The patella is a sesamoid bone located in the major extensor tendon of the knee joint, in the hindlimb of many tetrapods. Although numerous aspects of knee morphology are ancient and conserved among most tetrapods, the evolutionary occurrence of the patella is highly variable. Among extant (crown clade) groups it is found in most birds, most lizards, the monotreme mammals and almost all placental mammals, but it is absent in most marsupial mammals as well as many reptiles. Here we integrate data from the literature and first-hand studies of fossil and recent skeletal remains to reconstruct the evolution of the mammalian patella. We infer that patellae most likely evolved between four to six times in crown group Mammalia: in monotremes, in the extinct multituberculates, in one or more stem-mammal genera outside of therian or eutherian mammals, and up to three times in therian mammals. Furthermore, a patella was lost several times in mammals, not including those with absent hindlimbs: once or more in marsupials (with some re-acquisition), and at least once in bats. Our inferences about patellar evolution in mammals are reciprocally informed by the existence of several human genetic conditions in which the patella is either absent or severely reduced. Clearly, development of the patella is under close genomic control, although its responsiveness to its mechanical environment is also important (and perhaps variable among taxa). Where a patella is present it plays an important role in hindlimb function; especially in resisting gravity by providing an enhanced lever system for the knee joint. Yet the evolutionary origins, persistence and modifications of a patella in diverse groups with widely varying habits and habitats -- from digging to running to aquatic, small or large body sizes, bipeds or quadrupeds -- remain complex and perplexing, impeding a conclusive synthesis of form, function, development and genetics across mammalian evolution. This meta-analysis takes an initial step toward such a synthesis by collating available data and elucidating areas of promising future inquiry.

13 Running head: Patellar evolution in mammals

14

## 15 INTRODUCTION

16

17 This meta-analysis addresses the evolution of the ossified patella (tibial sesamoid or “kneecap”  
18 bone) in mammals. We compiled voluminous literature and firsthand observational data on the  
19 presence or absence of the patella in extinct and extant mammals, then conducted phylogenetic  
20 analysis of patellar evolution by mapping these data onto a composite phylogeny of mammals  
21 (Kielan-Jaworowska et al. 2004; Luo 2007a; Luo 2007b) using multiple phylogenetic  
22 optimization methods. We used the results to address patterns of acquisition and loss of this  
23 structure within Mammaliaformes. In particular, we investigated whether an ossified patella was  
24 ancestrally present in all crown group Mammalia, and lost in particular groups especially  
25 marsupials (Metatheria), or whether it evolved multiple times in separate crown clades.  
26 Furthermore, if the patella had multiple origins, how many times was it gained or lost, and what  
27 did it become if it was lost (such as a vestigial fibrocartilage versus complete loss)? These were  
28 our study’s key questions. We provide some broader context here first.

29

30 Some aspects of the morphology of the knee in tetrapods (four-legged vertebrates bearing limbs  
31 with digits) are evolutionarily ancient. Tetrapods had their ancestry amongst lobe-finned  
32 sarcopterygian fish, in which jointed, muscular fins transitioned into limbs. Early stages of  
33 distinct bony articulations between the femur and tibia-fibula are evident in the hind fins/limbs of  
34 Devonian (~370 million years ago; Mya) animals such as *Eusthenopteron*, *Panderichthys*, and  
35 *Ichthyostega* (Ahlberg et al. 2005; Andrews & Westoll 1970; Boisvert 2005; Dye 1987; Dye  
36 2003; Haines 1942). These fossil sarcopterygians also have subtle differences between the  
37 homologous joints in the pectoral fin/forelimb and the pelvic fin/hindlimb, indicating that  
38 specification of forelimb/hindlimb identity was already in place (Boisvert 2005; Daeschler et al.  
39 2006; Shubin et al. 2006). Furthermore, the morphology of the forelimb and hindlimb joints  
40 indicates divergent functions of these limbs, with the forelimb evolving into a more  
41 “terrestrialized” capacity earlier than the hindlimb (Pierce et al. 2012). Developmental and  
42 morphological modifications to the hindlimb and particularly the mid-limb joint between the  
43 stylopod and zeugopod continued, until a recognizable knee articulation of almost modern,  
44 derived aspect arose in tetrapods of the Carboniferous period, ~350 Mya (Dye 2003).

45

46 Sesamoids are best defined as “skeletal elements that develop within a continuous band of  
47 regular dense connective tissue (tendon or ligament) adjacent to an articulation or joint”  
48 (Vickaryous & Olson 2007). The tibial patella is a sesamoid bone that arises during development  
49 within the main extensor tendon of the knee, subsequently ‘dividing’ it (though there remains  
50 some continuity) into the quadriceps and patellar tendons (the latter is sometimes inappropriately  
51 called the patellar ligament) (Bland & Ashhurst 1997; Fox et al. 2012; Pearson & Davin 1921a;  
52 Tecklenburg et al. 2006; Tria & Alicea 1995; Vickaryous & Olson 2007). These tendons span  
53 from the quadriceps muscle group to the tibia (Fig. 1). The patella itself tends to be incorporated  
54 mainly into the vastus muscles of the quadriceps in mammals, with the tendon of *M. rectus*  
55 *femoris* lying more superficial to them (Tria & Alicea 1995), with variable degrees of attachment  
56 to it (Jungers et al. 1980). Hereafter, the term patella implies ossification and hindlimb  
57 localization unless otherwise specified (some literature inconsistently and confusingly refers to  
58 non-ossified cartilaginous structures in this location as patellae), and implicitly refers to either a  
59 single patella or the left and right patellae normally present in an individual. There is an “ulnar  
60 patella” in the forelimbs of some taxa (notably lizards, but also some frogs, birds and mammals  
61 (Barnett & Lewis 1958; Haines 1940; Maisano 2002a; Maisano 2002b; Pearson & Davin 1921a;  
62 Pearson & Davin 1921b; Romer 1976; Vanden Berge & Storer 1995; Vickaryous & Olson 2007)  
63 but a full discussion of this enigmatic structure is beyond the scope of this study. Figure 2 depicts  
64 the anatomical orientations used throughout this study to refer to tetrapod limbs.

65  
66 The patella appears broadly similar amongst mammals possessing it, as far as has been studied,  
67 although it varies greatly in size, generally in accordance with body size. It ossifies  
68 endochondrally; from a cartilaginous precursor (*i.e.* anlage (Vickaryous & Olson 2007));  
69 relatively late in gestation (*e.g.* sheep, goats (Harris 1937; Parmar et al. 2009)) or sometime after  
70 birth (*e.g.* rabbits, rats, mice, humans (Bland & Ashhurst 1997; Clark & Stechschulte 1998;  
71 Patton & Kaufman 1995; Spark & Dawson 1928; Tria & Alicea 1995; Walmsley 1940)). Very  
72 recently, the development of the patella in mouse embryos was re-examined and the claim made  
73 that the patella develops as a process that branches off the femur, strongly influenced by  
74 mechanical loading in that region (Eyal et al. 2015). Whether this truly happens as described in  
75 mice, let alone other mammals, and whether it can be accepted as unexpected support for the  
76 “traction epiphysis” origin of patellar sesamoids (*e.g.* Pearson & Davin, 1921a; Pearson &

77 Davin, 1921b), remains to be determined, but the surprising results deserve attention. The  
78 general form of the mature osseous patella in mammals is a hemispherical structure, with a  
79 superficial surface (covered by fibrocartilage (Clark & Stechschulte 1998) and quadriceps tendon  
80 fibres (Bland & Ashhurst 1997)) and a deep surface which articulates with the femur, gliding  
81 along the patellar sulcus or groove in this bone. In maturity, the patella is composed of an outer  
82 lamellar cortex enclosing an inner cancellous bone structure with marrow spaces, and has an  
83 articular hyaline cartilage lining on the deep surface for articulation with the patellar sulcus  
84 (groove) of the femur (Benjamin et al. 2006; Clark & Stechschulte 1998; Vickaryous & Olson  
85 2007).

86

87 The vastus muscles' tendons (especially *M. vastus intermedius*) may have a fibrocartilaginous  
88 region at the approximate position of the patella, called the "suprapatella" or "patelloid" (Fig. 1).  
89 the latter two terms are sometimes used synonymously, though "suprapatella" is more usual  
90 when an osseous patella is also present, and "patelloid" when it is not. The suprapatella is  
91 described as proximal to the patella, occasionally with a fat pad interposed between it and the  
92 ossified patella (Fig. 1), whilst the patelloid is described as occupying the same approximate  
93 region that a bony patella would (though absence of a patella makes this difficult to objectively  
94 assess) (Bland & Ashhurst 1997; Jungers et al. 1980; Ralphs et al. 1991; Ralphs et al. 1998;  
95 Ralphs et al. 1992; Reese et al. 2001; Walji & Fasana 1983). It is not clear whether the fibrous  
96 patelloid in some marsupials (and perhaps some bats (Smith et al. 1995)) is homologous to the  
97 suprapatella, equivalent to an evolutionarily reduced patella, or an independently occurring  
98 structure.

99

100 The human patellar anlage is first visible at O'Rahilly stage 19, and chondrifies at stage 22.  
101 Ossification begins 14 weeks after birth (Merida-Velasco et al. 1997a; Merida-Velasco et al.  
102 1997b; Tria & Alicea 1995), but is not grossly visible until 4-6 years of age (when multiple,  
103 eventually-coalescing centres of ossification can be seen radiographically (Ogden 1984)) and  
104 sometimes not in its fully ossified form until adolescence. The patella is the only sesamoid bone  
105 counted regularly among the major bones of the human body (Vickaryous & Olson 2007),  
106 although there are other, much smaller sesamoids in the hands and feet (and in some cases even  
107 the spine (Scapinelli 1963)). Other small sesamoids, such as the lunula, fabella, cyamella and

108 parafibula, also occur in the knee joint in many tetrapod species including some mammals (Fig.  
109 1); these occur sporadically in humans (Pearson & Davin 1921a; Sarin et al. 1999).

110  
111 The patella is covered by the thickest layer of articular cartilage in the human body (Palastanga  
112 et al. 2006). The patella may thus also play a protective role for the underlying joint architecture  
113 (Haines 1974), in addition to protecting the patellar tendon from excessive compressive stresses  
114 (Giori et al. 1993; Sarin & Carter 2000a; Wren et al. 2000). The patellar tendon itself, to the  
115 extent that its properties are known for some species (e.g. humans), is stiff and strong, able to  
116 withstand about twice as much stress as typical knee joint ligaments and enduring strains (i.e.  
117 lengthening) of up to 11-14% (Butler et al. 1986). Regional variations in the microscopic  
118 anatomy of the human patella have also been recognised, for example in tissue thickness and  
119 nerve arrangement), which may reflect load distribution (Barton et al. 2007; Eckstein et al. 1992;  
120 Toumi et al. 2006; Toumi et al. 2012). There is convincing evidence from numerous species that  
121 excessive loads on the patella can lead to degeneration of the articular cartilages and damage to  
122 the underlying bone, leading to osteoarthritis (Aglietti & Menchetti 1995; Hargrave-Thomas et  
123 al. 2013; Tria & Alicea 1995), so those regional variations of patellar structure are likely  
124 important. Similarly, the tissues involved in anchoring the patellar tendon to the proximal and  
125 distal surfaces of the patella as well as to the proximal tibia (tuberosity/tubercle) vary in their  
126 composition and presumably are adapted, and exhibit phenotypic plasticity, to reduce the risk of  
127 tendon avulsion from the bone (Evans et al. 1991).

128  
129 Functions of the patella notwithstanding, there was once some enthusiasm for its outright  
130 removal for treatment of certain joint problems. Patellectomy was first performed in 1860 and  
131 for some time was an established treatment option for several conditions (Pailthorpe et al. 1991;  
132 Sweetnam 1964). However, partial and complete patellectomies are now considered as last resort  
133 salvage procedures; this is also the mainstream view of the veterinary profession (Langley-  
134 Hobbs 2009). The historical lack of clarity on the pros and cons of patellectomy was summarised  
135 eloquently by *The Lancet*, stating, “Sadly, most of our interventions on the patella are empirical,  
136 and are supported more by the enthusiasm of proponents than by a very deep knowledge of the  
137 biology or biomechanics of this unusual joint. The knee cap could do with more scientific  
138 attention” (Editors 1992).

139

140 The latter complaint regarding lack of scientific attention to form, development, function and  
141 clinical treatment of the patella applies even more so to non-human tetrapods. One exception is a  
142 study that measured the inter- and intra-specific variability of the patellae and other bones  
143 (Raymond & Prothero 2012). They found generally greater variation in patellae (and other  
144 sesamoids) vs. “normal” long bones. Their inference was that this greater variability might  
145 pertain to the “intermembranous” [*sic*- intramembranous] development of sesamoids, vs. an  
146 endochondral location in long bones. However, the patella and most other major limb sesamoids  
147 of mammals are pre-formed in cartilage and thus clearly are endochondral bones (Farnum 2007).  
148 Yet the latter study reinforces that sesamoids are more variable than most other bones, in part  
149 due to their mechanical environment, in part due to their embedding in soft tissues (themselves  
150 quite variable) such as tendons and ligaments (Bland & Ashhurst 1997; Clark & Stechschulte  
151 1998), and perhaps due to other factors not yet understood. This uncertainty about the causes of  
152 variability in the patella may also relate to incomplete understanding of its mechanical loading  
153 and function *in vivo*, as follows.

154

155 Where a patella is present in its typical form, its primary function is to modify the mechanical  
156 advantage (ratio of output force to muscle force) at the knee joint, by increasing the moment arm  
157 of the tendon in which it is embedded and thereby altering the amount of force needed from the  
158 quadriceps muscles in order to generate a particular moment (torque; rotational force) about the  
159 knee joint (Alexander & Dimery 1985; Fox et al. 2012; Haines 1974; Heegaard et al. 1995;  
160 Herzmark 1938; Howale & Patel 2013; Tecklenburg et al. 2006). In humans, the patella causes  
161 the quadriceps muscle group’s moment arm about the knee to increase as the knee becomes more  
162 extended, causing the amount of quadriceps muscle force required per unit of patellar tendon  
163 force (i.e. at the insertion onto the tibial tubercle) to vary significantly across knee joint flexion-  
164 extension (Aglietti & Menchetti 1995; Fellows et al. 2005). By articulating with the femur, the  
165 patella also transmits some forces of the quadriceps muscle group directly onto the femur (the  
166 patellofemoral joint reaction force); forces which can reach a maximum of 20-25 times body  
167 weight (Aglietti & Menchetti 1995).

168

169 The mobility of the patella is an important aspect of its function. While, in humans, the patella  
170 mostly flexes and extends relative to the femur as the knee is flexed and extended, it also  
171 translates and pitches (tilts) and rolls (Aglietti & Menchetti 1995; Fellows et al. 2005), leading to  
172 variable contact between the patella and femur that is reflected in the angled facets of the human  
173 patella (Lovejoy 2007). In contrast to the situation in humans (as well as in early hominins such  
174 as *Australopithecus*), in chimpanzees and presumably many other primates (as well as other taxa  
175 such as sheep (Bertollo et al. 2012; Bertollo et al. 2013)), the patella remains in tight articulation  
176 with the femur throughout the knee's range of motion, reducing patellofemoral stresses  
177 especially when the knee is strongly flexed, as it habitually is in those non-human primates  
178 (Lovejoy 2007). Other primates show varying degrees of specialization of patellar morphology  
179 that alter the moment arm of the patellar tendon, with great apes apparently having a patella most  
180 specialized for widely varying knee joint postures (Pina et al. 2014). It has been claimed that in  
181 hominids and ursids (bears) alike, there is an association between plantigrady (flat-footedness),  
182 increased knee range of motion, and patellar mechanics (Lovejoy 2007); this is an interesting  
183 hypothesis that deserves further consideration.

184

185 In the elbow of humans and other mammals, there is an extension of the ulnar bone called the  
186 olecranon (process), which serves a lever-like function analogous to that of the patella  
187 (Herzmark 1938). However, a mobile sesamoid bone like the patella has a more flexible  
188 (“dynamic gearing”) function in improving mechanical advantage compared with an immobile  
189 retroarticular process like the olecranon (Alexander & Dimery 1985). There tends to be an  
190 inverse relationship between mechanical advantage and speed of joint motion (Hildebrand 1998),  
191 thus a high mechanical advantage is not necessarily useful in all cases, which may in part explain  
192 the variable occurrence, size and shape of the patella in animals with different lifestyles and  
193 modes of locomotion. Biomechanical studies of primates (Lovejoy 2007; Pina et al. 2014) and  
194 domesticated mammalian species (*e.g.* dogs (Griffith et al. 2007; Kaiser et al. 2001), sheep  
195 (Bertollo et al. 2012; Bertollo et al. 2013), horses (Schuurman et al. 2003; Wentink 1978)) have  
196 contributed some knowledge of how the patella functions in these groups, or in individual  
197 species, but a general “functional synthesis” for the patella is still lacking.

198

199 De Vriese performed pioneering comparative analyses and attempted syntheses of patellar size  
200 and morphology in comparison to other leg bones, between species and among multiple  
201 individuals in some species (De Vriese 1909). No clear correlations were observed between the  
202 size of the patella and other major hindlimb bones (femur, tibia, and fibula). A correlation was  
203 claimed between the sizes of the patella and the talus (or intermedium) in the ankle, although no  
204 clear, plausible mechanistic/functional justification was suggested and no statistical analyses  
205 were performed. Somewhat oddly, no relationship was evident between the size and shape of the  
206 patella and the femoral patellar groove (De Vriese 1909). The more restricted but quantitative  
207 analysis of Valois (Valois 1917) focused mainly on primates and challenged many of De  
208 Vriese's claims that mechanical or physiological explanations of patellar morphology have "no  
209 scientific merit". Haxton also criticised De Vriese for focusing on relative length of bones; his  
210 own "patellar index" based on relative width found no correlation with animal speed or size, but  
211 he inferred that the patella confers functional advantages in knee extension (Haxton 1944). There  
212 has been little examination of these questions in a modern comparative, rigorously statistical  
213 context since these studies. A notable exception is a study of the distal femur and patellar groove  
214 in bovid mammals, indicating increased mechanical advantage of the knee in larger species  
215 (Kappelman 1988).

216  
217 The occurrence of an ossified patella in the knee joint is not universal among tetrapods (Fig. 3).  
218 It is absent in extinct early Tetrapoda and crown clade Lissamphibia (Dye 1987; Haines 1942;  
219 Herzmark 1938; Vickaryous & Olson 2007), all non-avian dinosaurs, Crocodylia, and Testudines  
220 (turtles), and all other extinct tetrapods. In contrast, an ossified patella is present in many or most  
221 Squamata (lizards and kin) with limbs (Camp 1923; Carrano 2000; De Vriese 1909; Dye 1987;  
222 Dye 2003; Gauthier et al. 2012; Haines 1940; Haines 1942; Hutchinson 2002; Hutchinson 2004;  
223 Jerez & Tarazona 2009; Maisano 2002a; Regnault et al. 2016; Vickaryous & Olson 2007).  
224 Patellar status (used throughout our study to refer to presence/absence) is unknown for the  
225 (mostly extinct) Rhynchocephalia (sister group to Squamata), although a patella is at least  
226 sometimes present in the tuatara *Sphenodon* – the only extant rhynchocephalian (Regnault et al.  
227 2016). An apparent sesamoid bone was noted in the knee joint region of a specimen of  
228 *Macrocnemus*, a mid-Triassic (~235 Mya) reptile, which may be the earliest identified  
229 occurrence of a patella in any animal group (Rieppel 1989), although this structure may have

230 been a different sesamoid bone or ossicle. There have been anecdotal accounts of  
231 fibrocartilaginous or “fibrovesicular” patelloids in some reptiles such as turtles and crocodiles  
232 (Haines 1940; Haines 1942; Pearson & Davin 1921a; Pearson & Davin 1921b)), but these are not  
233 well-explored. Thus, although such fibrous tissues seem to be excellent candidates for  
234 intermediate character states between “absence of ossified patella (normal extensor tendon)” and  
235 “presence of ossified patella”, empirical grounding for this transformational sequence within  
236 Sauropsida is weak.

237  
238 No patella has been observed in early, stem-group birds throughout the Jurassic and Cretaceous  
239 periods, except in the well-documented Cretaceous Hesperornithes, diving birds with vestigial  
240 wings and an extremely large and unusually shaped patella, resembling that in some extant  
241 diving birds (Lucas 1903; Marsh 1875; Martin 1984; Martin & Tate 1976; Shufeldt 1884;  
242 Thompson 1890). A patella is found in some Cenozoic fossil bird specimens, most notably  
243 archaic penguins, and commonly among many crown clade birds (Dye 1987; Dye 2003;  
244 Hutchinson 2001; Hutchinson 2002; Ksepka et al. 2012; Shufeldt 1884; Vickaryous & Olson  
245 2007; Walsh & Suarez 2006). A recent study by Regnault *et al.* inferred that a patella was  
246 probably ancestrally present in the common ancestor of Hesperornithes and living birds over 70  
247 Mya (Regnault et al. 2014). However, the patella was lost (and in some cases replaced by fatty  
248 cartilaginous tissue) in some large flightless birds such as emus, cassowaries and the extinct moa,  
249 yet unexpectedly is present as a double ossification in the knee joints of ostriches (Chadwick et  
250 al. 2014).

251  
252 A patella is generally found in two of the three crown groups of Mammalia: Eutheria (Fig. 3) and  
253 Monotremata (see Fig. 4A-D), but not in most Metatheria (see Fig. 4E, F) (Dye 1987; Dye 2003;  
254 Vickaryous & Olson 2007). This raises the question whether this patella represents independent,  
255 convergent evolutionary origins in the Eutheria and Monotremata, or an ancestral origin for all  
256 three groups, with loss of the ossified patella amongst most Metatheria. To address this question,  
257 we conducted phylogenetic character mapping with Mesquite software (Maddison & Maddison  
258 2014) that reconstructed patellar evolution in Mammalia. Using likelihood methods, we also  
259 traced the most likely pattern of evolution over existing phylogenies, and considered alternate  
260 proposed topologies to test how they affected our reconstructions. Based on the predicted

261 evolutionary patterns and individual morphologies, we propose suggestions as to the lifestyle of  
262 particular taxa, and consider where general correlations between lifestyle and patellar  
263 presence/absence might exist (or not).

264

265 Mottershead called the patella “that prince among sesamoids” but questioned whether it is “not  
266 typical of its kind” (Mottershead 1988). But is there even a “typical” patella? Our synthesis of  
267 key data from morphology and function to phylogeny, development and genetics allows us to  
268 evaluate just how “typical” any patella is, even for a mammalian patella.

269

270

## 271 MATERIALS AND METHODS

272

273 We surveyed the literature and additional specimens (see Supplementary Table S1) and coded  
274 the patella as absent (score = 0), fibrocartilaginous (i.e., “patelloid”; score = 1), or ossified (score  
275 = 2) for each taxon in our analysis, with “?” denoting an ambiguous character coding. We used  
276 two phylogenetic optimization methods in Mesquite software to reconstruct possible  
277 evolutionary polarity of the patella in the clade Mammaliaomorpha (with a focus on  
278 Mammaliaformes), as follows. First, for broad reconstruction across Tetrapoda, we used a  
279 phylogeny based on Shedlock and Edwards (2009) and Gauthier et al. (1988), with average  
280 branch lengths they derived from several studies. Some aspects of the phylogeny remain  
281 controversial, such as the position of Testudines (turtles; Hedges 2012). Reconstruction was  
282 performed using Mesquite’s parsimony algorithm and unordered character states and results are  
283 illustrated in Figure 3. As this analysis only involved major clades and not any stem lineages, it  
284 was intended as purely illustrative of general patterns and the current state of knowledge, given  
285 that patellar evolution across Tetrapoda had not been analyzed phylogenetically before.

286 We adopted composite phylogenetic trees for our study taxa (Archibald 1998; Beck 2012; Bi et  
287 al. 2014; Cardillo et al. 2004; Forasiepi et al. 2006; Gatesy et al. 2013; Goloboff et al. 2009;  
288 Kielan-Jaworowska et al. 2004; Luo et al. 2003; Luo 2007a; Luo et al. 2002; Luo 2007b; May-  
289 Collado et al. 2015; Meredith et al. 2009; Meredith et al. 2011; Mitchell et al. 2014; O’Leary et  
290 al. 2013; O’Leary & Gatesy 2008; dos Reis et al. 2012; Rose 2006; Sánchez-Villagra et al. 2007;  
291 Song et al. 2012; Spaulding et al. 2009; Springer et al. 2003; Springer et al. 2007; Springer et al.

292 2009; Thewissen 1990; Thewissen et al. 2007; Wible et al. 2007; Zack et al. 2005). As defined  
293 by several authors, the clade Mammaliaformes includes crown group Mammalia plus closely  
294 related extinct stem-mammals such as the iconic *Morganucodon* and the more recently  
295 discovered *Sinoconodon*, and is characterised by diagnostic features involving the teeth, jaw and  
296 inner ear (Kielan-Jaworowska et al. 2004; Rose 2006). Extant mammals (crown group  
297 Mammalia) include three main clades: Placentalia, Marsupialia and Monotremata. Placentalia lie  
298 within the Eutheria; Marsupialia lie within the Metatheria, and Monotremata lie within the  
299 Australosphenida, all of which diverged during the Mesozoic, pre-dating the K-Pg extinction  
300 event ~66 Mya.

301  
302 We reconstructed patellar evolution amongst Mesozoic Mammaliaformes, including key fossils  
303 with hindlimb material. The main topology used was based on Bi et al. (2014), congruent with  
304 other sources (e.g. Rose 2006; Luo 2007b; O'Leary et al. 2013). We used parsimony  
305 optimisation, with both unordered and ordered states, and maximum likelihood optimisation. We  
306 also reconstructed ancestral states over an alternative topology with †*Eomaia* placed on the  
307 therian stem (after O'Leary et al., 2013) using parsimony optimisation and unordered states.  
308 Results are illustrated in Figures 5 and S4.

309  
310 To examine these evolutionary patterns in more detail, we performed further reconstructions of  
311 ancestral states within both Metatheria and Eutheria. For Metatheria, we used topology and  
312 approximate divergence times based on (Cardillo et al. 2004, Forasiepi et al., 2006, Forasiepi,  
313 2006, Sánchez-Villagra et al., 2007, Luo et al., 2003, Meredith et al., 2009, Springer et al., 2009,  
314 Beck, 2012, Mitchell et al., 2014), and ran reconstructions with parsimony optimisation for  
315 unordered and ordered states and maximum likelihood. An alternative topology with  
316 Microbiotheriidae nested slightly further within Marsupialia (after May-Collado et al., 2015) was  
317 also explored using parsimony optimisation and unordered character states. Results for  
318 Metatheria are illustrated in Figures 6 and S5.

319  
320 For Eutheria, our topology is based on O'Leary et al. (2013) with minor modifications and  
321 reconstructed with parsimony optimisation and unordered states. Results are illustrated in Figure  
322 7. For the four major crown placental groups, *per* O'Leary *et al.* (2013), the first divergence was

323 Xenarthra, followed by Afrotheria, and finally the branching of Boreoeutheria into  
324 Laurasiatheria and Euarchontoglires. Other studies have suggested Afrotheria as the first group  
325 to diverge, followed either by Xenarthra (Springer et al. 2003; Springer et al. 2007) or  
326 Laurasiatheria (Goloboff et al. 2009) or alternatively a basal branching between Boreoeutheria  
327 and Atlantogenata (comprised of Afrotheria+Xenarthra; dos Reis et al. 2012; Meredith et al.  
328 2011; Song et al. 2012). These alternative topologies did not change our fundamental results.  
329 Divergence order within Laurasiatheria was (see Figure 7 for subgroupings): Eulipotyphla  
330 (called Lipotyphla by O’Leary *et al.* (2013); Pholidota+Palaenodonta;  
331 Carnivora+Miacidae+Creodonta (Spaulding et al. 2009); Chiroptera; Condylarthra (see below);  
332 Mesonychia; Perissodactyla; Cetartiodactyla. Within Euarchontoglires, the order of divergence  
333 was (see figure for subgroupings): (Scandentia+Dermoptera)+Primates; (Glires+Rodentia).  
334 Regarding individual species, *Leptictidium* was placed with Macroscelidea based on its relation  
335 to the mapped *Leptictis*; *Carodnia* was placed within Afrotheria; Mesonychia (*Mesonyx et al.*)  
336 were placed between Euungulata (Perissodactyla and Cerartiodactyla) and Chiroptera;  
337 *Protungulatum* was placed between Mesonychia and Chiroptera. Among species broadly  
338 described as “condylarths”, *Phenacodus* (albeit a likely perissodactyl), *Hyopsodus*, *Tetraclaenus*  
339 and *Copecion* were grouped together (Thewissen 1990); *Mioclaenus* was grouped with  
340 *Hyopsodus* (Zack et al. 2005); *Meniscotherium* was grouped with *Phenacodus* (Wible et al.  
341 2007); *Arctocyon* and *Chriacus* were grouped together and with other condylarths (Archibald  
342 1998). O’Leary *et al.* (2013) placed *Notharctus* just outside Primates, but noted that this was  
343 possibly incorrect as they did not include other notharctids, therefore Notharctidae were here  
344 placed within Primates. *Plesiadapis* was placed as the sister taxon to Primates. O’Leary *et al.*  
345 (2013) placed *Rodhocetus* basal to Cetartiodactyla, but *Artiocetus* and *Basilosaurus* as basal  
346 Cetacea. For consistency with other studies including additional archaic Cetacea (O’Leary &  
347 Gatesy 2008; Thewissen et al. 2007), *Rodhocetus* was retained within the stem cetaceans (Gatesy  
348 et al. 2013). Additional archaic Perissodactyla and Artiodactyla not included in O’Leary *et al.*  
349 (2013) were here grouped with included group members. Additional stem placentals, including  
350 Taeniodonta, Pantodonta, Dinocerata and selected individual species, were not included in the  
351 study of O’Leary *et al.* (2013) and here were placed equally as stem groups. O’Leary *et al.*  
352 (2013) placed *Protolipterna* basal to Euungulata, but do not incorporate other archaic South  
353 American ungulates, whereas this study did not include Litopterna. Pending more analysis,

354 Notoungulata were here placed as stem placentals. Tillodontia, another stem placental group,  
355 was not included in this study due to lack of identified specimens with sufficient hindlimb  
356 material.

357  
358 Our analysis involved numerous challenges and caveats. Many anatomical studies of extant or  
359 extinct species omit any mention of the patella, leaving its provenance in these taxa as uncertain.  
360 Interpretation of patellar status is especially challenging in fossils due to the rarity of finds with  
361 extensive, articulated postcranial material, the potential occurrence of other small non-patellar  
362 bones in the knee joint, and the uncertain age of the animal at time of death versus the  
363 developmental timing of sesamoid ossification (usually unknown; often relatively late in  
364 ontogeny). For the present analysis, statements in the primary literature regarding patellar status  
365 were generally accepted at face value except when superseded by more recent observations.  
366 From some publications with high quality photographs, patellar status was tentatively interpreted  
367 even if not discussed in the original text. In some cases, patellar status was confirmed by direct  
368 observation (e.g. Fig. 4; Figs. S1-S3; Table S1). Drawings found in secondary citations were  
369 mostly not been taken as definitive evidence, as we noticed examples of discrepancies between  
370 primary references and such drawings found in review articles or even textbooks, which may  
371 simply assume patellar status in mammals. Also, many mammalian groups are found over long  
372 temporal and geological spans, thus we were cautious about using the presence of a patella in  
373 one or a few individual extant or fossil specimens to infer presence throughout the group,  
374 although in some cases there was clearly enough conservatism within a clade to score it for all  
375 members.

376  
377 An important knee structure related to the patella is the femoral patellar or intercondylar sulcus  
378 (groove) (Norell & Clarke 2001; Polly 2007). This sulcus is anatomically associated with a true  
379 patella (Figs. 1,4) in terms of its direct role in guiding the patellar sesamoid and tendon's path of  
380 movement during leg flexion/extension, and in mediolaterally confining the patellar tendon,  
381 which may enhance osteogenic stresses favouring the formation of a patella (Sarin & Carter  
382 2000b; Wren et al. 2000). In the absence of an observed patella in fossil specimens, this sulcus at  
383 the distal end of the femur is sometimes treated as evidence of a patella even in the absence of  
384 the observed bone itself. We deemed this conclusion to be unwarranted. For example, the

385 evolution of a patellar sulcus in early pygostylian birds substantially predated the evolution of an  
386 ossified patella in later ornithurine birds; moreover the sulcus was retained in some avian taxa  
387 that lost the patella (Clarke & Norell 2002; Hutchinson 2002; Livezey & Zusi 2006; Regnault et  
388 al. 2014). In contrast, a prominent sulcus is absent in many Squamata despite the presence of a  
389 patella (S.R. and J.R.H., pers. obs.). Together these observations indicate that these two  
390 anatomical features are not obligatorily coupled, so reliance on the observed presence of an  
391 ossified patella in fossil specimens was warranted. Nonetheless, at least among mammals the  
392 complete absence of a femoral patellar sulcus might be indicative of the absence of an ossified  
393 patella (Chester et al. 2012).

394

395

## 396 RESULTS AND DISCUSSION

397

398 Our overall evolutionary reconstruction of the patella for Mesozoic mammals is shown in Fig. 5,  
399 for Metatheria/Marsupialia in Fig. 6, and for Cenozoic Eutheria/Placentalia in Fig. 7, with details  
400 for specific taxa in Table S1 and alternative phylogenetic analyses in Figs. S4 and S5. Here we  
401 sequentially summarize and discuss our findings for five subgroups of Mammaliaforma  
402 (especially Mammaliaformes): (1) Mesozoic pre-therians and stem-therians; (2) Mesozoic  
403 Metatheria and Eutheria; (3) Cenozoic Monotremata; (4) Cenozoic Metatheria, and (5) Cenozoic  
404 Eutheria. We then conclude with a general synthesis of our study's insights (as well as  
405 uncertainties) and a consideration of how available and emerging data on developmental genetics  
406 of the patella might help shed light on the "evo-devo" of the patella, augmenting the  
407 phylogenetic and anatomical insights that this study focuses on.

408

### 409 1. Mesozoic pre-therian and stem-therian mammals

410 The earliest mammals as widely construed include *Sinoconodon*, the Morganucodonta and  
411 Docodonta. These were mostly small, probably insectivorous animals, that appear to have lacked  
412 a patella, although it is unclear whether the known specimens contain sufficient postcranial  
413 material or are from verified adults, to allow for definitive conclusions. The absence of a clear  
414 patella in two stunningly preserved docodonts (the scansorial [climbing-adapted] *Agilodocodon*  
415 and fossorial [digging-adapted] *Docofossor*) lends credence to the conclusion that it was

416 generally absent in early mammalians (Luo et al. 2015b; Meng et al. 2015). There is  
417 convincingly strong evidence of absence of a patella in earlier pre-mammals in lineages dating  
418 from the divergence of Synapsida and Sauropsida/Reptilia (~320 Mya), including the ancestral  
419 “pelycosaurs”, therapsids and cynodonts (Kemp 2005).

420

421 Australosphenida, the clade containing and thus ancestral to extant Monotremata, diverged from  
422 other mammals extremely early, possibly in the mid-Jurassic (Kielan-Jaworowska et al. 2004).

423 There is little postcranial material for any extinct members of this lineage however, and no  
424 hindlimbs (Kemp 2005). The patella in crown clade monotremes will be discussed below.

425

426 *Fruitafossor*, from the late Jurassic (150 Mya), diverged after the Australosphenida (Luo &  
427 Wible 2005). Its relationship to other early mammals is complicated by its mixture of characters  
428 in the molar teeth, middle ear and elsewhere. *Fruitafossor* is described as lacking a patella, and it  
429 is proposed to have had a fossorial lifestyle.

430

431 The Eutriconodonta were found abundantly across the world from the middle Jurassic to early  
432 Cretaceous periods (Kielan-Jaworowska et al. 2004). Among eutriconodonts, a poorly developed  
433 distal femoral patellar groove is found but a patella is absent.

434

435 The Allotheria were an extremely successful and widely dispersed group of mammals, among  
436 which the best understood are the multituberculates (Kielan-Jaworowska et al. 2004; Wilson et  
437 al. 2012). Generally Allotheria are found from the late Triassic to the Eocene periods, thus this  
438 group spans much of the heyday of the (classic) dinosaurs, and survived the K-Pg extinction  
439 (Kielan-Jaworowska et al. 2004). Multituberculates were predominantly small animals, either  
440 herbivorous or omnivorous (Kielan-Jaworowska et al. 2004). A patella is noted for the nearly  
441 complete multituberculate *Ptilodus*, a proposed scansorial animal from the early Cenozoic. A  
442 patella is also present in the Cretaceous multituberculate *Chulsanbaatar*. It is unclear whether a  
443 patella is typical of all members of the multituberculate group and is under-reported due to lack  
444 of hindlimb material for most group members, or whether it occurs only among selected species,  
445 although the former seems more plausible. A patella is not reported, however, for the early  
446 Jurassic basal *Rugosodon*, a proposed multituberculate specimen with one relatively intact knee

447 joint (Yuan et al. 2013), so it is conceivable that an ossified patella evolved later within the  
448 Allotheria (Fig. 5).

449  
450 Specimens of the diverse group “Haramiyida” are mostly restricted to cranial material, and the  
451 relationship of this ancient group to other Allotheria and Mammaliaformes has been  
452 controversial (Butler 2000; Kielan-Jaworowska et al. 2004; Rose 2006). However, several  
453 recently described more complete haramiyid specimens from the Jurassic with at least one  
454 preserved knee joint lack a patella (Bi et al. 2014; Zheng et al. 2013; Zhou et al. 2013). These  
455 new specimens have been interpreted to support an Allotheria clade including a paraphyletic  
456 “Haramiyida” (but a valid clade Euharamiyida including many “haramiyid” taxa) and  
457 Multituberculata (Fig. 5), although new analyses of a key specimen of *Haramiyavia* concluded  
458 that the haramiyids and multituberculates are not closely related (Luo et al. 2015a). The inclusion  
459 of the “Euharamiyida” in Allotheria pushes the divergence date of the group significantly earlier  
460 into the late Triassic, whereas multituberculates themselves appear only in the middle to late  
461 Jurassic. Final resolution of this controversy will undoubtedly require additional fossil material.

462  
463 Symmetrodonta were a group of diverse, small mammals widely distributed in time from the late  
464 Triassic to the late Cretaceous (Kielan-Jaworowska et al. 2004). In the subgroup of  
465 spalacotheroids, a patella is reported for one fairly complete specimen (*Zhangheotherium*) but  
466 not for another (*Akidolestes*) (Chen & Luo 2012; Luo & Ji 2005) (these two specimens are coded  
467 oppositely in character matrices in some subsequent publications, probably in error (Bi et al.  
468 2014; Zhou et al. 2013)); a patella was absent in *Maotherium*.

469  
470 Eupantotheria was a diverse group found commonly from the mid-Jurassic to the early  
471 Cretaceous (Kielan-Jaworowska et al. 2004). The patella is reported as absent in both an early  
472 European specimen (*Henkelotherium*, late Jurassic) and a later South American specimen  
473 (*Vincelestes*, early Cretaceous) (Fig. 5). Of the large group of dryolestid Eupantotheria, which  
474 possibly survived past the K-Pg boundary, patellar status is unknown.

475

476 The tribotherians were the earliest-diverging group to share key molar features with the therians.  
477 However, no postcranial specimens have been reported; thus nothing is known of their patellar  
478 morphology (Kielan-Jaworowska et al. 2004).

479  
480 The single specimen of *Juramaia* from the Jurassic (~160 Mya) unfortunately lacks hindlimb  
481 material; therefore its patellar status is unknown. Based on its forelimb, *Juramaia* is proposed to  
482 have been scansorial or possibly arboreal (Luo et al. 2011). The later specimen of *Eomaia* from  
483 the early Cretaceous includes all limb elements, and is described with a patella (Ji et al. 2002).  
484 Based on limb and foot features, *Eomaia* was probably scansorial or arboreal. In the original  
485 publication, *Eomaia* was described as the earliest eutherian mammal (Fig. 5), however a more  
486 recent and much more extensive analysis confidently placed *Eomaia* prior to the  
487 eutherian/metatherian divergence (O'Leary et al. 2013) and thus at least as a stem member of the  
488 clade Theria (see Figure S4). *Eomaia* (and presumably *Juramaia*) postdate the divergence of the  
489 Symmetrodonta, but their positions relative to the Eupantotheria remain to be determined, as  
490 does any close relationship between these two key taxa. Lacking a better alternative, here we  
491 refer to these taxa as “Theria”, and in Fig. 5 vs. Fig. S4, consider the consequences of *Eomaia*'s  
492 phylogenetic position on our conclusions.

493  
494 In surveying the available data mapped onto our composite phylogeny (Figs. 5, S4), it becomes  
495 evident that an ossified patella evolved multiple times (at least four) along the mammalian stem  
496 lineages during the Mesozoic era, whether using parsimony or maximum likelihood optimisation  
497 methods: at some highly uncertain time in the long mammalian lineage that led to Monotremata,  
498 in multituberculates/Allotheria, in *Zhangheotherium* or a direct ancestor, and likely twice (or  
499 between one to three times, depending on the placement of *Eomaia*; See Figs. 5 and S4) in the  
500 clade containing *Eomaia* and Theria (Metatheria and Eutheria). This remains the same if the  
501 Euharamiyida are not included with multituberculates but pre-dated crown Mammalia, as  
502 suggested by some recent studies (e.g. Luo et al. 2015a).

503

## 504 2. Mesozoic Metatheria and Eutheria

505 The two major extant mammalian groups, the Metatheria and Eutheria (together forming the  
506 clade Theria), diverged as early as the Jurassic (Fig. 5). The earliest fossil defined as

507 metatherian, *Sinodelphys*, dates from the early Cretaceous of China (125 Mya, approximately  
508 contemporary to *Eomaia*), and lacks a patella (Luo et al. 2003). A patella also seems absent in  
509 the less complete Cretaceous metatherian *Asiatherium* (Szalay & Trofimov 1996).

510  
511 The earliest occurrences of the patella in definitive eutherians (Figs. 5,7) are in the late  
512 Cretaceous *Ukhaatherium* (Horovitz 2003), a relatively unspecialized form, and in  
513 *Zalambdalestes* (Wible et al. 2005), a more specialized taxon sometimes described as resembling  
514 later lagomorphs (Rose 2006). Patellar status at the crown group node for Theria (plus *Eomaia*)  
515 remains ambiguous (Figs. 5,6,S4), as we consider below.

516

### 517 3. Cenozoic Monotremata

518 The origins of the Monotremata (egg-laying mammals) are poorly understood. They are  
519 considered extant members of the clade Australosphenida (the alternative term Prototheria has  
520 been superseded), and hence with early roots in the Mesozoic. Molecular studies based on the  
521 sequenced genome of the platypus corroborate the long held interpretation that the monotremes  
522 diverged prior to the metatherian/eutherian split, consistent with proposed fossil-based  
523 phylogenies (Warren et al. 2008). Unfortunately, there are almost no reported hindlimb  
524 specimens of any extinct monotreme (including probable early monotreme fossils found in South  
525 America; (Musser 2003)), with the exception of the Pleistocene *Zaglossus* (echidna) from  
526 Australia and New Guinea (which may be the same as the extant species of that name).  
527 Unfortunately, although fossil *Zaglossus* hindlimb elements exist, including an articulated knee,  
528 neither presence nor absence of the patella has been reported (Murray 1984). The extant  
529 monotremes, the platypus (*Ornithorhynchus anatinus*) and the echidnas (Tachyglossidae, two  
530 genera *Zaglossus* and *Tachyglossus*; four known species) all have substantial patellae (see Fig.  
531 4A, B, C, D) (Herzmark 1938; Rowe 1988). It is unclear when the two extant monotreme genera  
532 diverged although a date early in the Cretaceous has been proposed (Rowe et al. 2008), and it is  
533 impossible for now to date the appearance of the patella in the monotreme lineage. Regardless,  
534 an ossified patella is homologous for this crown clade (Fig. 5), and alternative phylogenetic  
535 topologies do not change the general pattern of patellar evolution (Fig. S4).

536

### 537 4. Cenozoic Metatheria

538 All extant Metatheria are within the subgroup of Marsupialia, however non-marsupials did exist  
539 earlier during the Cenozoic. As documented in the pioneering study of sesamoids in Marsupialia  
540 by Reese et al. (2001), the patella is absent in the great majority of extant marsupial species, both  
541 from Australia and the Americas (Flores 2009; Herzmark 1938; Holladay et al. 1990; Reese et al.  
542 2001; Rose 2006; Rowe 1988), including the sole surviving North American marsupial, the  
543 North American opossum (*Didelphis virginiana*, see Fig. 4E, F showing tendon lacking a true  
544 patella. Many marsupials have other sesamoids in the knee region (e.g. the parafibula, lateral  
545 sesamoid, or “sesamoid bone of Vesalli”), as well as a fibrocartilaginous “patelloid”, which may  
546 to some degree serve the mechanical function of a bony patella (Reese et al. 2001). However, the  
547 mechanics of a fibrous or bony patella remain essentially unstudied (to our knowledge) in non-  
548 placental mammals, so this is simply speculation. Studies have claimed some association  
549 between reduction of the patella in many marsupials and locomotor style or ecology (Holladay et  
550 al. 1990; Reese et al. 2001), but these deserve testing with more detailed sampling across  
551 phylogeny and ontogeny.

552

553 Nonetheless, a true, ossified patella is found in a small number of extant marsupial species  
554 among otherwise divergent clades, both from Australia: at least several Peramelidae or  
555 bandicoots, and the two marsupial mole species of *Notoryctes*); and from South America:  
556 *Tarsipes*, an opossum; and several, and possibly all, Caenolestidae or shrew opossums (see Fig.  
557 6: note collapse of several large clades in terms of total number of species, in which no species  
558 have been shown to possess a patella; Table S1).

559

560 Possibly uniquely among crown clade marsupials, bandicoots also possess a chorioallantois  
561 fused to the uterine epithelium (i.e. a true placenta) (Freyer et al. 2003; Padykula & Taylor  
562 1976), which combined with a patella led to the initial suggestion that they might actually be  
563 eutherians (Reese et al. 2001). However, more recent molecular and fossil-based phylogenetic  
564 studies provide no support for that hypothesis of eutherian bandicoots (Asher et al. 2004;  
565 Meredith et al. 2008b; Sanchez-Villagra et al. 2007; Westerman et al. 2012). Bandicoots clearly  
566 are metatherians, and their chorioallantois is thus a convergently evolved trait rather than  
567 plesiomorphic. It remains to be determined whether a patella is present in all or only some  
568 bandicoots, as so far it is only reported in the Peramelinae of dry or temperate forests of

569 Australia, not yet in the Peroryctinae of tropical rainforests of New Guinea, or the more distantly  
570 related bilbies (Groves & Flannery 1990; Meredith et al. 2008a; Westerman et al. 2012).

571 Similarly, a comprehensive study of the Caenolestidae remains to be performed, much as a more  
572 thorough study of the major marsupial clade Diprotodontia (wombats, kangaroos and kin) is  
573 needed.

574

575 Not surprisingly given the absence of a patella in most extant marsupials, the patella is absent in  
576 the early Cenozoic Metatheria *Pucadelphys*, *Mayulestes*, and the later *Herpetotherium*.

577 Unexpectedly, a patella is reliably reported in the Borhyaenoidea, an unusual group of dog-like  
578 carnivorous South American marsupials found from the Paleocene through the Miocene (Argot  
579 2002; Argot 2003a; Argot 2003b; Argot 2003c; Argot 2004; Argot & Babot 2011; de Muizon et  
580 al. 1997). Patellar status in some members of Borhyaenoidea (*e.g.* *Borhyaena* itself and *Lycopsis*  
581 (*Argot 2004*)), and in the more inclusive group Sparassodonta, is uncertain due to the incomplete  
582 state of specimens (C. Argot, pers. comm.) Szalay and Sargis (2001) noted other enigmatic  
583 fossils from the Palaeocene of Brazil that they assigned to Metatheria, but the phylogenetic  
584 relationships of those fragmentary remains are unclear and no patellae were shown (Szalay &  
585 Sargis 2001). However, no patella is reported in extant or recent carnivorous marsupials such as  
586 *Thylacinus*, thus it is not obligatorily correlated with that particular ecological adaptation.

587

588 Two related, pernicious problems remain for interpreting the evolution of the patella in  
589 Metatheria that may have ramifications for all of Mammalia/Mammaliaformes. First, Szalay and  
590 Sargis (2001:pp.164-5) reported the presence of an ossified patella in older individuals of  
591 *Didelphis virginiana* in their study of an ontogenetic series from this species. They stated (p.165)  
592 “In older individuals there is occasionally an elongated and small sesamoid ossification within  
593 the tendon of the quadriceps femoris where it crosses the knee joint when the knee is flexed.”  
594 However, this observation was not documented with illustrations or photographs (especially  
595 tissue histology or x-rays) and hence remains simply tantalizing. Similarly, Owen (Owen 1866)  
596 commented that some marsupials had no ossifications in their patellar tendon but others had  
597 “only a few irregular specks of ossification” and a “distinct but small bony patella in the  
598 *Macropus Bennettii*.” In contrast, Reese et al. (2001) and Holladay et al. (1990) respectively  
599 sampled 61 specimens (~39 adults) from 30 species of marsupials and 3 macropodid specimens

600 (of unknown maturity), documenting no ossified patellae except as noted in bandicoots  
601 (Holladay et al. 1990; Reese et al. 2001). It remains possible that patellar ossification occurs  
602 variably in older individuals among Metatheria, which would help explain its patchy description  
603 in known taxa.

604  
605 If the latter situation is the case (i.e., the literature is unclear about patellar ossification in  
606 marsupials because they have more inherent variability), then it relates to a second problem, a  
607 cladistic one of character coding and transformational homology (*sensu* (Brower & Schawaroch  
608 1996; Pinna 1991). Should character states of the patella in metatherians, or even all mammals  
609 and their kin, be coded as an ordered transformational series such as absent (0),  
610 fibrocartilaginous (1) or ossified (2), or as an unordered series (i.e. should evolutionary steps be  
611 required to go from 0-1-2 as 2 steps, or unordered allowing 0-2 transformations as 1 step)? We  
612 chose the unordered character option by default for all crown group mammals, but the legends  
613 for Figs. 5-7 explain how an ordered option changes (or does not change) our results. An  
614 endochondral ossification of the patella is certain, but a fibrocartilaginous or otherwise soft tissue  
615 composition of the patella (coded as state 1) is not unambiguously the necessary (i.e. ordered)  
616 precursor character state to state 2 (ossified patella in adults). The solution to both of these  
617 problems lies in more developmental data for the patella in diverse mammalian species, in  
618 addition to more scrutiny of the adult morphology in extant and fossil Mammalia (especially  
619 Metatheria).

620  
621 As noted briefly in the Introduction, many marsupials have a primarily fibrocartilaginous  
622 patelloid in place of an ossified patella and some other mammals may have a “suprapatella”. The  
623 developmental and evolutionary relationships of these structures remain somewhat unclear,  
624 particularly as some marsupials with an ossified patella (*e.g.* bandicoots) also possess a patelloid  
625 (Reese et al., 2001), suggesting that the patelloid is not developmentally equivalent to the patella  
626 in marsupials (Vickaryous & Olson 2007). If so, this would suggest independent evolutionary  
627 histories of these two structures. Further work is required to clarify the relationships of the  
628 patelloid and suprapatella at least in extant taxa, before definitive evolutionary trajectories can be  
629 inferred.

630

631 A non-osseous patelloid/suprapatella is also found in several closely related modern placental  
632 clades that lie far from the base of Eutheria (Fig. 7), suggesting that these represent independent  
633 acquisitions. We have not attempted to explicitly reconstruct the evolution of the patelloid in  
634 Eutheria. Lewis (1958) and Broome and Houghton (1989) speculated that the mammalian  
635 patelloid might be a precursor to the tibial epiphysis (Broome & Houghton 1989; Lewis 1958) --  
636 a so-called “traction epiphysis” (Vickaryous & Olson 2007) -- but considering that the patelloid  
637 evolved after the tibial tuberosity (and proximal epiphysis) of mammals, not before it, and lies  
638 proximal rather than distal to the patella, we reject this hypothesis. Furthermore, this same  
639 phylogenetic evidence indicates that the patelloid in Euarchontoglires, some Carnivora and  
640 bandicoots is not ancestrally associated with leaping or other behaviours (e.g. Jungers et al.,  
641 1980)-- as Walji & Fasana (1983) caution, its ancestral mechanical environment and roles in  
642 different behaviours remain unclear, although it does seem to be associated with knee  
643 hyperflexion like a typical fibrocartilaginous “wrap-around” tendon (e.g. Ralphs et al. 1991;  
644 Alexander & Dimery, 1985).

645  
646 Our unordered parsimony reconstruction indicated that an ossified patella was absent in the  
647 ancestor of Metatheria, then evolved in the ancestor of Borhyaenoidea and Marsupialia. The  
648 most likely pattern shows loss of the patella in the basal lineages of Marsupialia, with subsequent  
649 re-acquisition in certain groups (Notoryctidae, possibly with Thylacomyidae + Peramelidae, and  
650 Tarsipedidae) (Fig. 6). Ordered parsimony reconstruction resulted in subtle differences; making  
651 some nodes less ambiguous (i.e. state 1 within basal Marsupialia) and others more ambiguous  
652 (such as the ancestor of Borhyaenoidea and Marsupialia, which becomes equally parsimonious  
653 between states 1 and 2). In contrast, Maximum likelihood reconstruction suggested multiple  
654 evolutions of the osseous patella in Metatheria, perhaps preceded in some taxa by a patelloid, but  
655 this is unclear. Because presence of a patelloid has not been clearly excluded in some extant  
656 marsupials (e.g. Petauridae, Acrobatidae) and is unlikely to be fossilised, its reconstruction must  
657 be treated carefully. Finally, alternative placement of Microbiotheriidae did not drastically alter  
658 the reconstructions (Fig. S5).

659

660 *5. Cenozoic Eutheria*

661 The Placentalia include all extant Eutheria as well as some fossil stem taxa (Fig. 7). Although  
662 there is some fossil evidence for placentals pre-dating the K-Pg event (Archibald et al. 2011), as  
663 well as substantial molecular dating consistent with an older placental radiation, the timing of the  
664 placental radiation remains highly controversial. However, our major conclusions about patellar  
665 evolution in placentals are not dependent on how this controversy is ultimately resolved, as a  
666 recent large-scale phylogenetic analysis convincingly established the presence of a patella as a  
667 derived character state in the ancestral placental irrespective of its true date of divergence  
668 (O'Leary et al. 2013).

669  
670 Fossil evidence supports the presence of the patella in essentially all Cenozoic placental groups  
671 (Fig. 7; also see Table S1 and Figs. S1-S3, with citations therein). Specimens with sufficient  
672 hindlimb material to make a determination of the patella are rare in the early Cenozoic Paleogene  
673 period (~66-23 Mya), but Paleocene groups in which a patella has been reported include the  
674 Taeniodonta (small to medium sized fossorial animals), Pantodonta (early herbivores),  
675 Palaeonodonta (small, possible insectivores; perhaps related to pangolins), “Condylarthra” (a  
676 diverse assemblage of putatively related taxa, probably polyphyletic, including both herbivores  
677 and carnivores, many of which may be stem members of subclades within the placental crown  
678 group), and the important Plesiadapiformes, a sister group to crown clade primates (and possibly  
679 members of the clade Primates as well) (Bloch & Boyer 2007; Silcox 2007). In general, the  
680 evolutionary relationships between Paleocene taxa and more recent placentals remain enigmatic.

681  
682 Eocene placentals include examples whose close relationships to modern groups are well  
683 accepted. Among Eocene groups (Fig. 7, Table S1), a patella has been reported in older, extinct  
684 groups such as “Condylarthra”, Creodonta (carnivores), Mesonychia (carnivorous/omnivorous  
685 artiodactyls or cetartiodactyls), Dinocerata (large rhinoceros-like herbivores), Brontotheriidae  
686 (large equid-like herbivores), and Notoungulata (fairly diverse South American hoofed  
687 herbivores; probably related to Afrotheria) (O'Leary et al. 2013), as well as in extinct species (in  
688 parentheses, see Table S1 for citations) recognized as stem members of several extant groups:  
689 Glires (*Rhombomylus*), Perissodactyla (*Propalaotherium*), early Sirenia retaining hindlimbs  
690 (*Pesoziren*, *Protosiren*), Proboscidea (*Numidotherium*, *Moeritherium*, *Barytherium*), Rodentia  
691 (the horse-sized *Pseudotomus*, *Paramys*), Pholidota (*Eomanis*), Artiodactyla (*Gervachoerus*),

692 early Cetacea retaining hindlimbs (*Maiacetus*) and Chiroptera (*Icaronycteris*, *Tachypteron*). A  
693 patella is also reported for several Eocene primates, including the lemur-like Notharctidae  
694 (*Northarctus*) and the tarsier-like *Omomys* and *Archicebus*, in addition to the enigmatic primate  
695 *Darwinius*.

696  
697 Despite an extensive literature search, we found no reports attesting to the presence of the patella  
698 in certain important and widely cited Paleocene and Eocene species, including: *Protungulatum*,  
699 frequently cited as the earliest true placental; *Miacis*, *Vulpavus*, *Viverravus* and *Didymictis*,  
700 which are stem Carnivora (Gregory 1920; Heinrich & Houde 2006; Heinrich & Rose 1995;  
701 Heinrich & Rose 1997; Samuels et al. 2013); *Pakicetus*, a fully quadrupedal early cetacean  
702 (though sometimes reconstructed with a patella as in Fig. 7 and Fig. S1 M, N) (Thewissen et al.  
703 2001); *Leptictis*, possibly related to crown clade lagomorphs (Rose 1999); *Sinopa*, a creodont  
704 (Matthew 1906); and the early primates *Adapis*, *Leptadapis*, *Teilhardina*, and *Cantius* (Dagosto  
705 1983; Gebo et al. 2012a; Gebo et al. 2012b; Rose & Walker 1985; Schlosser 1887; Szalay et al.  
706 1975). There is no reason to expect that the patella is missing in these species. These absences  
707 are more likely due to incompleteness of the fossil record and/or literature descriptions and  
708 images. Moreover, the massive collections of Eocene specimens from the Messel and Green  
709 River lagerstätten in Germany and Wyoming have not yet been fully described (Grande 1984;  
710 Schaal & Ziegler 1992). There are many examples of the patella in specimens from extant  
711 placental groups across the more recent Miocene, Oligocene, Pliocene and Pleistocene, but a  
712 comprehensive search of the literature for those geologic epochs was deemed redundant for our  
713 major conclusions.

714  
715 Based on fossil evidence plus extensive genomic DNA sequencing, there is a consensus that  
716 crown clade placentals can be historically and geographically defined by four major groups:  
717 Xenarthra, Afrotheria, Euarchontoglires (further divided into Euarchonta; featuring Primates;  
718 and Glires) and Laurasiatheria (Rose 2006). These in turn may be resolved, with somewhat less  
719 consensus, into 19 crown clade “orders” (Fig. 7) (O’Leary et al. 2013). In two of these orders, the  
720 afrotherian clade Sirenia and the cetacean branch of (Cet)artiodactyla (laurasiatherian clade),  
721 extant members have extensively reduced or absent hindlimbs and thus lack skeletal knee  
722 structures, including a patella. In contrast, the patella is retained among the aquatic seals and sea

723 lions in Carnivora, although unlike Sirenia and Cetacea these animals still display some  
724 terrestrial habits and thus presumably still employ the antigravity mechanism that the patella is  
725 involved in at the knee. A patella is documented as present in at least some members of all other  
726 17 placental “orders” (e.g. Figs. 7,S1-S3,4G,H; Table S1) (de Panafieu & Gries 2007; De Vriese  
727 1909; Dye 1987; Herzmark 1938; Lessertisseur & Saban 1867; Rose 2006).

728

729 The evolution of the Cetacea presents an interesting scenario regarding patellar evolution (Fig.  
730 7). Cetaceans evolved from a common ancestor with other (cet)artiodactyls (Spaulding et al.  
731 2009; Thewissen et al. 2007). Early members, *Diacodexis* and *Indohyus*, shared morphological  
732 similarities with both extant groups of Cetacea (toothed and baleen whales) and yet retained a  
733 patella (Rose 1982; Thewissen et al. 2007), much as stem Sirenia did (Domning 2001; Zalmout  
734 2008). Patellar status in *Pakicetus*, a presumptive early cetacean with full hindlimbs, remains  
735 uncertain based on the primary literature, but presence is likely considering the presence of a  
736 patella in its closest relatives. *Rodhocetus* and *Ambulocetus*, probably semi-aquatic early  
737 cetaceans, still had large hindlimbs and patellae (Madar et al. 2002). The pelvis and hindlimbs  
738 are greatly reduced in the later cetaceans *Dorudon* and *Basilosaurus*, but a patella is still present  
739 in these animals (Gingerich et al. 1990; Uhen 2004). It is not clear exactly when the patella was  
740 lost in later cetaceans with increasingly reduced hindlimbs.

741

742 Bats present another interesting case of patellar evolution (Fig. 7; Table S1). The patella is  
743 generally present in bats (Pearson & Davin 1921b). A patella is also reported in a well-preserved  
744 hindlimb of an early Eocene bat, *Icaronycteris*, of intermediate form but proposed to be a  
745 microchiropteran (Jepsen 1966). However, in studies of multiple genera of modern bats  
746 including members from both of the major subgroups Megachiroptera and Microchiroptera  
747 (which is possibly paraphyletic), a patella was noted as absent in four species of the  
748 megachiropteran *Pteropus* (flying foxes of various sizes), and a few individual species of  
749 *Cephalotes*, *Epomophorus* and *Vespertilio* (De Vriese 1909; Lessertisseur & Saban 1867; Smith  
750 et al. 1995). No obvious lifestyle distinction was noted for the *Pteropus* genus as compared to  
751 many other bats, hence the loss of the patella in members of this particular subgroup (and others)  
752 remains mysterious. In general, bat hindlimbs are highly derived, adapted to hanging and pulling  
753 rather than pushing. A few bats such as the vampire bats are actively quadrupedal (Adams &

754 Thibault 2000; Riskin & Hermanson 2005). Bat hindlimbs are articulated in abduction, so that  
755 the knee faces dorsally; as in the original ancestral orientation for Tetrapoda (Fig. 2) (Neuweiler  
756 2000; Schutt & Simmons 2006). There remains a need for a comprehensive study of the patella  
757 in bats (Smith *et al.* only studied 31 specimens of 13 species), but this is challenging due to the  
758 existence of >900 extant bat species (Jones et al. 2002). The microstructure of the “patelloid” in  
759 *Pteropus* is generally similar to that in many marsupials (e.g. deep layer of fibrocartilage;  
760 superficial layer of dense connective tissue contiguous with the quadriceps/patellar tendon)  
761 (Smith et al. 1995). This also raises the question of whether the patella only ossifies later in  
762 adulthood in *Pteropus*, rather than not ossifying at all.

763

#### 764 *General evolutionary patterns and ambiguities*

765 Considering the above distributions of patellar presence/absence in Mammalia (Figs. 5-7; Figs.  
766 S4,S5) and our data matrix (Table S1), the simplest interpretation of the evolutionary record of  
767 the patella in mammals (by parsimony-based mapping of presence/absence) is that this structure  
768 arose independently at least four times (but possibly up to six), mostly during the Mesozoic era:  
769 1, in Australosphenida ancestral to modern monotremes; 2, in Multituberculata (later than  
770 *Rugosodon*); 3, in Symmetrodonta (specifically in Spalacotheroidea that were ancestral to  
771 *Zhangheotherium* but not *Akidolestes*); 4-6, in early Theria (including Eutheria, Metatheria,  
772 *Eomaia* and related stem groups; depending on topology between one and three times this clade);  
773 Conceivably, a single common patelloid precursor may pre-date the evolutions of the bony  
774 patellae, or the patella may have arisen fewer times and undergone loss (and re-gain) in some  
775 lineages, similarly to the pattern in Metatheria. Each of these scenarios remain difficult to test  
776 purely with fossil evidence, however, due to the typical lack of preservation of cartilaginous  
777 structures.

778

779 Once the bony patella evolved in Eutheria, it was highly conservative in its presence. There are  
780 very few examples of fossil or extant Eutheria in which the hindlimb remains intact but the  
781 patella is absent. A caveat is that many fossil specimens are not sufficiently complete for a  
782 definitive rejection of patellar occurrence in those taxa. Still, the evolutionary stability of the  
783 patella in Eutheria stands in contrast to its general variability across mammals, and suggests

784 some conserved functional requirement and/or ontogenetic mechanism that remains to be  
785 determined.

786

787 Although an ossified patella is absent in the majority of Metatheria, it is reported in several  
788 groups (Figs. 6, S5). This likely represents loss and regain(s) of the early metatherian patella.  
789 Importantly, in this case the presence of a fibrocartilaginous “patelloid” in most marsupials  
790 shows a clear evolutionary polarity from an ossified patella to a non-ossified patelloid, and back  
791 again in the case of the secondary gain of ossification, in each case within Metatheria (Reese et  
792 al. 2001). This “patella to patelloid” transition suggests the reverse may also be possible – that a  
793 soft tissue patelloid may represent the evolutionary precursor to an ossified patella – but it has  
794 yet to be clearly documented. There is no obvious lifestyle or biomechanical correlate among all  
795 four groups of patella-bearing Metatheria: the notoryctid moles are underground burrowers, and  
796 bandicoots may dig for insects, but *Tarsipes* is a nectar feeder and the borhyaenoids were largely  
797 terrestrial carnivores. In contrast, other Australasian carnivorous marsupials including the  
798 recently extinct thylacine, and the extant quoll, numbat and Tasmanian devil are not reported to  
799 have a patella.

800

801 The large size of the patella in the monotreme platypus might be related to its aquatic (and partly  
802 fossorial; burrowing of dens) lifestyle. Reduction of the patella in the Cetacea and Sirenia is not  
803 intrinsically correlated with their aquatic lifestyle, but with the reduction of the hindlimbs as part  
804 of their particular adaptations. Elsewhere in groups with aquatic adaptations, for example in  
805 various diving birds, an unusually large patella is found. The other monotremes, the echidnas,  
806 also burrow and the long-beaked species (*Zaglossus*) lives in underground dens-- further  
807 suggesting an association between fossorial habits and the presence or enlargement of a patella in  
808 Monotremata, as well as in some fossil Mammaliaformes (multituberculates?) but curiously not  
809 in other fossorial stem taxa (*e.g.* the docodont *Docofossor*). It seems premature to weave detailed  
810 scenarios around the high degree of convergent evolution of the patella in mammals until the  
811 function and genomic control of the patella are better understood, and improved phylogenetic  
812 sampling improves resolution of when it evolved in particular lineages.

813

814 *Patellar developmental genetics*

815 Molecular phylogenomics provides a potential independent or synergistic approach to resolving  
816 issues of patellar evolution. If specific genomic sequence signatures could be associated with  
817 patellar status, then comparison of the genomes of the various extant but widely separated groups  
818 with a patella might indicate whether these represent convergence events or a common ancestral  
819 event (*i.e.* identified via shared evolutionarily transmitted genetic markers required for patellar  
820 development). For example, it has recently been shown that the ability to taste sweet  
821 carbohydrates in hummingbirds represents a trait convergence. Hummingbirds diverged from the  
822 insectivorous swifts, in which the sweet taste receptor is inactivated by mutations in the receptor  
823 coding gene. In hummingbirds, the ability to taste sweet has been re-acquired, apparently  
824 through molecular adaptation of the umami receptor to detect sweet molecules (Baldwin et al.  
825 2014). It would be helpful to understand the (developmental) genetics of the patella as a step  
826 toward the identification of such sequence signatures. Developmental genetic studies in two  
827 mammals, humans and mice, have identified genes required for correct patellar specification.  
828 The known functions of some of these genes are informative regarding their requirements.

829  
830 There are currently approximately 12 human genetic disorders with identified molecular bases  
831 that regularly include abnormal, reduced or absent patellae (hypoplasia or aplasia) as an  
832 important aspect of the phenotype (reviewed by Bongers *et al.* (2005), see also Warman *et al.*  
833 (2011) and Supplementary Table S2 for details). There are also several genes whose genetics in  
834 mice indicates relevance to patellar development at least in rodents. A detailed discussion of all  
835 these syndromes and genes is beyond the scope of this study. However, the known patellar genes  
836 can be broadly organized according to three major developmental processes: limb specification  
837 and pattern formation (transcription factors such as *LMX1B*, *TBX4*, *PITX1* and mouse  
838 *Hoxaaccdd-11*, *OSR1*, *OSR2*, *SOX11*, and signalling factor *WNT7A*); bone development,  
839 biochemistry and regulation (*GDF5*, *CHRNA2*, *SLC26A2*, *COL9A2*, *AKT1*); and genes involved  
840 in DNA replication and chromatin (*ORC1*, *ORC4*, *ORC6*, *CDT1*, *CDC6*, *GMNN*, *CDC45*,  
841 *RECQL4*, *KAT6B*, *ESCO2*). Of these, the genes of replication and chromatin are the most  
842 unexpected, and potentially of the most interest for evolutionary studies. Patellar ossification  
843 may be dependent on the timing of DNA replication in particular cells, or else may be affected  
844 by aberrant gene regulation resulting from mutations in replication and chromatin factors. In

845 either case, the target genes mis-regulated in these syndromes, if they can be identified, may  
846 provide useful evolutionary markers to distinguish convergent from homologous patellar status.

847

848 Developmental studies in mouse or chick embryos, sometimes with induced paralysis, document  
849 the additional importance of local environmental factors in patellar ontogenesis (Hosseini &  
850 Hogg 1991; Mikic et al. 2000; Nowlan et al. 2010a; Nowlan et al. 2010b; Osborne et al. 2002;  
851 Rot-Nikcevic et al. 2006). Similarly, embryonic development and hindlimb activity in the case of  
852 particular marsupials may be important in understanding the diversity of patellar states in this  
853 group. A better understanding of these environmental processes will also be helpful to  
854 disentangle genomic versus epigenomic regulation of patellar development, and hence evolution.

855

856

## 857 CONCLUSIONS

858

### 859 *How “the mammalian patella” evolved*

860 The widespread, repeated evolution of the patella across evolution argues for an important role in  
861 locomotor biomechanics. In animals lacking a patella (*e.g.* Lissamphibia, Testudines,  
862 Crocodylia; as well as many extinct lineages of tetrapods), the consequences of this ancestral  
863 absence for hindlimb function remain mostly unstudied. This mystery is striking, in particular,  
864 within Mammalia where most marsupials lack an ossified patella, as did numerous fossil stem-  
865 mammals, despite seeming to share common ecological niches and the associated locomotor  
866 requirements. This sporadic occurrence in marsupials and stem mammals contrasts with its near  
867 universality and evolutionary stability in the Eutheria as noted above.

868

869 The exact number of independent origins of a patella among mammals remains unclear, but we  
870 have estimated at least four convergent episodes inside Mammaliaformes, and several instances  
871 of patellar loss (with apparent re-gain in some marsupials). The pattern of acquisition and loss  
872 will require revisiting as new fossil material is discovered, as our evolutionary reconstructions  
873 are dependent on single specimens for many ancient taxa. Moreover, patellar status has not been  
874 verified for all >5,000 eutherian and >330 metatherian species (Wilson & Reeder 2005), so it is  
875 possible that additional placental species (other than the fully aquatic forms) may be found

876 lacking, or marsupials having, a patella. A recent evolutionary study documented many  
877 apparently independent evolutionary origins of the caecal appendix in mammals; thus the  
878 convergent evolution of complex anatomical structures like the patella has precedent (Smith et  
879 al. 2013). Similarly, blue coloration among tarantula spiders apparently involves at least eight  
880 independent evolutionary acquisitions, among different microscopic anatomical structures  
881 affecting spectral reflectance hence general external color (Hsiung et al. 2015). A better  
882 understanding of the genomic signatures required for development of such novel structures  
883 should be very helpful to deconstruct the observed complex patterns of evolution, distinguishing  
884 between convergent evolution (homoplasy) and shared inheritance (synapomorphy/homology).  
885

886 Given that the patella evolved, and was also lost, multiple times in mammals and other  
887 Tetrapoda (Fig. 3), one thing is clear. Much as we have referred to “the patella” throughout this  
888 study, there is no such thing—perhaps not even a single “mammalian patella”. The story of  
889 patellar evolution is one of many patellae; a story of diverse evolutionary origins as well as  
890 forms, functions, ontogenies and perhaps even diverse underlying genetics. Mottershead (1988)  
891 wondered if the patella is “not typical of its kind” for a sesamoid bone (Mottershead 1988). Yet  
892 even patellae are not necessarily typical for patellae, let alone other sesamoids-- there are double  
893 or fatty patellae in some birds (Regnault et al. 2014), proximal suprapatellae and/or  
894 fibrocartilaginous patelloids in many marsupials, no patellae at all in many species, and even  
895 amongst those animals that have patellae, there are numerous shapes and sizes of patellae (Figs.  
896 4, S1-S3), suggesting still-unappreciated lifestyle constraints in patellar (and knee joint)  
897 mechanics.

898

### 899 *Future prospects*

900 Our discussion of patellar evolution in Mammalia has identified several areas where key  
901 questions remain unresolved, in addition to uncertainties about the amount of  
902 convergence/parallel evolution in origins of the patella and about specific roles of (and  
903 interactions between) genetic/developmental factors in patellar formation/loss. Considering that  
904 mechanical loads are known to play an important role in the development of sesamoid bones (in  
905 particular in early ontogeny), studies linking these loads to genetic/developmental control as well  
906 as broad evolutionary patterns could prove very insightful, especially in explaining the

907 seemingly large amount of patellar homoplasy in mammalian evolution. Mammals may be less  
908 sensitive (*i.e.* more genetically assimilated (Vickaryous & Olson 2007)) than birds in terms of  
909 the relative influence of mechanical loads on bone (including sesamoid) ontogeny (Nowlan et al.  
910 2010b) - this idea deserves better testing as insight into load-based influences improves.  
911 Furthermore, indications that some bones within an organism may be more responsive to their  
912 loading regime (Nowlan et al. 2010a) may be of great relevance to interpreting patellar biology  
913 and evolution, but at present strong inferences cannot be drawn about how variable the patella's  
914 responsiveness to mechanics is within or among organisms. There is clearly much room for  
915 further study of the patellae of mammals and other tetrapods, and here we have noted directions  
916 in which these might most beneficially be directed.

## 917 ACKNOWLEDGEMENTS

918

919 Tremendous thanks are due to the many investigators who have generously given their time and  
920 energy to educating MES in the fine points of hindlimb anatomy and tetrapod evolution. Special  
921 thanks to John Wible, Zhe-Xi Luo, Maureen O'Leary, Daniel Gebo, Emmanuel Gheerbrant, Jin  
922 Meng, Pascal Tassy, Cyrille Delmer, Salamet Mahboubi, Xijun Ni and Bruce Shockey for help  
923 with information on early mammals, Bonnie Smith, Norberto Giannini and Bill Schutt for help  
924 with bats, Mike Archer, Vera Weisbecker, Robin Beck, Tom Grant and Kurt Galbreath for help  
925 with monotremes, Guillermo Rougier, Jose Bonaparte, Eric Sargis, Anna Gillespie, Analia  
926 Forasiepi and Natalie Warburton for help with marsupials, Cheri Deal, David Skidmore, Judith  
927 Hall, Philippe Campeau and Les Biesecker for information on patellar genetics, Virginie Millien  
928 and Anthony Howell for access to and discussion of materials at the McGill University Redpath  
929 Museum of Natural History in Montreal, and Michel Gosselin for access to and documentation  
930 of materials at the Canadian Museum of Nature in Ottawa. We thank Matthew Lowe (curator,  
931 University Museum of Zoology, Cambridge, UK) for access to osteological specimens of  
932 mammals. We also thank numerous reviewers of earlier versions of the manuscript for many  
933 valuable suggestions.

1451 FIGURES

1452

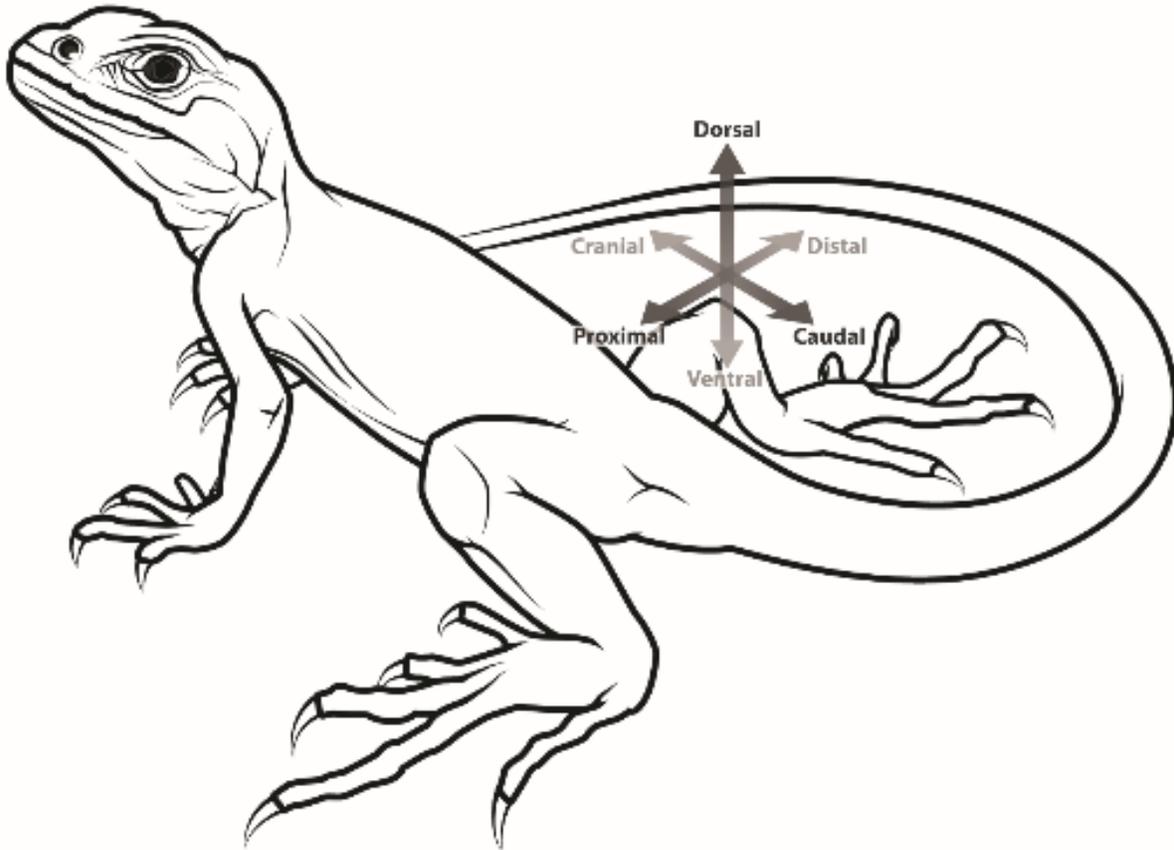

1453 Figure 1. Generalized knee showing sesamoid bones found in various mammals, although  
 1454 possibly no species includes all of these (patella, lunula, cyamella, fabella and parafibula). Also  
 1455 shown are relevant muscles, ligaments and other anatomical elements that lie close to the  
 1456 sesamoids of the knee joint. The knee is in medial view and the medial collateral ligament has  
 1457 been removed.

1458

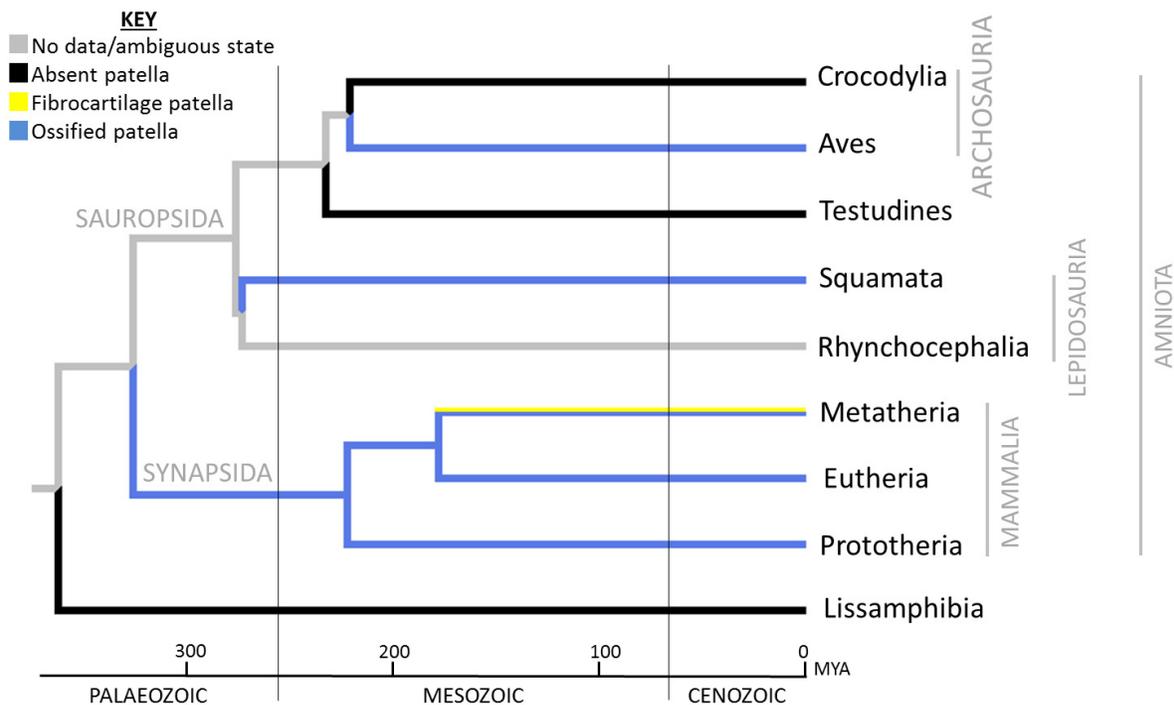

1459

1460 Figure 2. Generalized tetrapod with anatomical/developmental axes defined for the hindlimb:  
1461 cranial/caudal (towards the head/tail respectively), proximal/distal (toward/further from the trunk  
1462 respectively), dorsal/ventral (towards the back/belly respectively).  
1463

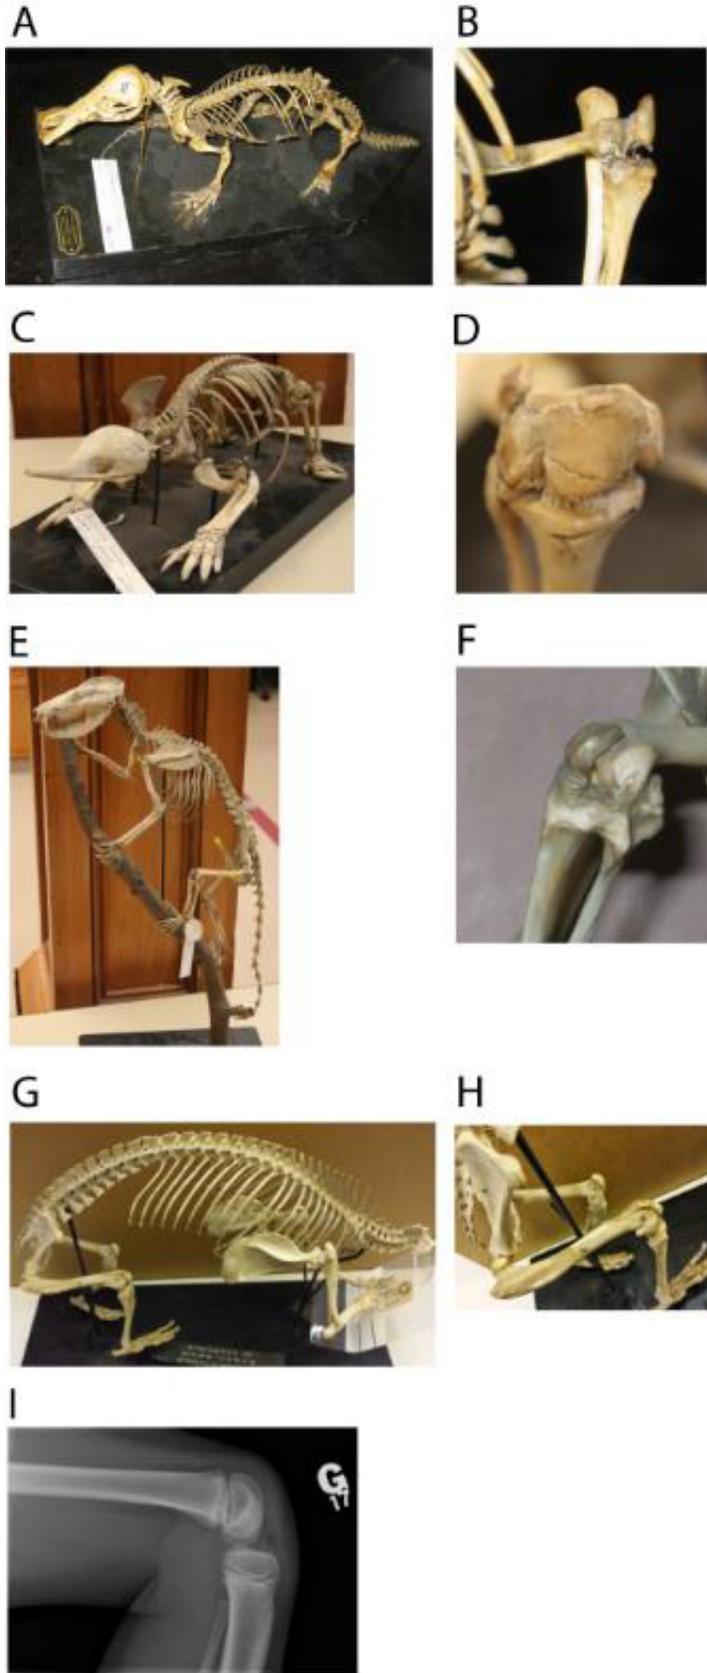

1464

1465 Figure 3. Reconstruction of ancestral patellar states in Tetrapoda, showing the major extant  
 1466 clades. Reconstruction was performed using Mesquite's parsimony algorithm and unordered  
 1467 character states, where 0 (black) = absent patella, 1 (yellow) = soft tissue patella/patelloid, and 2  
 1468 (blue) = ossified patella; see Methods for further details. The distribution of the ossified patella  
 1469 among extant clades has been interpreted as three occasions of independent evolution (in Aves,  
 1470 Squamata, and Mammalia) (Dye, 1987, Haines, 1940), a conclusion strongly reinforced by  
 1471 specific fossil evidence (absence or equivocality of a patella in all outgroups). Reconstruction  
 1472 within Mammalia is explored in more depth in Figures 5-7. MYA= millions of years from  
 1473 present.  
 1474

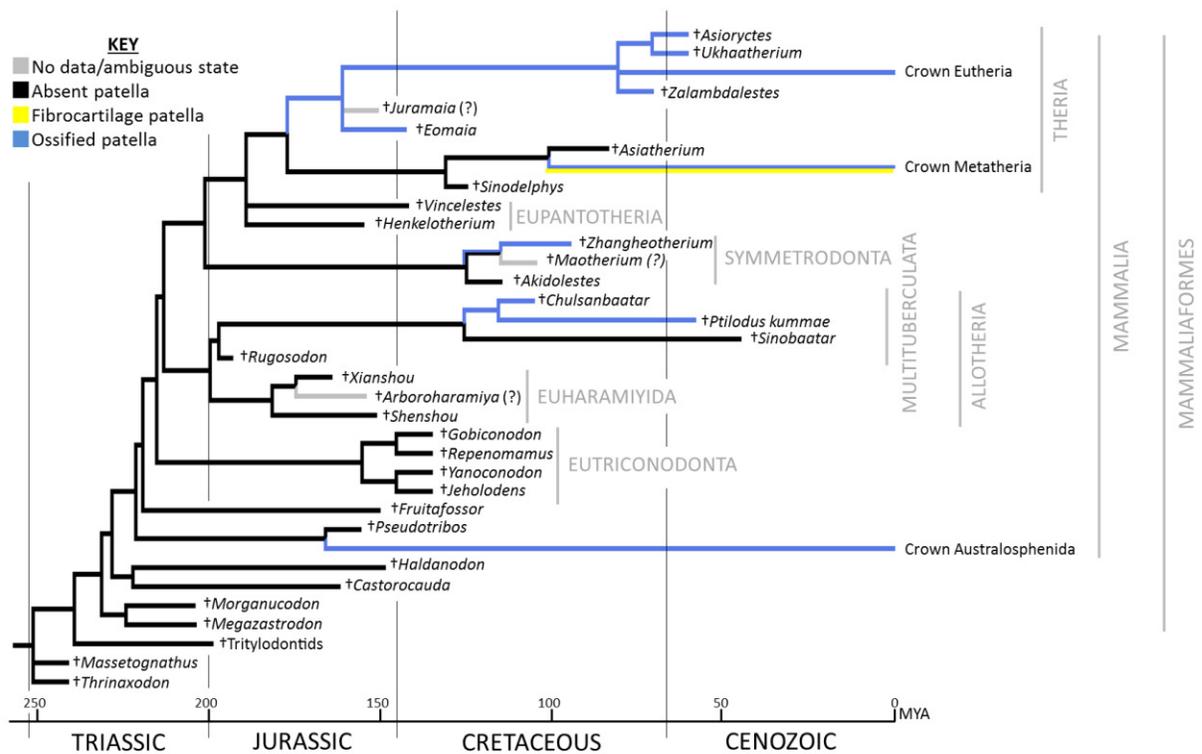

1475

1476 Figure 4. Examples of tetrapods with or without patellae. A, B. *Ornithorhynchus anatinus*  
1477 (Monotremata: duck-billed platypus, Redpath Museum specimen 2458). C, D. *Tachyglossus*  
1478 *aculeatus* (Monotremata: echidna, Redpath Museum specimen 2463). E, F. *Didelphis virginiana*  
1479 (Metatheria: North American opossum, Redpath Museum specimen 5019). G, H. *Procavia*  
1480 *capensis* (Eutheria: Afrotheria: Cape hyrax, Uncatalogued Horniman Museum specimen,  
1481 London, UK). I, knee of patient with Meier-Gorlin Syndrome (Guernsey et al. 2010). For more  
1482 images of mammalian patellae (or lack thereof in some marsupials), see Figures S1-S3.  
1483

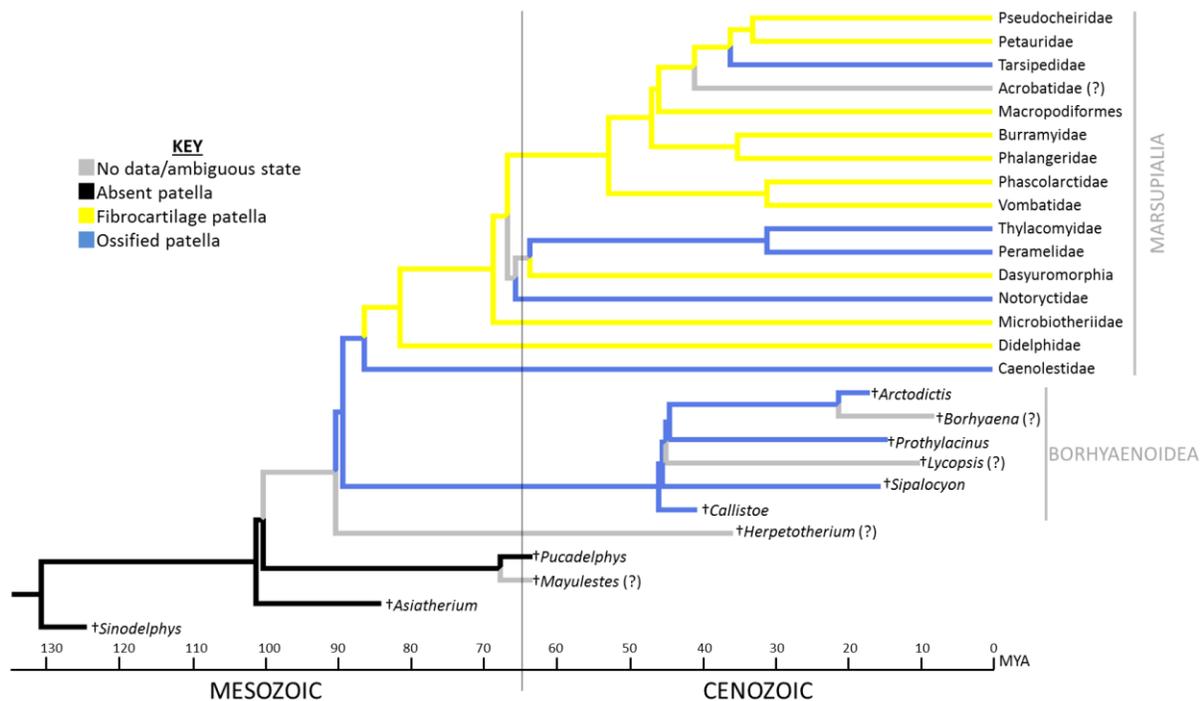

1484

1485 Figure 5. Reconstruction of ancestral patellar state in Mesozoic mammals, using Mesquite's  
 1486 parsimony algorithm and unordered character states, where 0 (black) = absent patella, 1 (yellow)  
 1487 = soft tissue (i.e. fibrocartilaginous in adults) patella/pateloid, and 2 (blue) = ossified patella.  
 1488 Uncertain patellar state is indicated by grey branches and question mark (?) following taxon  
 1489 name, and key fossils with hindlimb material are denoted by †. This reconstruction suggests that  
 1490 a bony patellar sesamoid has evolved at least five times within Mammaliaformes. Reconstruction  
 1491 using ordered parsimony and maximum likelihood methods similarly resulted in five instances of  
 1492 ossified patellar evolution. An alternative topology with †*Eomaia* placed on the therian stem  
 1493 (after O'Leary et al., 2013), shown in Figure S4, similarly found 4-6 instances of bony patella  
 1494 evolution. Evolution within Metatheria is explored in more detail in Figure 6, and within  
 1495 Eutheria in Figure 7. MYA= millions of years from present.  
 1496

1497

1498 Figure 6. Reconstruction of ancestral patellar state in Metatheria, using Mesquite's parsimony  
 1499 algorithm and unordered character states, where 0 (black) = absent patella, 1 (yellow) = soft  
 1500 tissue (i.e. fibrocartilaginous in adults) patella/patelloid, and 2 (blue) = ossified patella. Uncertain  
 1501 patellar state is indicated by grey branches and question mark (?) following taxon name, and key  
 1502 fossils with hindlimb material are denoted by †. The reconstruction suggests that the ossified  
 1503 patella evolved between 1-5 times in Metatheria, with loss and reversion (to a fibrocartilaginous  
 1504 patella/patelloid and back) or as independent instances. States 0 (no patella) and 1 (fibrocartilage  
 1505 patella in adults) are equally parsimonious at the base of the tree. Ordered parsimony  
 1506 reconstruction yields similar results but state 1 is most parsimonious ancestrally. Maximum  
 1507 Likelihood analysis results in five independent instances of patellar evolution (in Borhyaenoidea,  
 1508 Caenolestidae, Notoryctidae, Thylacomyidae + Peramelidae, and Tarsipedidae), with an  
 1509 ancestral state of either 0 or 1 depending on the states assigned to the earliest fossils such as  
 1510 *Sinodelphys*. An alternative topology with Microbiotheriidae nested slightly further within  
 1511 Marsupialia (after May-Collado et al., 2015), shown in Figure S5, similarly shows between 1-5  
 1512 instances of bony patella evolution but with more internodes of ambiguous character state (i.e.  
 1513 equivocal between states 1 and 2). MYA= millions of years from present.  
 1514

1515  
 1516

1517 Figure 7. Reconstruction of ancestral patellar state in Eutheria, using Mesquite's parsimony  
1518 algorithm and unordered character states, where 0 (black) = absent patella, 1 (yellow) = soft  
1519 tissue (i.e. fibrocartilaginous in adults) patella/patelloid (state not present in Eutheria other than  
1520 some bats; see main text), and 2 (blue) = ossified patella. Uncertain patellar state is indicated by  
1521 grey branches and question mark (?) following taxon name, and key fossils with hindlimb  
1522 material are denoted by †. Our reconstruction suggests that the ossified patella evolved only once  
1523 within Eutheria and (as far as is currently known) has only been lost by the bat genus *Pteropus*  
1524 (not counting groups which have lost hindlimbs; e.g. *Trichechus manatus*/crown Sirenia,  
1525 *Tursiops truncatus*/crown Cetacea). Taxa within Euarchontoglires (e.g. rats, mice, guinea pigs,  
1526 rabbits, most primates), some Carnivora, and possibly some Chiroptera have been found to  
1527 possess a suprapatellar structure similar to the patelloid, shown by vertical black bars at the  
1528 appropriate branches. MYA= millions of years from present, Pε = Paleocene, Eo = Eocene, OG  
1529 = Oligocene, MI = Miocene (most recent Cenozoic epochs not labelled).  
1530
