temperature. GWR efforts increased the explanatory value of these three environmental variables with better spatial precision (adjusted $R^2 = 0.71$).

Conclusions. The spatial granularity resulting from the geographically weighted approach provides a better understanding of how environmental spatial heterogeneity is related to WNV risk as implied by WNV infected dead birds, which should allow improved planning of public health management strategies.

17 **Abstract**

18 **Background.** The primary aim of the study reported here was to determine the effectiveness of
19 utilizing local spatial variations in environmental data to uncover the statistical relationships
20 between West Nile Virus (WNV) risk and environmental factors. Because least squares
21 regression methods do not account for spatial autocorrelation and non-stationarity of the type of
22 spatial data analyzed for studies that explore the relationship between WNV and environmental
23 determinants, we hypothesized that a geographically weighted regression model would help us
24 better understand how environmental factors are related to WNV risk patterns without the
25 confounding effects of spatial non-stationarity.

26 **Methods.** We examined commonly mapped environmental factors using both ordinary least
27 squares regression (LSR) and geographically weighted regression (GWR). Both types of models
28 were applied to examine the relationship between WNV-infected dead bird counts and various
29 environmental factors for those locations. The goal was to determine which approach yielded a
30 better predictive model.

31 **Results.** LSR efforts lead to identifying three environmental variables that were statistically
32 significantly related to WNV infected dead birds (adjusted $R^2=0.61$): stream density, road
33 density, and land surface temperature. GWR efforts increased the explanatory value of these
34 three environmental variables with better spatial precision (adjusted $R^2 = 0.71$).

35 **Conclusions.** The spatial granularity resulting from the geographically weighted approach
36 provides a better understanding of how environmental spatial heterogeneity is related to WNV
37 risk as implied by WNV infected dead birds, which should allow improved planning of public
38 health management strategies.

39

40 **Introduction**

41 West Nile Virus (WNV) is a vector-borne disease that was first detected in the United
42 States in 1999 (Nash et al. 2001). Within a few years the virus had spread across the North
43 American continent (Hayes et al. 2005). WNV has had important environmental and human
44 impacts, including a decline in numerous bird species (CDC) and increased morbidity and
45 mortality among humans. This has also resulted in increased economic burdens due to initial
46 acute health care needs of infected individuals and subsequent long-term costs associated with
47 infection, estimated at approximately \$56 million per year between 1999 and 2012 (Barrett
48 2014). Because that study indicated how difficult predicting and planning for WNV outbreaks
49 was, we became interested in developing a spatially explicit model using environmental factors
50 in an attempt to improve WNV risk predictions.

51 There are two important considerations that should typically be examined when
52 developing spatially explicit environmental disease risk models (Miller 2012). The first should
53 be an examination of potential spatial autocorrelation (the degree to which a set of spatial
54 features and their associated data values tend to be clustered together in space). This involves
55 accounting for whether environmental factors and the corresponding disease rates in
56 geographically proximate areas are more or less clustered together than they are in
57 geographically distant areas. Second, data non-stationarity (changing means, variances and
58 covariances in data across space) should be investigated and controlled when necessary
59 (Fotheringham 2009a; Miller 2012). Geographically weighted regression (GWR) can be used for
60 these two considerations and can often produce improved models that enable better spatial
61 inference and prediction. Recent studies have applied GWR modeling to drug-resistant

62 tuberculosis versus risk factors (Liu et al. 2011); environmental factors versus typhoid fever
63 (Dewan et al. 2013); local climate and population distribution versus hand, foot, and mouth
64 disease (Hu et al. 2012); and environmental factors and tick-borne disease (Atkinson et al. 2012;
65 Atkinson et al. 2014; Wimberly et al. 2008a; Wimberly et al. 2008b), all showing that predictor
66 variables varied spatially across large geographic regions, implying that the results for such
67 studies may be improved using GWR.

68 The spatially explicit model that is discussed in this paper uses GWR to account for
69 spatial heterogeneity for two reasons: (a) WNV disease risk observed across space may be
70 related to similar environmental variables that increase vector habitat suitability and (b)
71 environmental variables that influence WNV risk are not typically uniformly distributed across
72 geographic space. Although many epidemiological models of WNV risk have been developed, it
73 appears that there has been little research to explicitly examine techniques that account for
74 spatial heterogeneity. Most models assume that the impact of various environmental factors are
75 constant across the study region, which is unrealistic as larger areas display substantial variations
76 in distribution of environmental, socio-economic, and demographic conditions (Goovaerts 2008).

77 Due to the unavailability of reliable and complete data, developing models of WNV risk
78 pose additional challenges. Human case data is lacking due to issues of under-reporting and
79 limited surveillance. Our alternative strategy was to assess WNV infected dead bird counts as a
80 surrogate measure of human risk because “infection rates” in dead birds can be more precise
81 because of the genetic markers tested in dead birds may be more reliable than case data and/or
82 surveillance data. Additionally, others have also used mosquito habitat suitability as a surrogate
83 for estimating WNV risk for human infection (Cooke et al. 2006). For our study, we followed a
84 similar approach and used a model of mosquito habitat suitability condition as a predictor of the

85 spatial distributions of infected birds, which in turn can be used to estimate WNV disease risk
86 among human populations. Further, because the environmental variables considered in this study
87 are known to vary across space, we account for spatial autocorrelation and non-stationarity using
88 GWR following the approach of (DeGroot et al. 2008) in order to improve the predictability of
89 a model.

90

91 WNV transmission and risk factors

92 The WNV transmission cycle was an important component of our modeling efforts. The
93 first step in the WNV transmission cycle primarily occurs when a competent female mosquito
94 vector bites an infected bird reservoir host, which in turn results in the virus being transmitted to
95 the mosquito (Blair 2009). This occurs when the female mosquito is seeking a blood meal to
96 obtain nutrients necessary for egg development. After taking an infectious blood meal, a
97 mosquito may pick up a permanent infection. The infected mosquito now has the potential to
98 transmit the virus to another bird or animal when it feeds again. Once infected, birds may fly to
99 other locations where the virus can be transmitted to susceptible mosquitoes. Subsequently, the
100 disease may be transmitted by infected mosquitoes to humans or other mammals that act as
101 incidental hosts. Dead birds found to be infected with WNV are often the primary indicators for
102 presence of the disease in a geographic region and have proven to be useful for disease
103 prediction modeling and identifying areas for human infection risk (Cooke et al. 2006; Ruiz et al.
104 2004; Valiakos et al. 2014). This relationship allows an assumption of a positive correlation
105 between infected dead birds and WNV risk. Since the New York outbreak in 1999, WNV has
106 been recovered from 26 mosquito species in North America, including *Culex pipiens*, *Culex*
107 *salinarius*, *Culex restuans*, *Ochlerotatus canadensis*, *Oc. japonicus*, *Aedes vexans*, and *Culiseta*

108 *melanura* (CDC 2000; Control & Prevention 2001). Results from a study (Goddard et al. 2002)
109 assesses the vector competence of California mosquitoes. The results indicate that mosquitoes in
110 the genus *Culex* (*Cx.*) are the principal hosts of WNV in California. The study also analyzed that
111 on the basis of vector competence and host-feeding patterns, *Cx. tarsalis* may be the principal
112 vector in rural agricultural ecosystems; and *Cx. pipiens* complex and *Cx. stigmatosoma* as
113 important vectors in urban settings.

114 Vector and pathogen reservoirs overlap when certain environmental conditions are
115 present (Rochlin et al. 2011). Table 1 provides an overview of the environmental conditions that
116 are associated with WNV transmission, which were utilized for our research. These include
117 characteristics of a place such as the mosquito species habitat: climatic conditions, topography
118 and land use/land cover classes such as vegetation, water, and urbanized areas. Spectral indices
119 acquired from satellite imagery provide information about environmental characteristics like
120 temperature, vegetation cover, and moisture (Rodgers & Mather 2006). Liu and Weng (Liu &
121 Weng 2012) in a study on WNV risk in southern California found that one of the main factors
122 contributing to the WNV propagation included land surface temperature. They related higher
123 temperature to viral replication in mosquitoes for WNV to be disseminated throughout the year.
124 The results also show that areas with lower elevations tended to be more susceptible to WNV
125 invasion as mosquito population propagates in the plain habitats with warmer temperatures
126 compared to areas with higher elevation that have lower temperatures.

127 **Table 1 approximately here**

128 Statistical Considerations

129 Miller (2012) suggests that a ‘global’ model is the one that assumes that the parameters
130 (commonly mean and variance) of some process are constant across geographic space

131 (commonly mean and variance), typically referred to as the spatial stationarity of a process.
132 Miller suggests that in the case these parameters vary across geographic space (spatial
133 heterogeneity), then such models may lead to inaccurate predictions and subsequent problems for
134 decision-making. In an ecological context, spatial heterogeneity usually results from the
135 interaction of various environmental processes that operate at different scales (Legendre 1993).
136 Fotheringham (Fotheringham 2009b) used local statistics for linking the concepts of spatial
137 autocorrelation and heterogeneity that are deemed important when developing spatial models.
138 Local statistics disaggregate a global mean value into locally computed values for each spatial
139 unit. It is based on a conceptualization of Tobler's first law in Geography (Tobler 1970) that
140 specifies that "everything is related to everything else, but near things are more related than
141 distant things." Spatial autocorrelation is a commonly used measure of the degree of spatial
142 heterogeneity.

143 GWR is a local regression method that can be used for diagnosing spatial heterogeneity
144 between dependent and explanatory variables over space (Fotheringham et al. 2003). It is
145 performed within local windows centered on the nodes of a regular grid. Each observation within
146 the local window is weighted based on its proximity to the center of that window. This approach
147 has several advantages: it avoids abrupt changes in the local statistics computed for adjacent
148 windows, helps visualize spatial variability within the geographic entity, and allows analysis of
149 regionally aggregated data (Goovaerts 2008). A model's predictive ability, particularly in
150 ecological modeling, is influenced not only by the strength of relationships between the species
151 and its environment, but whether the model recognizes if the relationships are operating at
152 multiple spatial scales. GWR provides a framework for exploring scale-dependent effects. It tests

153 the effect on a model's predictive ability by systematically increasing the size of the local
154 window (Miller 2012).

155 GWR can be used for mapping the spatial distribution of a model's coefficient values in
156 order to identify potential missing variables or to suggest other underlying factors associated
157 with the observed non-stationarity (Miller 2012). GWR is also useful for exploratory data
158 analysis and visualization; for example Kupfer and Farris (Kupfer & Farris 2007) used a 'leave-
159 one-out' (jackknifing) methodology to compare residuals from GWR and ordinary least squares
160 regression. They found that GWR often had more accurate predictions for sites that were
161 difficult to predict (where both models had overall higher residuals), which is why we used a
162 GWR framework for explicitly modeling the spatial relationships between WNV and its
163 environmental risk factors.

164

165

166

167 **Materials & Methods**

168 Study area

169 The model was built for the state of California, which was the national epicenter of WNV
170 activity in 2004 and 2005 (Jean et al. 2007). WNV was first detected there in July 2003 (Reisen
171 et al. 2004). It is the third largest state by area in the United States and is made up of 58 counties.
172 California has the largest population in the U.S., but it is unevenly distributed across the state.
173 The state also has a variable landscape with a large valley in the middle, bounded by mountain
174 ranges.

175

176 Environmental factors and data sources

177 Our model utilized various environmental factors (Table 1) that have been suggested as
178 descriptive in local WNV risk distribution: surface slope, density of roads, density of streams,
179 monthly mean temperature, monthly mean evapotranspiration, and land cover classes like
180 vegetation, developed land, cultivated land, and open surface water. All environmental
181 parameters except roads and streams (Table 2) were acquired in grid format and resampled to
182 120 meter resolution as suggested by Cooke et al. (2006). Data resampling was done using the
183 resampling tool available in ArcGIS software. The modeling method utilized in this study was
184 based on analyzing data in raster format, and therefore road and stream vector data were
185 converted to raster format using the ‘Kernel Density Estimation’ tool in ArcGIS to create road
186 density and stream density grid files. The tool assumes a Gaussian distribution and thus assigns
187 more importance towards the center of kernel in comparison to the features that are further apart.

188 Various dynamic environmental data including Normalized Difference Vegetation Index
189 (NDVI), Land Surface Temperature (LST), and Evapotranspiration (ET) were downloaded from
190 the Moderate Resolution Imaging Spectroradiometer (MODIS) toolbox incorporated in
191 ArcGIS®. The Land Surface Temperature tool accesses MOD11-A1, the daily averaged LST
192 product. The MOD11 product uses the algorithm which is optimally used to separate ranges of
193 atmospheric column water vapor and lower boundary air surface temperatures into tractable sub-
194 ranges. The NDVI is calculated according to the formula $NDVI = (NIR - VIS) / (NIR + VIS)$
195 where NIR is the near-infrared radiance and VIS is observed radiation in the visible spectrum.
196 NDVI data is available from either satellite with MODIS (Aqua or Terra) as a monthly average.
197 The time lag between the hatching of a mosquito egg to an adult mosquito taking blood meals
198 and becoming infected with WNV to the subsequent infection of a human and the appearance of

199 WNV disease symptoms was taken into account and therefore environmental data used for this
200 study was taken for the month of July, the month prior to peak WNV human incidence cases
201 (Campbell et al. 2002).

202 **Table 2 approximately here**

203

204 Least Squares Regression (LSR) modeling

205 WNV disease annual incidence rate (cases per 100,000 populations) was used as the
206 measure of disease severity in this study. Annual WNV-infected dead birds sentinel data,
207 averaged for 2004-2010, was used as a surrogate of WNV risk and was the dependent variable
208 for modeling purposes in this study because several other studies (Chaintoutis et al. 2014; Eidson
209 et al. 2001a; Eidson et al. 2001b; Eidson et al. 2001c; Guptill et al. 2003; Johnson et al. 2006;
210 Mostashari et al. 2003; Nielsen & Reisen 2007; Patnaik et al. 2007; Ruiz et al. 2004) have
211 suggested links between infected dead birds and WNV human infection rates. Since wild birds
212 are the primary reservoir hosts for WNV and indicator of human infection risk, we utilized this
213 association to develop the disease prediction model. We determined the utility of this
214 relationship by correlating the dead birds data with the human incidence rate ($r^2 = 0.409$,
215 determined by utilizing Ordinary Least Squares modeling within the Modeling Spatial
216 Relationships tools within the Spatial Statistics Tools toolbox incorporated in ArcGIS® Arc
217 Toolbox). While infected dead bird counts only explain about 40% of reported human cases in
218 California, it is a highly significant predictor ($p=0.01$). Hence we used a dead bird model, with
219 infected dead birds as a dependent variable, to assess WNV risk among human population.

220 Interpretations of ordinary Least Squares Regression (LSR) model performance were
221 based on assessing multi-collinearity, robust probability, adjusted R^2 , and Akaike's information
222 criterion (AIC) (Akaike 1974). Multi-collinearity was assessed through the variance inflation

223 factor (VIF) statistic, which measures redundancy among explanatory variables. Explanatory
224 variables associated with VIF values larger than about 7.5 indicate that these variables are
225 providing similar information, and they were removed one at a time from the model based on
226 VIF value until the model became unbiased. Robust probability indicates the statistically
227 significant variables that are important to the regression model. Examining VIF values and
228 robust probability, we ran and re-ran LSR models until narrowing down to non-redundant and
229 significant variables: land surface temperature; stream density, and; road density. Akaike's
230 information criterion (AIC) was then used to determine the best LSR model.

231 The next step was to explore GWR models that might better explain the variation in
232 infected dead bird counts based upon environmental data. Spatial autocorrelation (Global
233 Moran's I) was utilized to assess whether the environmental factors exhibited a random spatial
234 pattern (Goodchild 1986), and where adequate models have a random distribution of the
235 residuals (Mitchell 2005).

236

237 Geographically Weighted Regression (GWR) modeling

238 Under conditions of non-stationarity in LSR modeling, geographically weighted
239 regression (GWR) was explored to potentially improve modeling results. These results were
240 determined by utilizing Geographically Weighted Regression modeling within the Modeling
241 Spatial Relationships tools within the Spatial Statistics Tools toolbox incorporated in ArcGIS®
242 Arc Toolbox. The same explanatory variables that were used in LSR modeling were used to run
243 GWR rather than starting with the full global set of parameters so as to avoid introducing
244 "improvement" that could not be attributed solely to which modeling approach was applied. In
245 other words, if GWR modeling was not applied to the same variables as LSR modeling, but

246 yielded better results, we would not know if the improvement was due to the modeling approach
247 or the environmental data that was used to build each model.

248 Once key environmental factors were identified during LSR modeling, we proceeded to
249 explore the spatial variability of local regression coefficients to determine whether the
250 underlying process exhibited spatial heterogeneity (Fotheringham et al. 2003). A GWR local
251 model was applied to analyze how the relationship between infected dead bird counts and
252 environmental factors changed from one county to another. Unlike conventional LSR regression
253 modeling, which produces a single regression equation to summarize global relationships among
254 the independent and dependent variables, GWR detects spatial variation within relationships in a
255 model and produces information useful for exploring and interpreting spatial non-stationarity
256 (Fotheringham et al. 2003).

257 A spatial kernel was used to provide geographic weighting for the local window centered
258 on the grid nodes used in our model. There are two possible categories of spatial kernels:
259 fixed/adaptive and bandwidth, which is a key coefficient that controls the size of the kernel
260 (Akaike 1974). These kernels tend to be Gaussian or Gaussian-like which implies that distant
261 samples are weighed lesser than the proximal ones. There are three potential bandwidth
262 approaches: Akaike information criterion (AIC), cross validation (CV), and bandwidth
263 parameter. For our GWR model, the AIC approach was chosen because the distribution of
264 infected dead birds was not consistent in the study area. The following settings were used in
265 ArcGIS GWR: Bandwidth method = AIC and Kernel type = Adaptive.

266 Finally, we examined independency and normality of residuals, to evaluate the fit of the
267 model. Local collinearity, the square root of the largest eigenvalue divided by the smallest
268 eigenvalue, of our GWR model was also assessed but no data points were removed as they

269 compromised model diagnostics. The adjusted coefficient of determination (Adjusted R²) was
270 used for comparing LSR and GWR models to determine which approach would provide a better
271 understanding of the relationship between environmental conditions and West Nile Virus risk
272 (Fotheringham et al. 2003).

273

274 **Results**

275 LSR modeling identified land surface temperature (VIF = 1.046), stream density (VIF =
276 1.177), and road density (VIF = 1.143) as statistically significant ($p < 0.05$) variables related to
277 WNV risk:

278

$$279 \text{ WNV risk} = -75.87 + 595.60 (RD) + 1.89 (LST) - 146.89 (SD) \quad (1)$$

280

281 Where:

282 WNV risk = average infected dead bird count

283 RD = road density

284 LST = land surface temperature

285 SD = stream density

286 The histogram of the LSR model's residuals approximates that of a normal curve, with a
287 non-significant (0.134, $p < 0.05$) Jarque-Bera statistic (Jarque & Bera 1980), and the Moran's I
288 Index Z-score (1.23) all imply that the model is unbiased and significantly different than random.

289 However, the Koenker statistic (0.000007*, $p < 0.05$) confirmed non-stationarity in
290 the LSR model indicating that there is not a consistent relationship between the explanatory
291 variables and WNV risk across the study area. Further, the presence of mild heteroskedasticity

292 was noted in the LSR model. We conclude that the LSR model is stable but non-stationary,
293 suggesting that proceeding with GWR model was warranted.

294 The GWR model in this study was implemented using the following algorithm:

295

$$296 \text{ WNV risk}_{(i)} = \beta_{i0} + \beta_{(i1)} RD_{(i)} + \beta_{(i2)} LST_{(i)} - \beta_{(i3)} SD_{(i)} + \varepsilon_{(i)} \quad (2)$$

297 Where β coefficients are county (i) specific, and RD is road density, LST is land surface
298 temperature, and SD is stream density.

299

300 Comparing the fit of the global LSR model (assumes homogeneity of variables across
301 space) and local GWR model (makes no assumption of homogeneity), we found that the global
302 LSR adjusted R^2 was 0.61 (R^2 was 0.66, $P < 0.05$, Fig. 1) with analysis run on all 58 counties. The
303 local GWR adjusted R^2 was 0.71 (R^2 is 0.75, $p < 0.05$, Fig. 2) with a bandwidth of 54, which
304 suggests that there has been some improvement by using a local modeling approach. Our
305 preferred measure of model fit, AIC, gave a value of 567.7 for the global model and 551.4 for the
306 local model. The difference of 16.3 is relatively strong evidence of an improvement in the model
307 fit to the data. Further, the problem of heteroskedasticity that was noted in the OLS model was not
308 observed in the GWR model.

309 We also tested the results using different bandwidth parameter. Several iterations were
310 run but it was observed that although a smaller band-width criterion gave an improved
311 combination of AICc and adjusted R^2 values, it also compromised the model diagnostics by
312 introducing local collinearity and thus instability in the model. Addressing local collinearity by
313 removing the Counties having condition number greater than 30 affected the model's overall

314 results. Thus, it is better to have a larger band-width rather than violating model assumptions and
315 to avoid the unstable prediction (Charlton & Fotheringham ; Nakaya 2014).

316
317 **Figure 1 approximately here**

318 **Figure 2 approximately here**

319
320 Mapping the values of the standardized residual across California (Fig. 3a) provides a
321 representation of: (a) areas with unusually high or low residuals and (b) whether the residuals
322 were spatially autocorrelated. Counties with excessively large positive residuals would under-
323 predict WNV risk, and counties with excessively large negative residuals would over-predict
324 WNV risk. The spatial autocorrelation of GWR residuals for our model resulted in a Moran's I
325 value of -0.11 ($p=0.18$), implying little evidence of any autocorrelation in them.

326 **Figure 3 approximately here**

327 Local coefficient estimates for significant factors were mapped using quantile
328 classification method. Figure 3b shows the variation in the model's coefficient estimates for the
329 land surface temperature (LST) variable. The map for the local coefficients reveals that the
330 influence of this variable in the model varies considerably over California, with a strong north-
331 south direction. The range of the local coefficient is from 1.26 for the northernmost counties to
332 3.06 for the southernmost counties – evidence that points to heterogeneity in the model structure
333 within California. The global coefficient and all the local coefficients for this variable are
334 positive – there is agreement between the two models on the direction of the influence of this
335 variable. Figure 3c shows a similar distribution in north-south direction of positive road density
336 coefficient. Figure 3d reveals the opposite for stream density coefficients, with larger values in
337 the north and smaller values in south. Contrary to our initial thoughts, stream density

338 demonstrated a negative relation to disease risk. This may reflect that flowing water is normally
339 not suitable for larval development of the various species of mosquitos that commonly transmit
340 WNV or that rasterizing the stream database into stream density introduces a component that is
341 not yet fully understood.

342 Our best ordinary least squares model, the global LSR model (equation 1) produced an
343 adjusted R^2 of 0.61 ($p < 0.05$) with a corresponding corrected AIC of 567.70. Utilizing the same
344 environmental variables, our best local GWR model (equation 2) produced an adjusted R^2 of
345 0.71 ($p < 0.05$) with a corresponding corrected AIC of 551.4. A 16 point decrease in the AIC and
346 approximately 16% improvement in the model performance suggest that incorporating spatial
347 data improves the predictive ability of WNV risk.

348

349 **Conclusions**

350 One of the frequent technical issues in modeling disease risk is to incorporate local rather
351 than global associations in these models (Foley et al. 2009). In spatial regression models, a
352 global model can be used to examine the relationship between disease risk and potential
353 explanatory factors which are based on the assumption that the relationship is a stationary spatial
354 process (Miller 2012). For a small and homogenous region of interest, it is reasonable to assume
355 that the explanatory factors would not change significantly across the region, and the relationship
356 between WNV risk and the potential factors would also be unchanged. However, important
357 variables such as topography, climate, and population distribution change greatly when it comes
358 to a large region like California with an area of over 163,000 square miles. California is
359 geographically diverse and is equally varied in its range of climates with several climatic sub-

360 regions recognized. It would be unexpected to find that the spatial stationarity assumption holds
361 in such a large area.

362 The distinct north-south pattern revealed in our study could be attributable to typical
363 latitudinal expressions of temperature and precipitation, especially since California has a north-
364 south length of 1,350 kilometers. This environmental pattern is also a likely contributor to the
365 distribution of different mosquito species in the United States, especially notable in its
366 manifestation in California. A recent report (CDC 2013) shows that while *Cx. tarsalis* is
367 distributed throughout California, *Cx. pipiens* is a more important mosquito vector in northern
368 California, while *Cx. quinquefasciatus* is more important in southern California. While WNV
369 can be found in a wide variety of ecosystems, the north-south pattern of infected birds detected
370 in this study may be expressed more noticeably in California due to the north-south differences
371 in mosquito species distributions as observed in the Centers for Disease Control report.

372 Our results concur that understanding WNV risks is improved when considering spatial
373 heterogeneity of the variables that affect the risk (Beck et al. 1994). Besides improving
374 prediction accuracy, spatial heterogeneity can also provide insights into the underlying
375 ecological processes controlling the distributions of vector populations and zoonotic pathogens
376 (Wimberly et al. 2008a) because GWR models consider spatial heterogeneity by separating the
377 large heterogeneous region into smaller, more homogeneous local regions. Fotheringham
378 (Fotheringham 2009a), stated that an advantage of using GWR is that it accounts for much of the
379 spatial autocorrelation in the residuals that is usually found in global modeling. Further, it is
380 possible that a variable that is insignificant at the global level might be important locally.

381 There are several limitations of this study. First, it is assumed that factors suitable for
382 mosquito habitat increase the likelihood of WNV spread in human populations. On the surface

383 this seems to be reasonably apparent; however, we do not have specific evidence that this is true.
384 Second, it is also assumed that the probability of human infection is higher in counties with
385 multiple confirmed WNV bird cases, another reasonable conjecture with several references in the
386 literature, but without direct confirmation. Potential problems with this assumption include
387 varying human population density (e.g. two areas with the same number of infected dead birds
388 reported but one area's human population density is substantially different than the other),
389 variations in level of public concern (as reports of infected dead birds increase, more people
390 begin looking for dead birds), and resource availability might bias the reporting of dead birds
391 (wealthy areas devote disproportionate resources to the issue). Thus, proper surveillance methods
392 that take into consideration these limitations while collecting infected dead bird data will
393 contribute to more meaningful results. Third, our approach assumes that people are infected
394 within the county of their residence, ignoring the possibility of contracting an infection while
395 traveling outside the county limits. Lastly, road density could also be correlated with dead bird
396 surveillance effort and might be a potential bias for reporting dead birds. We recognize that if
397 these assumptions do not hold, modeling WNV risks based on infected dead birds may yield
398 biased results. However, if the assumptions do hold, the local modeling approaches should
399 improve predictions of WNV risks.

400 The research described in this paper suggests that a spatially explicit local model using
401 GWR approaches to adjust for spatial autocorrelation and non-stationarity can yield improved
402 predictions compared to ordinary LSR modeling of WNV risk. A spatially explicit modeling
403 technique may be useful in policy-making and decision-making depending on the granularity and
404 resolution of available data. Identifying the spatial variations in relationships by estimating local
405 regression parameters allows the spatial distribution and interaction of predictor variables to be

406 explored. Analyzing local variations in relationships provides those concerned with public health
407 policy the ability to target resources and to achieve improved outcomes through location-specific
408 activities (Comber et al. 2011) because spatial heterogeneity can improve predictions by
409 capturing geographic shifts in the ecological drivers (Wimberly et al. 2008a). While
410 environmental data used in this research were of fine resolution, WNV disease human incidence
411 data and infected dead bird data that is used is available only at a coarser county scale. We had to
412 assume that aggregating the environmental data up to the county adequately represented the
413 environmental conditions presented in the county, but we knew that data aggregation was likely
414 to introduce some uncertainty into the model. The dead bird model applied in this study can be
415 used for better understanding of WNV risk and the techniques used could be replicated at finer
416 spatial scales thus leading to better intervention efforts.

417 In summary, WNV, a globally emerging infectious disease, was found to be
418 heterogeneously related to environmental factors at the county level throughout California during
419 the time that our data were collected. Our findings may assist those conducting risk assessments
420 for WNV transmission in local areas by helping local public health entities allocate resources and
421 improve preparedness for an outbreak according to region-specific conditions.
