

Religious attendance after elevated depressive symptoms: is selection bias at work?

In an attempt to determine if selection bias could be a reason that religious attendance and depression are related, the predictive value of elevated depressive symptoms for a decrease in future attendance at religious services was examined in a longitudinal panel of 1,319 Dutch adults. Religious attendance was assessed yearly over five years using the single question, “*how often do you attend religious gatherings nowadays?*” Depressive symptoms were assessed four times within the first year using the Depression subscale of the Brief Symptom Inventory. Logistic regression models of change in attendance were created, stratifying by baseline attendance status. Attenders who developed elevated symptoms were more likely to maintain (Relative Risk Ratio =1.65; 95% CI: 1.07 to 2.56) or increase (Relative Risk Ratio =1.82; 95% CI: 1.14 to 2.88) their attendance level as compared to those without elevated symptoms, after controlling for health and demographic covariates. Non-attenders were unlikely to start attending after elevated depressive symptoms. This study provides empirical evidence against selection bias in studies of religion and depression.

8 Religious attendance after elevated depressive symptoms: is selection bias at work?

9 **Abstract** In an attempt to determine if selection bias could be a reason that religious attendance
10 and depression are related, the predictive value of elevated depressive symptoms for a decrease in
11 future attendance at religious services was examined in a longitudinal panel of 1,319 Dutch
12 adults. Religious attendance was assessed yearly over five years using the single question, “*how*
13 *often do you attend religious gatherings nowadays?*” Depressive symptoms were assessed four
14 times within the first year using the Depression subscale of the Brief Symptom Inventory.
15 Logistic regression models of change in attendance were created, stratifying by baseline
16 attendance status. Attenders who developed elevated symptoms were more likely to maintain
17 (Relative Risk Ratio =1.65; 95% CI: 1.07 to 2.56) or increase (Relative Risk Ratio =1.82; 95%
18 CI: 1.14 to 2.88) their attendance level as compared to those without elevated symptoms, after
19 controlling for health and demographic covariates. Non-attenders were unlikely to start attending
20 after elevated depressive symptoms. This study provides empirical evidence against selection
21 bias in studies of religion and depression.

22 **Keywords:** depression, religious attendance, selection effects

23 **Introduction:**

24 Attendance at religious services is usually reported to be inversely related to depression
25 (Baetz et al. 2004; Maselko et al. 2009; Hayward et al. 2012; Balbuena et al. 2013). However,
26 as with many findings in the literature on religion, the results have not been consistent, with other
27 studies reporting a null (Schnittker 2001; Ellison and Flannelly 2009; Miller et al. 2012) or
28 curvilinear relationship of attendance and depression (Taylor et al. 2012). This inconsistency has
29 been due in part to the predominance of cross-sectional designs, which cannot establish

30 causation. Caution is therefore required in inferring causation from cross-sectional studies. We
31 are aware of only three longitudinal studies examining the relation of depression to subsequent
32 religious attendance. Recently, it was reported (Maselko et al. 2012) that women having an onset
33 of depression prior to age 18 were more likely to stop attending religious services as adults
34 compared to those with adult-onset MDE and those with no lifetime MDE. Similarly, a
35 longitudinal study (Horowitz and Garber 2003) reported that depressive episodes in grades 7-11
36 predicted lower levels of religious attendance in grade 12. The latter result is ambiguous because
37 religious attendance in grade 6 also predicted lower odds of depression in grades 7-12, although
38 the effect was just shy of statistical significance. Miller and colleagues (Miller et al. 2002)
39 followed a cohort of 146 individuals who had an MDE in childhood together with a control group
40 of 123 who had no psychiatric disorder over 11 years. At follow-up, the rates of religious
41 attendance between groups did not differ by childhood depression status. It is noteworthy that
42 these studies covered the adolescence-to-adult transition period. Late adolescence is generally a
43 time of profound change. The quest to establish one's identity and career (Arnett 2000) and
44 experimentation with cohabitation, drugs, and alcohol (Thornton et al. 1992; Benda and Corwyn
45 1997; Uecker et al. 2007) could precipitate internal conflicts with religious doctrine, leading to
46 declines in religious attendance. In short, the developmental processes occurring during
47 adolescence confounds the relation of depression with religious attendance, in either causal
48 direction.

49 Selection effects might work in two ways to confound the relation of depression with
50 subsequent religious attendance. First, depressed individuals may withdraw from public worship
51 as part of the overall social disengagement that occurs in depression (Maselko et al. 2012). An
52 fMRI study reported that depressed patients showed lower activation of the amygdala, indicating
53 lower satisfaction, when presented with happy faces (Derntl et al. 2011). Hence, participating in
54 social activities, including church, is less satisfying for depressed individuals. Secondly,

55 churchgoers might be less susceptible to depression. A meta-analysis of 94 studies reported a
56 positive correlation of agreeableness, conscientiousness, and sociability with religious social
57 investment (Lodi-Smith and Roberts 2007). In summary, theory suggests that depressed
58 individuals select themselves out of the churchgoing demographic while healthy ones select
59 themselves into it. These selection effects, if operative, would likely overestimate the protective
60 value of religion for mental health.

61 Although these effects support reverse causation, the protective value of religiosity also
62 has empirical support. Coping with adversity through religion is well-documented in the
63 literature (Pargament 1997). “Turning to God or religion” as a coping strategy has been reported
64 in cancer patients (Bussing et al. 2007), newly bereaved individuals (Brown et al. 2004), and new
65 immigrants (Connor 2009). A study comparing religiosity and spirituality before and after HIV
66 patients were informed of the diagnosis (Ironson et al. 2006) reported that religiosity (including
67 attendance) increased after the diagnosis became known. Furthermore, increased religiosity was
68 associated with greater CD4 preservation, indicating slower HIV progression (Ironson et al.
69 2006). A US longitudinal study reported that depressed individuals were more likely to seek
70 religious consolation—defined as searching for meaning in problems and difficulties (Ferraro and
71 Kelley-Moore 2000). Importantly, even those with no initial religious affiliation sought religious
72 consolation after depression. This finding seems to support the “no atheists in foxholes”
73 aphorism. However, adversity or trauma can also cause individuals to turn away from God or
74 religion (Fontana and Rosenheck 2004; Chen and Koenig 2006). We are not aware of
75 longitudinal studies reporting changes to religious *attendance* per se (vis-a-vis religiosity broadly
76 speaking) after a depressive episode aside from the three studies in adolescence (Miller et al.
77 2002; Horowitz and Garber 2003; Maselko et al. 2012) already mentioned.

78 In this paper, our main objective was to study whether elevated depressive symptoms
79 introduce selection bias in a longitudinal follow-up of religious attendance. Our research

80 questions were as follows. First, do religious attenders who develop elevated depressive
81 symptoms subsequently decrease their attendance level? Second, do non-attenders who develop
82 elevated symptoms begin to attend services?

83 **Materials and Methods**

84 *Sample*

85 The data is from the Longitudinal Internet Studies for the Social Sciences (LISS) panel, a
86 random sample of adults living in the Netherlands (Scherpenzeel 2011). The panel of almost
87 8,000 individuals was drawn from the Dutch-speaking population based on a list of addresses
88 provided by Statistics Netherlands. The recruitment strategy is described in more detail
89 elsewhere (Scherpenzeel 2011). LISS is a continuing study in which participants complete online
90 questionnaires monthly on topics including family, economic situation, health, and religion.
91 Waves of religion and depression assessments were not simultaneous, so we used the notation R_i
92 and D_i to refer to religion and depression waves, respectively. 7,418 individuals participated in
93 R_1 , which occurred in early 2008, but a much smaller number ($n = 1,804$) participated in D_1 in
94 December 2007. Those with high or very high depressive symptoms at D_1 ($n = 419$), those that
95 skipped the religious attendance question ($n = 66$), and those that did not answer the D_1 questions
96 ($n = 5,614$) were not included in our sample of 1,319 individuals. We excluded those with high or
97 very high symptoms because we wanted to establish a baseline attendance level that was not
98 confounded by depression. Figure 1 gives the breakdown of these groups: (a) religious attenders
99 without elevated symptoms, (b) non-attenders without elevated symptoms, and (c) excluded
100 individuals. Our sample ranged in age from 16 to 87, with a 10% trimmed mean of 48.67.

101 (Insert Figure 1 around here)

102 In the sample, 715 individuals did not attend services and 604 attended services at R_1 .
103 (Explained in Measures section below.) The characteristics of these groups are described in Table
104 1. Depression and religious attendance levels of these two groups—non-attenders and attenders

105 —were measured prospectively over the next four years. Our main analytic strategy was to
106 compare the proportion of individuals that changed their attendance level, stratified by baseline
107 attendance. Aside from D₁, depression was assessed another three times in 2008 (D₂ to D₄). D₂ to
108 D₄ preceded four waves of attendance assessment (R₂ to R₅), as indicated in Figure 1. Note that
109 while the depression waves covered a mere 9 months, the religion waves covered 4 years. The
110 change in attendance level was indexed to R₁ attendance.

111

112 (Insert Table 1 around here)

113 *Measures*

114 Religious attendance was assessed with the single question, “*Aside from special*
115 *occasions such as weddings and funerals, how often do you attend religious gatherings*
116 *nowadays?*” This was answered on a 7-point Likert scale coded as *1 = everyday, 2 = more than*
117 *once a week, 3 = once a week, 4 = at least once a month, 5 = only on special religious days, 6 =*
118 *less often, and 7 = never*. We reverse coded the scale for ease of interpretation—i.e., larger
119 number indicated higher attendance. Among attenders, we used a dichotomous attendance
120 variable for decreased (coded 0) and same/increased (coded 1) and a categorical version:
121 decreased, unchanged, and increased attendance. These categories were formed by subtracting
122 the R₁ attendance level from a given follow-up assessment. For non-attenders in R₁, a
123 dichotomous variable with unchanged (coded 0) and increased (coded 1) was used.

124 Our substantive predictor was assessed using the Depression subscale of the Brief
125 Symptom Inventory (Derogatis 1975). The subscale consists of 6 items rated on a 5-point scale
126 from “Not at all” to “Extremely”. The BSI is itself a short version of the SCL-90 (Derogatis and
127 Melisaratos 1983). BSI Depression had an internal reliability ranging from 0.70 to 0.92 in four

128 different studies (Derogatis and Melisaratos 1983; Boulet and Boss 1991; Kellett et al. 2003;
129 Johnson et al. 2008) and correlated with the Beck Depression Inventory, $r = .71$ and $r = .77$, in
130 two other studies (Stukenberg et al. 1990; Prinz et al. 2013). Two studies validated BSI
131 Depression against either DSM-III or DSM-IV-TR major depression (Stukenberg et al. 1990;
132 Johnson et al. 2008). ROC analyses reported area under the curve as 0.83 in community dwelling
133 older adults, but a more modest 0.65 among psychiatric inpatients.

134 For copyright reasons, the LISS dataset only provided the normative category of each
135 respondent and not the responses to individual questions. These normative categories of BSI
136 depression were: *1 = below average*, *2 = average*, *3 = above average*, *4 = high*, and *5 = very*
137 *high*. We dichotomized them into low (below average to above average) and elevated (high to
138 very high). The cut-off was chosen because it resulted in a better approximation of the
139 prevalence of depression in the Netherlands (Bijl et al. 1998) compared to alternative cut-offs.

140 *Covariates*

141 We controlled for possible confounders including chronic conditions, income, marital
142 status, age, and gender. Chronic conditions were assessed with the single question, “*Do you*
143 *suffer from any kind of long-standing disease, affliction or handicap, or do you suffer from the*
144 *consequences of an accident?*” Income was assessed using a monthly personal gross income
145 with five categories: 0-500, 501-1500, 1501-2500, 2501-3500, and 3501 and higher Euros per
146 month. Marital status was used as an index of social support and was categorized into 1=
147 Married; 2=Separated/Divorced/Widowed; 3= Not Married. All covariates were measured
148 between December 2007 and April 2008.

149 *Statistical analysis*

150 We first compared demographic characteristics of attenders, non-attenders, and excluded
151 participants. To examine whether elevated depressive symptoms predicted subsequent decreased
152 attendance, we crosstabulated dichotomized attendance with level of symptoms among attenders,
153 for each religion follow-up year. Chi-square tests of association were performed. To examine
154 change longitudinally and control for confounders, we created a multinomial logistic regression
155 model among attenders. Relative risk ratios of maintaining or increasing attendance over
156 decreasing attendance were calculated.

157 To examine if non-attenders start attending services after elevated depression, a binary
158 logistic regression model was created with change in attendance (0 = no change; 1 = attended) as
159 dependent variable. We entered the covariates in all regression models to control for confounding
160 and robust standard errors were calculated to account for correlated errors in repeated
161 observations.

162 *Missing data*

163 Missing values for the covariates at baseline did not differ between attenders and non-
164 attenders. To examine whether our results would be biased by differential attrition between
165 attenders and non-attenders, we performed multiple imputation on our dependent and predictor
166 variables using a set of 20 socio-demographic and psychological variables assessed at baseline.
167 (These variables are available from the authors upon request.) The imputation procedure was
168 implemented using REALCOM-IMPUTE (Carpenter et al. 2011) software and 10 imputed
169 datasets were generated, which were then analyzed using Stata 12.1. Our regression models were
170 then repeated using the multiply imputed data.

171 **Results:**

172 Excluded individuals were more likely to be younger, earn €500 or less per month, have
173 lower self-rated health, and be less likely to report chronic conditions compared to attenders and
174 non-attenders. Religious attenders were more likely to be female, older, and married as
175 compared to non-attenders. Attenders and non-attenders were similar in self-rated health and in
176 the proportion having chronic conditions. The chi-square tests in each of the four follow-up
177 waves showed no association between depression status and subsequent decrease in attendance.
178 In post-hoc analysis, we stratified first by gender and then by age category, but used Fisher's
179 exact tests because of lower numbers. In gender-stratified analysis, no associations were found
180 in each attendance follow-up. In age-stratified analysis, no associations were found in the first
181 two years after depression assessments took place. In R₃, those below 48 years old and with
182 elevated symptoms were less likely to decrease attendance, $P = .02$. In R₄, those above 48 and
183 with elevated symptoms were less likely to decrease attendance, $P = .04$. (See Table 2. The
184 tables stratified by gender or age category are available from the authors by request.)

185 (Insert Table 2 around here)

186 In multinomial logistic regression modeling, elevated symptoms predicted maintaining
187 (Relative Risk Ratio = 1.65; 95% CI: 1.07 to 2.56) or increasing (Relative Risk Ratio = 1.82; 95%
188 CI: 1.14 to 2.88) baseline attendance levels among attenders. Among non-attenders, elevated
189 symptoms were unrelated to a subsequent increase in attendance with one exception. In the
190 multiply imputed model, they were less likely to start attending (OR: 0.28, 95% CI: 0.14 to 0.55)
191 than those with low symptoms.

192 (Insert Table 3 and Figure 2 here.)

193 **Discussion:**

194 The main finding in this study is that elevated BSI depression does not cause a subsequent
195 decrease in attendance. On the contrary, elevated BSI depression predicts same or increased

196 levels of attendance as compared with prior to elevated BSI depression. None of our results
197 across three analytical strategies showed a decrease in attendance. Although unstratified analyses
198 did not yield a significant association, gender and age-stratified results indicated an association of
199 continued or increased attendance with elevated symptoms. The longitudinal model among
200 attenders, with covariates controlled for, indicated that elevated symptoms predicted same or
201 increased attendance. As a secondary finding, non-attenders were not likely to seek recourse in
202 religion by starting to attend services.

203 Our main finding addresses the issue of selection bias in studies of religious attendance
204 and mental health. To recap, when depressed individuals stop attending services, the apparent
205 protection afforded by attendance would be inflated. This selection bias would be most
206 pronounced in cross-sectional studies. In longitudinal epidemiologic studies, bias remains an
207 issue because there might be differential attrition in attendance by depression status. Since we
208 found that attenders who develop elevated symptoms become less likely to drop out of worship,
209 then they might in effect be overrepresented among churchgoers. Therefore, the protective effect
210 of religious attendance might in fact be underestimated, contrary to the reverse causation
211 argument.

212 The motive for religious attendance by those with elevated symptoms suggests a different
213 interpretation: attendance confers social benefits. Religious individuals turn to their faith in times
214 of distress as a means of coping (Brown et al. 2004; Ironson et al. 2006; Bussing et al. 2007).
215 Religious worship is a source of social support and allows individuals to cope with life-
216 threatening conditions by providing “medicine for the spirit.” A longitudinal study (Li and
217 Ferraro 2005) on depression and volunteering among older adults reported that elevated
218 depression at wave 2 predicted seeking out volunteering opportunities at wave 3. This was
219 explained as a compensatory mechanism to alleviate negative affect, via social integration. These
220 older adults had physical health problems in addition to depression and the former were the

221 operative barriers. Consistent with this finding, Chen and Koenig (Chen and Koenig 2006)
222 reported that in elderly, medically ill individuals, an increased severity of illness predicted a
223 decrease in organizational religiousness. Importantly, the association was completely mediated
224 by physical activity limitations. Together with our own results, these suggest that it is not
225 depression *per se* that causes a disengagement from participation in religious service. In effect,
226 reverse causation and non-random attrition might be more relevant to studies examining religious
227 attendance and physical health.

228 The null association (or negative association in multiply imputed data) of elevated
229 depression with subsequent attendance among non-attenders indicates that non-attenders do not
230 start attending in the face of adversity. Paradoxically, Ferraro and Kelley-Moore (Ferraro and
231 Kelley-Moore 2000) reported that depression, cancer, and chronic conditions lead to consolation-
232 seeking even among those with no religious affiliation. The two points of view can be reconciled
233 because attendance is not necessary for consolation-seeking. The need to find meaning in illness
234 is shared by believers and non-believers who may turn to nature, arts, music, and relationships
235 (Burnard 1988). An intriguing study (Farias et al. 2013) reported that rowers about to enter a
236 competition reported greater belief in science as compared with those in a training session. The
237 authors concluded that affirming one's secular worldview serves a similar function as religious
238 faith in moments of stress or existential anxiety. Hence, affiliated individuals cope by means of
239 religion while non-attending ones seek support and meaning elsewhere. It appears that
240 depressive symptoms are not a strong driver of entry into or exit from the churchgoing
241 demographic. More empirical research is needed to validate this interpretation.

242 Our study has several important limitations. First, we relied on the depression subscale of
243 the BSI to assess depressive symptoms. It has been argued that although the global BSI scale is a
244 valid measure of distress, it is not intended to screen for particular psychiatric disorders (Asner-
245 Self et al. 2006). We set the BSI cut-off for depression at "high" or "very high" but there is no

246 way to tell whether this is in concordance with clinically diagnosed depression. We therefore
247 allow for the possibility that a major depressive episode causes selection bias even though
248 elevated depressive symptoms do not. Secondly, there were no assessments of depression from
249 2009 to 2012—the period during which religious attendance was compared to initial attendance.
250 As such all religious attendance changes were indexed to depression levels in 2008 only. We
251 cannot rule out the possibility that attendance levels after 2008 were related to unmeasured
252 elevated symptoms after 2008. Third, the sample that we worked with was restricted to LISS
253 respondents who responded to both religion and mental health modules and might not be
254 representative of the Dutch national population. Fourth, while we have ruled out sampling bias in
255 terms of attrition in attendance, we could not address whether personality traits such as greater
256 resilience to depression characterized attenders in the first place. Finally, other health-related
257 reasons, including physical disability, might be correlated with depression and could cause
258 selection bias. This is beyond the scope of our study. The major strength of this study was that
259 depression assessments were proximal to those of religion. Our sample also consisted of a small
260 fraction (5%) of late adolescents and is less affected by the well-reported decline in religious
261 attendance in adolescence.

262 Within the limitations of our study, we conclude that elevated depressive symptoms do
263 not cause religiously affiliated individuals to subsequently decrease attendance at religious
264 services.

Table 1 (on next page)

Characteristics of Included and Excluded Respondents from the Longitudinal Internet Studies for the Social Sciences (LISS), Netherlands

Table 1: Characteristics of Included and Excluded Respondents from the Longitudinal Internet Studies for the Social Sciences (LISS), Netherlands

Characteristic	(A) Attenders and not initially depressed (n = 604)	(B) Non-Attenders and not Initially depressed (n = 715)	(C) Excluded † (n = 6,099)	Pairwise Significant differences††
Mean age (sd)	50.56 (18.09)	47.15 (16.91)	44.36 (15.27)	A > B > C
Female	319 (52.81%)	334 (46.71%)	3,267 (54.63%)	B < A = C
Marital status				
<i>Married</i>	377 (62.42%)	388 (54.27%)	3,639 (60.85%)	% married: A = C > B
<i>Sep/Divorced/Widowed</i>	86 (14.24%)	95 (13.29%)	606 (10.13%)	
<i>Never married</i>	141 (23.34%)	232 (32.45%)	1,735 (29.01%)	
Income				
<i>0 to 500</i>	62 (10.26%)	66 (9.23%)	796 (13.05%)	% in lowest bracket:
<i>501 to 1500 Euro</i>	76 (12.58%)	63 (8.81%)	706 (11.58%)	A = B < C
<i>1501 to 2500 Euro</i>	94 (15.56%)	124 (17.34%)	906 (14.85%)	
<i>2501 to 3500 Euro</i>	55 (9.11%)	102 (14.27%)	679 (11.13%)	
<i>3501 Euro and over</i>	55 (9.11%)	68 (9.51%)	560 (9.18%)	
<i>Missing</i>	262 (43.38%)	292 (40.84%)	2,452 (40.20)	A = B = C
Mean Self-rated health (SD)	3.23 (0.76)	3.19 (0.75)	3.13 (0.76)	A = B B = C A > C

Has a chronic condition				
Yes	167 (27.65%)	171 (23.92%)	1,394 (22.86%)	A = B B = C A > C
Missing	42 (6.95%)	51 (7.13%)	986 (16.17%)	A = B < C

†Exclusion criteria were: (a) Did not respond to mental health module, (b) elevated BSI depression at first depression assessment, (c) Did not respond to religious attendance question

†† Bonferroni-adjusted t-tests for continuous variables and chi-square tests for categorical variables were applied

Table 2(on next page)

Elevated BSI Depression vs Decrease in Attendance among Service Attenders at R₁ in the Longitudinal Internet Studies for the Social Sciences (LISS), Netherlands

Table 2: Elevated BSI Depression vs Decrease in Attendance among Service Attenders at R₁ in the Longitudinal Internet Studies for the Social Sciences (LISS), Netherlands

2009 Attendance vs Baseline	Elevated Depression		χ^2	p
	No	Yes		
<i>Same/higher</i>	241 (65%)	61 (74%)	2.6 9	. 10
<i>Decreased</i>	130 (35%)	21 (26%)		
2010 Attendance vs Baseline				
<i>Same/higher</i>	210 (65%)	45 (73%)	1.1 9	. 27
<i>Decreased</i>	111 (35%)	17 (27%)		
2011 Attendance vs Baseline				
<i>Same/higher</i>	173 (60%)	41 (68%)	1.2 9	. 26
<i>Decreased</i>	113 (40%)	19 (32%)		
2012 Attendance vs Baseline				
<i>Same/higher</i>	153 (53%)	35 (66%)	2.9 3	. 09
<i>Decreased</i>	134 (47%)	18 (34%)		

† If the individual had a norm-referenced score of “high” or “very high” in any of the three assessments in 2008, the individual was assigned to *elevated* and otherwise to *not elevated*.**The tabulation is restricted to those who attended religious services at first religion assessment. Abbreviation: BSI = Brief Symptom Inventory

Table 3(on next page)

Logistic Models of Change in Religious Attendance Levels over 5 years from the Longitudinal Internet Studies for the Social Sciences (LISS), Netherlands

Table 3: Logistic Models of Change in Religious Attendance Levels over 5 years from the Longitudinal Internet Studies for the Social Sciences (LISS), Netherlands

	Attendees		Non-attendees	
	Complete cases (n = 544)	Multiply imputed data (10 imputations)	Complete cases (n = 636)	Multiply imputed data (10 imputations)
	Relative Risk Ratio (95% CI)	Relative Risk Ratio (95% CI)	Odds ratio (95% CI)	Odds ratio (95% CI)
<i>Outcome: Decreased Attendance</i>	(Reference Category)			
<i>Outcome: Maintained Attendance</i>	(Reference Category)			
Elevated Depression	1.65 (1.07-2.56)*	1.59 (1.07-2.36)*	N/A	N/A
Year	0.85 (0.78 -0.93)**	0.88 (0.83-0.95)**	N/A	N/A
<i>Outcome: Increased Attendance</i>				
Elevated Depression	1.82 (1.14-2.88)*	1.54 (1.02-2.32)*	0.93 (0.46-1.85)	0.28 (0.14-0.55) ***
Year	1.16 (1.07- 1.25)***	1.14 (1.07- 1.22)***	1.64 (1.47-1.84)***	1.65 (1.45-1.88) ***

†In these models, the following covariates have been controlled: existing chronic condition, gender, marital status, income, and age. *P* values: *** = .001, ** = .01, * = .05

Figure 1

Respondents Breakdown and Assessments Schedule

Top panel: included and excluded individuals from the Longitudinal Internet Studies for the Social Sciences (LISS), Netherlands. Bottom panel: Schedule of assessments.

Abbreviations: R = religion, D = Depression; Subscripts are assessment waves; BSI = Brief Symptom Inventory

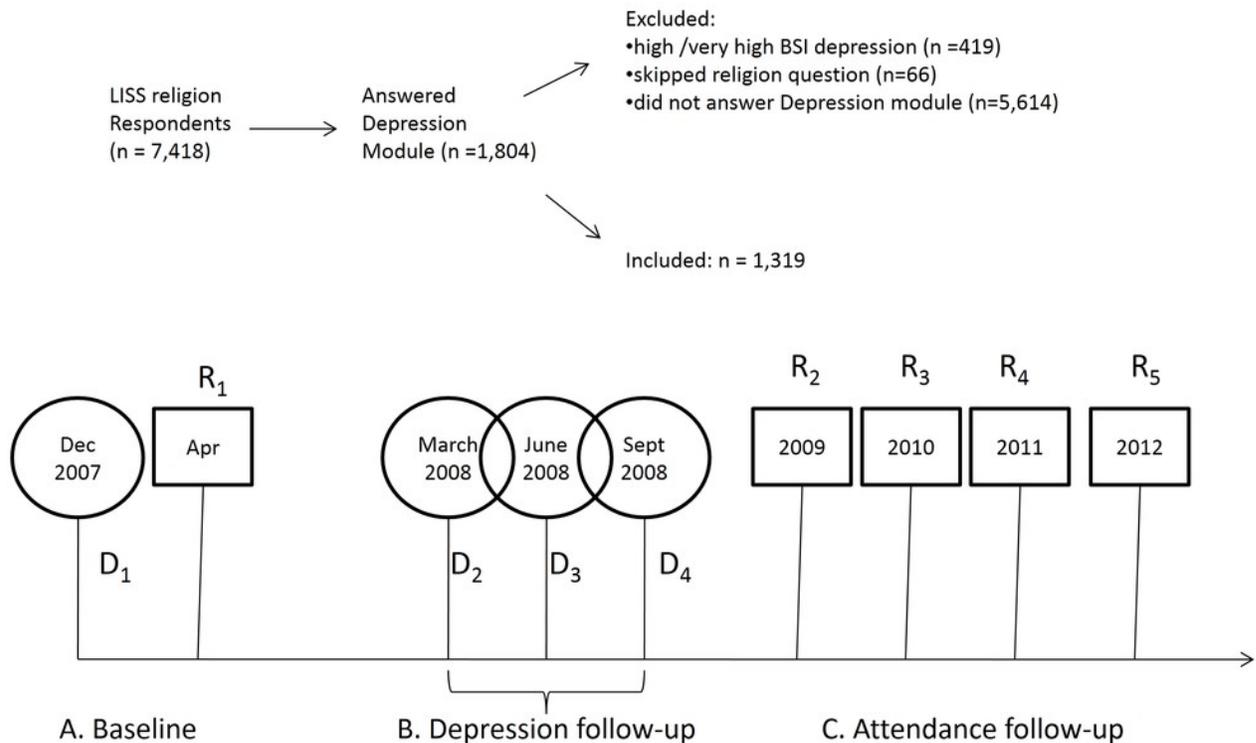

Figure 2

Incidence of elevated BSI depression vs probability of future decrease in attendance, BSI = Brief Symptom Inventory ienc
