**Background.** Zones of contact between closely related taxa with divergent migratory routes, termed migratory divides, have been suggested as areas where hybrid offspring may have intermediate and inferior migratory routes, resulting in low fitness of hybrids and thereby promoting speciation. In the Rocky Mountains of Canada there is a narrow hybrid zone between Audubon's and myrtle warblers that is likely maintained by selection against hybrids. Band recoveries and isotopic studies indicate that this hybrid zone broadly corresponds to the location of a possible migratory divide, with Audubon's warblers migrating south-southwest and myrtle warblers migrating southeast. We tested a key prediction of the migratory divide hypothesis, that genetic background would be predictive of migratory orientation among warblers in the center of the hybrid zone.

**Methods.** We recorded fall migratory orientation of wild-caught migrating warblers in the center of the hybrid zone as measured by video-based monitoring of migratory restlessness in circular orientation chambers. We then tested whether there was a relationship between migratory orientation and genetic background, as measured using a set of species-specific diagnostic genetic markers.

**Results.** We did not detect a significant association between orientation and genetic background. There was large variation among individuals in orientation direction. Mean orientation was towards the NE, surprising for birds on fall migration, but aligned with the mountain valley in which the study took place.

**Conclusions.** Only one other study has directly analyzed migratory orientation among naturally-produced hybrids in a migratory divide. While the other study showed an association between genetic background and orientation, we did not observe such an association in yellow-rumped warblers. We discuss possible reasons, including the possibility of a lack of a strong migratory divide in this hybrid zone and/or methodological limitations that may have prevented accurate measurements of long-distance migratory orientation.

24

25

26 **Abstract:**

27

28 **Background.** Zones of contact between closely related taxa with divergent migratory routes,  
29 termed migratory divides, have been suggested as areas where hybrid offspring may have  
30 intermediate and inferior migratory routes, resulting in low fitness of hybrids and thereby  
31 promoting speciation. In the Rocky Mountains of Canada there is a narrow hybrid zone between  
32 Audubon's and myrtle warblers that is likely maintained by selection against hybrids. Band  
33 recoveries and isotopic studies indicate that this hybrid zone broadly corresponds to the location  
34 of a possible migratory divide, with Audubon's warblers migrating south-southwest and myrtle  
35 warblers migrating southeast. We tested a key prediction of the migratory divide hypothesis, that  
36 genetic background would be predictive of migratory orientation among warblers in the center of  
37 the hybrid zone.

38 **Methods.** We recorded fall migratory orientation of wild-caught migrating warblers in the  
39 center of the hybrid zone as measured by video-based monitoring of migratory restlessness in  
40 circular orientation chambers. We then tested whether there was a relationship between  
41 migratory orientation and genetic background, as measured using a set of species-specific  
42 diagnostic genetic markers.

43 **Results.** We did not detect a significant association between orientation and genetic  
44 background. There was large variation among individuals in orientation direction. Mean  
45 orientation was towards the NE, surprising for birds on fall migration, but aligned with the  
46 mountain valley in which the study took place.

47 **Conclusions.** Only one other study has directly analyzed migratory orientation among naturally-  
48 produced hybrids in a migratory divide. While the other study showed an association between

49 genetic background and orientation, we did not observe such an association in yellow-rumped  
50 warblers. We discuss possible reasons, including the possibility of a lack of a strong migratory  
51 divide in this hybrid zone and/or methodological limitations that may have prevented accurate  
52 measurements of long-distance migratory orientation.

53

54

55 **Introduction:**

56 Breeding and wintering ranges of many species are separated by thousands of kilometers.  
57 Long-distance seasonal migration exhibited by many taxa moving between these disjunct areas is  
58 a complex and energetically demanding task that has been studied for decades (Berthold 1996).  
59 However, the physiological mechanisms, controls and senses involved in navigation of many  
60 taxa are still unclear, as are the contributions of various cues to migratory behavior (Berthold and  
61 Terrill 1991; Alerstam 2006). Much of our understanding of migratory directionality and  
62 navigation comes from studies of blackcap warblers (*Sylvia atricapilla*) in Europe. In an  
63 influential series of studies, Helbig and colleagues (Helbig 1991; Berthold et al. 1992; Helbig  
64 1994; Helbig 1996) reared blackcaps from populations that exhibited different migratory routes.  
65 They found that, even in captivity in a common environment, populations recapitulated their  
66 natural routes, as assayed by Emlen funnels (Emlen 1970). These studies also found that lab-  
67 crossed hybrids between the parental types tended to show intermediate migratory orientations.

68 Few studies have collected similar data in wild populations, primarily due to logistical  
69 challenges. Such observations are particularly pertinent to studies of migratory divides, where  
70 populations that differ in migratory directionality come into contact and interbreed (e.g., Helbig  
71 1991; Bensch et al. 1999, 2009; Irwin and Irwin 2005; Rugg 2007; Rohwer and Irwin 2011;  
72 Ilieva et al. 2012). For example, if hybrids between divergent populations have a mixture of  
73 alleles responsible for migration and exhibit an intermediate migratory orientation, as has been  
74 observed in lab-raised blackcap warblers (Helbig 1991; Helbig 1994; Helbig 1996), such a novel  
75 phenotype may be inferior and represent an important fitness detriment. This is because, in a  
76 number of systems, intermediate routes have been suggested to take hybrid individuals over  
77 regions that are provide greater challenges in finding food (e.g., deserts) or navigating (e.g.,

78 mountains). If so, inferior routes of hybrids can cause lower survival and/or lower fecundity (if  
79 arriving on the breeding grounds in poor condition hampers reproduction), thereby contributing  
80 to postmating reproductive isolation and promoting further differentiation and speciation of the  
81 two populations (Helbig 1991; Irwin and Irwin 2005).

82         To date, the only study to directly assay the migratory behaviour of wild individuals  
83 differing in their genetic constitution across a migratory divide is in a study of Swainson's  
84 thrushes (*Catharus ustulatus*; Delmore et al. 2012; Delmore and Irwin 2014; Delmore et al.  
85 2016). In a hybrid zone between coastal and inland forms of Swainson's thrushes in western  
86 Canada, migration was studied using both light-level geolocators, to directly track migration  
87 routes and wintering locations (in Central and South America), and orientation chambers to  
88 measure migratory direction of birds beginning fall migration. Hybrids exhibited greater  
89 variability in their routes than parentals did, with some taking routes that were intermediate to  
90 parental forms and took them over the arid regions of the southwestern USA. Moreover, among  
91 Swainson's thrushes within the hybrid zone, genetic background was predictive of migratory  
92 route as well as orientation direction, and one particular genomic region showed a particularly  
93 strong association with longitude (i.e., west to east) of migratory route and wintering location  
94 (Delmore et al. 2016).

95         Given the prominence of the idea that differences in migratory behavior may cause  
96 reproductive isolation within hybrid zones (e.g., Helbig 1991; Bensch et al. 1999, 2009; Bearhop  
97 et al. 2005; Irwin and Irwin 2005; Ruegg 2007; Rolshausen et al. 2009, 2013; Liedvogel et al.  
98 2011; Rohwer and Irwin 2011; Ilieva et al. 2012), it is important to test whether there is  
99 association between genetic background and migratory orientation within a variety of hybrid  
100 zones. Here, we provide another direct examination of this question with a large-scale study of

101 birds sampled on fall migration within a hybrid zone between Audubon's / myrtle warblers  
102 (*Setophaga auduboni* and *S. coronata*) in western North America. Within this hybrid zone there  
103 are a full range of hybrid genotypes, indicating that multiple generations of hybrids and  
104 backcrosses are present and that reproductive isolation is far from complete. However, the  
105 narrowness of this hybrid zone and sizeable amounts of linkage disequilibrium in the center of  
106 the zone suggest that some form of moderately strong selection maintains it (Brelsford and Irwin  
107 2009). Assortative mating and other pre-mating reproductive barriers are unlikely to be strong  
108 between these taxa (Brelsford and Irwin 2009; Brelsford et al. 2011; Toews et al. 2014a),  
109 implying a potentially sizeable role for post-mating selection against hybrids, possibly based on  
110 inferior migratory behaviour. Band recovery and isotopic data from birds outside the hybrid zone  
111 suggests the two parental taxa differ in their migratory movements (Figure 1; Toews et al.  
112 2014a,b). If migratory traits are genetically controlled and inherited additively—as the studies of  
113 blackcaps and Swainson's thrushes suggest—we expected a correlation of orientation and  
114 ancestry in the hybrid zone. Specifically, we predicted that individuals more genetically  
115 Audubon's-like would orient SSW, individuals more myrtle-like would orient SE, and hybrids  
116 would orient intermediate between these two (i.e. south).

117 We used a video-based orientation cage method, initially developed by Fitzgerald and  
118 Taylor (2008). These orientation cages are similar in many respects to traditional Emlen funnels  
119 (Emlen 1970), but in this case the behaviour of birds was scored using video cameras. As  
120 compared to the scratch marks quantified with Emlen funnel experiments, this method has a  
121 number of benefits, including: (1) scoring of the videos can be automated, ensuring objectivity,  
122 (2) a longer period of observation can be obtained for each individual, (3) specific time periods  
123 can be analyzed in isolation and (4) any behavioural changes over the course of the trial can be

124 quantified. We designed our study to assay the orientation of individuals in the evening of the  
125 day they were captured, which previous research suggests is predictive of later orientation (Ilieva  
126 et al. 2012). We then genotyped each individual with species diagnostic genetic markers and  
127 tested whether there was a correlation between orientation and genetic background.

## 128 **Methods**

### 129 *Study site and orientation trials*

130       Between August 15<sup>th</sup> and September 12<sup>th</sup> of 2011 we captured migratory yellow-rumped  
131 warblers ( $n = 181$ ) near Kananaskis, Alberta, a site at the center of the Audubon's / myrtle  
132 warbler hybrid zone (Brelsford and Irwin 2009). Our sampling was concentrated in two areas:  
133 along the southern edge of Barrier Lake (51.0235°N, 115.0608°W) and within the hamlet of Lac  
134 Des Arc (51.0536°N, 115.1589°W; Figure 1C). We set up mist-nets before dawn and used  
135 passive netting along with song playback (using a tape of a variety of yellow-rumped warblers as  
136 well as begging calls from nestlings; previous experience showed that similar recordings could  
137 be used to attract all phenotypes in the hybrid zone) to increase our likelihood of catching  
138 individuals of our target species. These sites, timing, and capture methodology were chosen to  
139 capture birds that were beginning their migratory movements, but it is possible that some of the  
140 individuals sampled were close to their breeding territories or natal areas. Immediately after  
141 capturing each individual we took morphometric measurements (bill, tarsus, wing and tail length;  
142 according to Pyle 1997), photographs, a blood sample (10-40 $\mu$ L), and applied a unique  
143 aluminum USFWS leg band. Birds were then transported approximately three kilometers from  
144 the capture site to the location where the orientation trials were performed (51.0286°N,  
145 115.0242°W). This site is a large, recently clear-cut field (~400m<sup>2</sup>; <10 years old) near the  
146 Kananaskis Biogeoscience Institute and has clear views in all directions.

147           Each individual was placed individually into one of 12 outdoor holding / orientation  
148 cages (Figure 2) and given water and small mealworms throughout the day. The cages were a  
149 modified design based on Fitzgerald and Taylor (2008), who used similar cages to study  
150 orientation in yellow-rumped warblers (Figure 2). The cages were leveled, oriented with a  
151 compass, and spaced approximately 3-5 meters apart. The cage frames were made out of pine  
152 boards, with the top and bottom of the cages made from composite plywood. The perch was  
153 made with a 9” plastic embroidery hoop, held up by four 7/16” dowels, and placed horizontally  
154 such that birds could perch on the hoop (Figure 1C). Since research suggests that birds may use  
155 magnetic cues for navigation, the wood pieces were joined with non-magnetic brass screws and  
156 stainless steel staples were used to affix screen mesh to the top and sides of the cage (Alerstam  
157 1993; Muheim et al. 2006). During the day the sides of the cages were covered with a blue,  
158 opaque tarp for sun shelter, with part of the tarp rolled up to provide sufficient airflow (Figure  
159 2A). Using the same cages to both hold the individuals during the day and run the orientation  
160 trials in the evening has a number advantages over traditional use of Emlen funnels (Emlen  
161 1970). Most importantly, this likely reduces the stress inherent in holding individuals indoors in  
162 artificial environments and moving individuals between holding and assay cages shortly before  
163 the trials, as is necessary with funnels (Emlen 1970). We were careful in assessing the welfare of  
164 the birds: if individuals did not immediately fly to the perch, showed any signs of stress (e.g.  
165 panting), or were not eating properly they were released during the day (less than 15% of birds  
166 captured).

167           Before we started each orientation trial, we removed the food and water dishes and closed  
168 each tarp around the sides of each cages, allowing each individual to see only out of the top of  
169 the cage, which had a full view of the sky. Through a hole in the bottom of each cage we

170 attached a D-Link Wireless Network Camera (DCS-932L) pointing directly up, with the top of  
171 the camera oriented northwards. Unlike cameras that point down (e.g. Muheim et al. 2014), these  
172 upward-facing cameras do not obstruct a bird's view of the sky. The cameras we used have an  
173 infrared LED light for illumination during low light conditions. This light was applied  
174 consistently across all of the trials, and we are aware of no evidence that birds can see infrared  
175 light. The cameras were set such that the video image was recorded with the right side of the  
176 video representing the west side of the cage and the left side of the video representing the east  
177 side of the cage. We recorded 320p x 240p 30 frame-per-second video from each cage  
178 simultaneously using the D-ViewCam software on a PC laptop via a D-Link router. We began  
179 recording approximately one hour before sunset and ran the trials until approximately 30 minutes  
180 past sunset. Each evening we ran the trials until the last individual stopped moving, after which  
181 we released all of the individuals. We tested each bird once and recorded the behaviour of 1 to  
182 10 individuals each evening, averaging 6 birds per evening, with a total of 124 individuals for  
183 which we collected complete orientation data. All animal care and experimentation was  
184 conducted according to the University of British Columbia protocol Nos. A11-0054 (Project  
185 title: Orientation in migratory songbirds) and A09-0131 (Project title: Geographic variation in  
186 birds of western Canada). Field permits were provided by the Canadian Wildlife Service, Prairie  
187 and Northern Region office (AB Scientific Permit 11-AB-SC023) and Alberta Parks (11-107).

### 188 *Video analysis*

189 From the D-ViewCam software we exported each video in “.asf” format, noting the start  
190 and end time of each trial. We analyzed the video data with radR, an open source platform  
191 developed for acquiring and analyzing radar data (Taylor et al. 2010) that was more recently  
192 adapted to analyze video files. In brief, radR uses contrast to score individual pixels, and then

193 uses movement, area and intensity to define objects. We sampled the videos at three frames per  
194 second. For each detected object we extracted the X and Y coordinates of its centroid, as  
195 weighted by the area of the object. Given that the light conditions change over the evening, we  
196 used three groups of parameters to accurately and consistently identify the bird as the primary  
197 object relative to the background (see supplementary material for parameters used). We defined  
198 the center of the circular perch as the center of our analytical coordinate system and created an  
199 exclusion zone within the circular perch, such that the program would identify the bird only in  
200 the region from the perch outwards (Figure 3). This makes our results more comparable to  
201 previous funnel studies, which only recorded jumps where the individual contacts the side of the  
202 funnel (Fitzgerald and Taylor 2008). From this data radR generates a list of time-stamped X and  
203 Y coordinates for points where it identified an object (see supplementary material for an example  
204 of data extracted for a single individual).

205       Using R 3.0.3 (R-core Development Team 2013) we applied a number of additional  
206 filters, primarily to remove noise (i.e. objects that were not the bird) and remove times when the  
207 bird was not moving (i.e. sitting on the perch). To remove noise, we first removed all data where  
208 there were three or more objects identified at a single time-stamp, as three or more objects were  
209 invariably an artifact of background noise. Sometimes radR identified the bird as two separate  
210 objects, primarily when the individual was above one of the four perch dowels, such that parts of  
211 the bird stuck out on either side of the dowel. For time-stamps with two objects, we averaged the  
212 XY values that were less than 500 pixels apart to include only those times that an individual was  
213 above the dowels (i.e. the dowels are slightly less than 500 pixels wide in the video image) and  
214 visually inspected the data to confirm this was accurate. To ignore points where the bird was  
215 sitting motionless on the perch we removed consecutive time points that had a lower XY

216 distance than a predetermined threshold, which we calculated by studying videos of individuals  
217 sitting quietly on the perch (50 pixels for the current analysis). Each of the points that passed  
218 these filters were then transformed into an angle relative to North ( $N=0^\circ$ ,  $E=90^\circ$ ,  $S=180^\circ$  and  
219  $W=270^\circ$ ) and given a timestamp (in seconds) relative to the time of sunset for that evening.

220 From these data we estimated three behavioural traits for each individual: mean  
221 orientation, rho and activity, defined as follows. We calculated mean orientation using the  
222 “circular statistics” package in R (Agostinelli and Lund 2007). We used the mean of angles  
223 observed over the entire observational period (restricting the time range to only those times when  
224 the birds were more active did not meaningfully change the results). We used the same R  
225 package to estimate rho, an estimate of angular variance that varies between 0 and 1 (i.e. a  
226 measure of the concentration of points, with a value of 1 being perfectly concentrated). Finally,  
227 we used the total number of time points at which an object (i.e., a moving bird) was detected by  
228 radR over the trial as the total activity for each individual.

229 To assess robustness of estimating the mean orientation for each individual using the data  
230 generated from radR, we chose five orientation videos at random and scored them by eye, blind  
231 to the output from radR. For this we visually estimated the angle of the bird (if present in the  
232 frame) every 30 seconds, over the entire video, and also recorded whether the bird was on the  
233 perch or in mid-flight. We then calculated the difference in angle between this estimate and that  
234 obtained from radR for the full dataset and also from only those points where the bird was  
235 observed to be in flight. Our data filtering appeared to be effective as our data from a random  
236 selection of videos analyzed by eye (for 5 birds) was consistent with the output from radR. When  
237 we compared all of the points observed by eye, including those where the individual was sitting  
238 on the perch, the resultant mean angles were within  $\pm 22^\circ$  relative to the output from radR after

239 filtering. If we included only those points where the individual was in flight (by excluding those  
240 times we observed by eye for which the individual was on the perch), which our filters within  
241 radR were designed to remove, the resultant mean angles were within  $\pm 11^\circ$  of the radR output.

242

### 243 *Molecular analysis*

244 Blood samples were taken using a small needle and capillary tube from the brachial vein,  
245 stored in Queen's lysis buffer (Seutin et al. 1991), and left at ambient temperature until returned  
246 to the laboratory. DNA was extracted using a standard phenol-chloroform procedure and  
247 resuspended with 50 – 200  $\mu$ L of buffer (depending on the size of the pellet) containing 10 mM  
248 Tris-HCl and 1 mM EDTA, at pH 8.0, and stored at 4° C. We sexed individuals molecularly  
249 using the procedure described in Fridolfsson and Ellegren (1999). We genotyped individuals at  
250 three molecular markers. The full PCR and genotyping protocol for two of the three nuclear  
251 markers (*CHDIZ* and *numt-Dco1*) was presented in a previous publication (Brelsford and Irwin  
252 2009). For the third nuclear marker, an 850 base pair fragment of *RIOK2*, we used the forward  
253 primer 5'-ATGGGTGTTGGCAAAGAATC-3', the reverse primer 5'-  
254 GCTCCTCTTCRTTWGCAACA-3', and a PCR annealing temperature of 60°C. The enzyme  
255 *XmnI* cuts an allele common in Audubon's warblers, but leaves intact an allele common in  
256 myrtle warblers. To generate a genetic hybrid index we scored a zero for each Audubon's allele  
257 and a one for each myrtle allele for the three markers and divided this by the total number of  
258 alleles (6 for males, 4 for females) resulting in an index that ranges between 0 (all Audubon's  
259 alleles) to 1 (all myrtle alleles).

## 260 *Combining genotype and migratory behaviour*

261           To test whether orientation is associated with genetic background, we used two statistical  
262 approaches. First, we used a circular linear model to test whether orientation varied linearly with  
263 hybrid index (Agostinelli and Lund 2007). Second, we used a circular ANOVA to test whether  
264 mean orientation angle differed in any way (not necessarily linearly) among these five genetic  
265 groups: those with all Audubon's alleles (h-index = 0; Group A), those with mostly Audubon's  
266 alleles ( $0 < \text{h-index} < 0.5$ ; Group AH), those with mixed genotypes (h-index = 0.5; Group H),  
267 those with mostly myrtle alleles ( $0.5 < \text{h-index} < 1$ ; Group MH), and those with all myrtle alleles  
268 (h-index = 1; Group M). While the linear model would assume that each hybrid class as an  
269 intermediate migratory orientation compared to the two classes on either side of it, the ANOVA  
270 does not make that assumption, allowing situations in which hybrid classes might have more  
271 extreme orientations than either parental group.

272           To test whether there was a significant mean orientation of all of individuals considered  
273 together, regardless of their genetic background, we used a Rayleigh test. This is a procedure to  
274 test the null hypothesis that the orientation angles are distributed randomly, with the alternative  
275 being that the distribution is clumped in certain direction(s). The test statistic is  $r$ , or rho, and is  
276 the magnitude of the mean vector (Fitzgerald and Taylor 2008).

## 277 **Results**

### 278 *Molecular data*

279           We obtained genotypes from 166 of the 181 yellow-rumped warblers captured at the  
280 beginning of fall migration through the Kananaskis area, including 123 individuals with  
281 orientation data. Based on the three genetic markers, our data set consisted of individuals with a  
282 broad range of genetic backgrounds, spanning from Audubon's warblers (h-index = 0) through a

283 broad array of hybrid genotypes to myrtle warblers ( $h\text{-index} = 1$ ), consistent with the expectation  
284 based on prior research of a broad mixture of hybrid classes (F1's, F2's, backcrosses, etc.) and  
285 pure-type individuals (Brelsford and Irwin 2009). The daily composite allele frequencies varied  
286 relatively little over the study period: the daily proportion of myrtle alleles was usually between  
287 0.3 to 0.6, with an average over the study period of 0.4 (Figure 4A). Our molecular sexing of  
288 individuals indicated that we captured an excess of male birds with 73% of all of the individuals  
289 identified as males (Figure 4B). This was likely due to our use of song playback during mist  
290 netting.

### 291 *Orientation trials*

292 In the orientation trials, initial observations of yellow-rumped warblers in the orientation  
293 chambers indicated that their activity begins to increase approximately one hour before sunset.  
294 During this time of increased activity their behavior also changed qualitatively, from primarily  
295 sitting on the perch and/or flying occasionally to and from the bottom of the cage, to performing  
296 more short flights from the perch to the top of the cage, consistent with *zugunruhe* (i.e. migratory  
297 restlessness; Emlen 1970). The activity of the birds increased to a peak at around 20-30 minutes  
298 before sunset (Figure 5), and then gradually declined. Following sunset their activity sharply  
299 declined, such that we recorded virtually no movements after 40 minutes post-sunset. At the end  
300 of most evenings individuals usually stopped moving within 5-10 minutes of each other with  
301 remarkable consistency (the steep decline to the right of Figure 5).

302 Of the 123 individuals where we had genotype and orientation data, we found that 96  
303 birds showed strong evidence of orientation behavior (i.e., within-individual  $r > 0.1$ ; total  
304 activity  $> 500$ ). We used all 123 individuals in analyses; analyses using only those individuals  
305 with strong orientation did not qualitatively change results. Of the five genetic groups, our

306 sample contained  $n = 6$  for Group A (i.e., genetically Audubon's),  $n = 45$  for Group AH,  $n = 41$   
307 for Group H,  $n = 22$  for Group MH and  $n = 9$  for Group M (i.e., genetically Myrtle). We did not  
308 detect a significant difference in mean orientation between the genetic groups ( $F = 1.23$ ,  $P =$   
309  $0.09$ ) and there was no significant linear relationship between mean orientation and genetic  
310 hybrid index ( $t = 0.779$ ,  $P = 0.22$ ). Hence we could not reject the null hypothesis of no  
311 association between genetic background and orientation.

312 While there was considerable variability in orientation among individuals, there was a  
313 significant mean orientation towards  $25^\circ$  or NNE (Figure 6A;  $n = 123$ , among-individual  $r =$   
314  $0.320$ ,  $P < 0.01$ ), with a 95% confidence interval between  $5^\circ$  and  $46^\circ$ . Separating the birds by  
315 their genetic hybrid index, each group had mean orientations similar to N or NE, although only  
316 Groups M (h-index = 1) and H (h-index = 0.5) showed evidence of significant mean orientations  
317 compared to the null of an even distribution of orientation angles: Group A,  $38^\circ$  ( $n = 6$ ,  $r =$   
318  $0.634$ ,  $P = 0.09$ ); Group AH,  $3^\circ$  ( $n = 45$ ,  $r = 0.230$ ,  $P = 0.09$ ); Group H,  $54^\circ$  ( $n = 41$ ,  $r = 0.373$ ,  $P$   
319  $< 0.01$ ); Group MH,  $359^\circ$  ( $n = 22$ ,  $r = 0.321$ ,  $P = 0.10$ ); and Group M,  $15^\circ$  ( $n = 9$ ,  $r = 0.733$ ,  $P <$   
320  $0.01$ ).

## 321 Discussion

322 Here we have provided the second study of potential association of genetic ancestry and  
323 migratory orientation in an avian hybrid zone. Our use of video-based orientation trials and  
324 automated video analysis enabled us to sample a large number of individuals during fall  
325 migration while also gathering high resolution and orientation chamber movement data for each  
326 bird, a benefit over previous Emlen funnel methods. Despite these methodological advantages  
327 and prior evidence for a possible migratory divide across the Audubon's / myrtle warbler hybrid  
328 zone (Toews et al. 2014a), we did not find an association between genetic background and

329 orientation. We discuss below the possibilities that this result was due to (1) lack of any true  
330 association between genetic background and migratory route within this hybrid zone, (2) short-  
331 term orientation during the time of the study not being indicative of long-distance migration  
332 orientation; or (3) methodological limitations that hindered the detection a true association.

333         First, the prior evidence for a migratory divide across the yellow-rumped warbler hybrid  
334 zone is mixed, raising the possibility that our results are due to no actual association of genetic  
335 ancestry and migratory differences in the center of the zone. Banding data and wintering range  
336 maps of Audubon's and myrtle warblers indicate that Audubon's warblers largely winter in the  
337 southwestern USA, whereas myrtle warblers mostly winter in the southeastern USA (Toews et  
338 al. 2014a). However, sizeable numbers of myrtle warblers winter in the southwest (Hunt and  
339 Flaspohler 1998). It has been postulated that most of these belong to a distinct form of myrtle  
340 warbler (the subspecies *hooveri*) breeding in Alaska, the Yukon, and northern British Columbia  
341 (McGregor 1899; Toews 2017). However, it is also possible that some myrtle warblers from  
342 Alberta also migrate to the southwestern USA, and that the current hybrid zone between  
343 Audubon's and myrtle warblers in western Alberta does not correspond to a migratory divide.  
344 Isotopic data (Toews et al. 2014a) is mostly supportive of the hybrid zone coinciding with a  
345 migratory divide, because sites just outside of the hybrid zone differed in their hydrogen isotopic  
346 signatures in a way consistent with the expected difference between southwestern and  
347 southeastern USA, and birds within the hybrid zone showed a broader mixture of signatures.  
348 Taking this evidence together, it is likely that there is at least some sort of transition in average  
349 migratory orientation between Audubon warblers in central British Columbia and myrtle  
350 warblers in central Alberta, but it is possible that that the transition zone is very broad, with birds

351 in the center of the hybrid zone having no or only a weakly detectable relationship between  
352 ancestry and migratory orientation.

353         Second, it is possible that the behavior that we observed in the chambers is indicative  
354 only of short-term and short-distance orientation rather than longer-term and longer-distance  
355 migratory orientation. Among individuals we found a lot of scatter in directional tendencies, with  
356 a mean migratory orientation that was surprisingly towards the NNE ( $26^\circ$ ), odd for birds on fall  
357 migration, which is expected to be generally southward. A possible explanation is that  
358 individuals may be moving northeast, out of the valleys in the Rocky Mountains, to later turn  
359 south. The orientation of the valley near the capture location and orientation experiment area is  
360 approximately  $23^\circ$  (NNE; estimated using Google Earth™), very close to the observed  
361 orientation of the birds when grouped together ( $26^\circ$  NNE). Our sample likely included many  
362 hatch-year birds, raising the possibility that the northward orientation of some birds may be  
363 indicative of regional-scale post-fledging movements (such as those made by blackpoll warblers;  
364 Brown and Taylor 2015), the incidence and function of which are still unknown. While previous  
365 orientation studies have tested the effect of ecological barriers on migratory behaviour (i.e. water  
366 bodies; Sandberg and Moore 1996; Ilieva et al. 2012), this is one of the first studies to assay  
367 orientation in and around mountainous areas. Using high-resolution radar technology, Williams  
368 et al. (2001) found evidence that nocturnal migrants responded to local topological features by  
369 changing their orientation during fall migration, especially those birds migrating below 300m, as  
370 is assumed with yellow-rumped warblers. Given the type of data these methods collect, however,  
371 it is challenging to assign these types of observations to specific species or even species groups  
372 (Williams et al. 2001). For the warblers in our study, individuals might have a memory of the  
373 axis of the valley at the time of capture, and then orientation in that direction. We recommend

374 that future orientation studies around mountainous areas should consider including additional  
375 orientation localities in valleys of varying orientations. It would also be useful to assay  
376 individuals each evening over a longer period (i.e. 1-2 weeks) to test whether this orientation is  
377 maintained or dissipates with time. This could provide a robust test of the role of topological  
378 features in influencing migratory movements.

379         Finally, it is possible that the observed chamber orientations are not representative of  
380 movements the birds would make if they were outside of the chambers. All experiments using  
381 orientation chambers with captive birds run the risk that migratory movements in specific  
382 systems may not be well represented by cage movements, although it is remarkable how often  
383 there is a strong association (e.g., Helbig 1991, 1996; Alerstam 1993; Van Doren et al. 2017).  
384 The movements and pattern of activity of the warblers in our study were qualitatively similar to  
385 previous descriptions of *zugunruhe*, suggesting that the yellow-rumps in our sample were  
386 expressing behaviours consistent with migration. But given the unexpected mean orientation  
387 toward the northeast, the lack of any relationship with genetic background, and the reasonably  
388 short duration of the movement behavior each evening, we acknowledge that it is plausible that  
389 orientation cage behaviors in our study are not indicative of orientation in free-moving birds.  
390 Given this concern, we suggest that tracking studies using direct tracking technology such as  
391 radio towers and miniaturized geolocator tags may be more useful for studying large-scale  
392 migratory orientation (Taylor et al. 2011; Delmore et al. 2012; Veen 2013; Delmore and Irwin  
393 2014).

394         In conclusion, we used molecular genetic methods and a video-based orientation assay  
395 that provided objective, high resolution temporal data for many individuals in a semi-natural  
396 setting. Our results show no significant association between genetic ancestry and chamber

397 orientation of migrating yellow-rumped warblers within a hybrid zone that was postulated to  
398 correspond to a migratory divide. These results provide an interesting contrast to Swainson's  
399 thrushes, in which genetic ancestry within a hybrid zone is predictive of migratory orientation as  
400 measured both by geolocators and orientation chambers (Delmore et al. 2016). We suggest that,  
401 with future modifications, these methods could provide a powerful tool for understanding  
402 migratory orientation in many species. In particular, when replicated in multiple locations, one  
403 could use these orientation assays to examine the effect of local topographical features. Or, if  
404 assayed orientations were verified by geolocators, one could identify potentially maladaptive  
405 migratory tendencies in hybrid individuals. We hope these methods will contribute to the  
406 understanding of migratory divides, and of migration more generally.
