Background. The demography of a coral colony is not a binary trajectory of life and death. Based on the flexibility afforded by colonial organization, most reef-building corals employ a variety of dynamic survival strategies, including growth and shrinkage. The demographic flexibility affects coral size, shape and reproductive output, among other factors. It is thus critical to quantify the relative importance of key dynamics of recruitment, mortality, growth and shrinkage in changing the overall cover of coral on a reef.

Methods. Using fixed photographic quadrats, we tracked the patterns of change in the cover of one common central Pacific coral, *Porites superfusa*, before and after the 2009 ENSO event.

Results. Coral colonies suffered both whole and partial colony mortality, although larger colonies were more likely to survive. In subsequent years, recruitment of new colonies and regrowth of surviving colonies both contributed to the modest recovery of *P. superfusa*.

Discussion. This study is unique in its quantitative comparisons of coral recruitment versus regrowth during periods of areal expansion. Our data suggest that recovery is not limited simply to the long pathway of settlement, recruitment and early growth of new colonies but is accelerated by means of regrowth of already established colonies having suffered partial mortality.

9 Introduction

10 Understanding patterns of mortality and recovery among reef-building corals is
 11 foundational to the development of accurate predictions of coral population trajectories (Baird &
 12 Marshall 2002). Recruitment has been recognized as important for long-term recovery after
 13 major and frequent disturbances, especially for coral populations that have suffered widespread,
 14 whole-colony mortality (Dollar & Tribble 1993). However, many disturbance events are less
 15 extreme, leading to a combination of partial and complete mortality. We define partial mortality
 16 of colonial corals as the response to a stress event that leads to tissue loss, but with the survival
 17 of some colony area. For colonies suffering from partial mortality, regeneration of tissue
 18 following stress is a critical mechanism in assuring individual colony survival (Chadwick &
 19 Loya 1990). As such regrowth of corals has been suggested as an important mechanism in coral
 20 population recovery (Diaz-Pulido et al., 2009; Gilmour et al., 2013). In this context, analyzing
 21 recovery characteristics can help project population resilience.

22 Given the colonial nature of most reef-building corals, the definition of an ‘individual’
 23 presents real challenges (Hughes, Ayre & Connell 1992). Coral ecological literature often refers
 24 to an individual as a colony. Interactions and population dynamics are sometimes best described
 25 at the colony scale, including patterns of size-specific mortality, competition for space on the
 26 benthos, and vulnerability to storm damage (e.g., Hughes & Jackson 1980; McCook, Jompa &
 27 Diaz-Pulido 2001; Baird & Marshall 2002; Madin et al., 2014). In contrast the physiological
 28 definition of an individual is the polyp (Harper 1985). In particular both asexual (fission/
 29 budding) and sexual (spawning/ brooding) modes of reproduction occur at the scale of the polyp.
 30 When tracking demographic responses to environmental change or disturbance, it is critical to
 31 account for dynamics occurring at both the scale of the colony and the scale of the polyp.

Corals are capable of four known mechanisms of loss and recovery: complete-colony mortality, partial colony mortality (tissue loss), recruitment, and partial-colony growth (sometimes referred to as regrowth) (Fig 1). A few recent studies have documented the relative importance of recruitment and regrowth as mechanisms of coral population recovery following a disturbance (Diaz-Pulido et al., 2009; Gilmour et al., 2013; Roff et al., 2014), however, the colonial mechanisms of coral recovery have not been regularly quantified.

Due to its remote location and lack of local anthropogenic impacts, Palmyra Atoll is an ideal location for studying demographic rates of corals in response to global change (Knowlton & Jackson 2008; Sandin et al., 2008; Williams et al., 2011). Palmyra is a US National Wildlife Refuge and is part of the Pacific Remote Island Areas National Marine Monuments and is protected from fishing and other impacts. In 2009, Palmyra Atoll experienced a mild bleaching event associated with an El Nino Southern Oscillation (ENSO) event (Williams et al., 2010). During the 2009 ENSO event, sea surface temperatures reached 1.5°C above the maximum long-term monthly temperatures, and the anomaly continued for four months (Williams et al., 2014). October 2009 through March 2010 had over 4 DHW (degree heating weeks) with November through March over 8 DHW (NOAA Coral Reef Watch).

This study examines patterns of change in an encrusting coral, *Porites superfusa*, on Palmyra Atoll during and after the thermal stress event. Specifically, our objectives were to address two complementary questions: (1) Does *P. superfusa* cover change through time from 2009 to 2012 on Palmyra Atoll? (2) What are the relative rates of colony survivorship (recruitment/ mortality) versus colony growth (growth/ shrinkage) during and after a bleaching event?

55 **Materials & Methods**

56 *Study Species*

57 *Porites superfusa* is a small coral that is relatively ubiquitous on Palmyra Atoll, reaching
58 almost 400 cm² in area with an overall mean colony size of 9.9 cm² (median = 4.4 cm²). Our
59 targeted design involved this species because it is one of the most numerous corals in the area,
60 and its compact morphology allows study of multiple individuals within square meter
61 photoquadrats (see below). In 2009, the *P. superfusa* population showed extensive evidence of
62 bleaching with a notable reduction in cover in the permanent photoquadrats.

63

64 *Surveys*

65 Four forereef sites on Palmyra Atoll were selected, two sites on the north and two sites on
66 the south shore, each approximately 2 km apart (Fig 2). Sites were chosen to be representative of
67 Palmyra's forereef habitats. These sites all had high initial densities (C_{2009}) of *Porites superfusa*
68 colonies, and as they are evenly spaced across the island they should capture within-island
69 differences in the forereef habitat. Sites were surveyed four times at approximately annual
70 intervals (September 2009, July 2010, September 2011, and September 2012).

71 At each site, one 50 m transect was permanently marked, parallel to shore and at a depth
72 of 10 m. In 2009, ten permanent photoquadrats were established at each site, positioned every 5
73 m along the transects. The corners of plots were marked with stainless steel eyebolts held in
74 place with marine epoxy (US Fish and Wildlife Special Use Permit 12533-16006). Each
75 photoquadrat was imaged with a Canon G12 camera attached to a PVC frame (0.54 m²) by
76 SCUBA divers (Sandin et al., 2008). These marked plots were revisited and re-surveyed,

enabling the tracking of individual colony fates through time. In sum, 40 0.54 m² plots were surveyed annually for a total of four time points each.

Image analyses

Within each photograph, colonies of *P. superfusa* ranged in area from 0.2 cm² to 440 cm². Due to the limitations of the photographic resolution, the tracking of the smallest colonies was not possible and thus we focused our study on colonies exceeding 1 cm². Photographs were analyzed using ImageJ to calculate the size (estimated as 2-dimensional area when viewed from the top down) and survivorship of each *P. superfusa* colony within the images (Fig 3, Abramoff, Magalhaes & Ram 2004). Each colony was tagged digitally and tracked through time (similar to methods of Hughes & Jackson 1985). Fates of the colonies were placed into one of five categories – complete mortality, partial mortality, true recruits, growth, and ‘resurrected’ recruits. Complete mortality was defined as the death of the entire visible coral, with its previous location overgrown by other organisms (Fig 3B-1). Partial mortality (i.e., injury, shrinkage) was recorded when colonies lost tissue (Fig 3B-2). True recruitment (or settlement) indicated a new coral recruit had claimed substrate in an area previously without *P. superfusa* (Fig 3B-3). Growth occurred when a previously present colony created additional tissue (Fig 3B-4). ‘Resurrected’ recruits were defined as apparent recruits that appear in a location where a colony had been recorded as suffering mortality in previous time points (Fig 3C-5, Fig 1). Because of the limitations of the photographic census, it was impossible to determine whether such recruits were new recruits (new colony settling at the same location) or regrowth from microscopic areas of cryptic remnant tissue. Individual colony cover and total *P. superfusa* cover were calculated per

quadrat. Data are reported in two formats: colony-specific fates and total live *P. superfusa* cover summed within quadrats tracked through time.

Data analyses

Analyses assessed patterns of variation in starting live *P. superfusa* cover across sites, thus determining whether changes through time were similar among years. One-sample t-tests were used to calculate differences of *P. superfusa* cover among sites in 2009 and to determine differences between absolute change and proportional change in coral cover between time points. Absolute change was the difference in coral surface area (cm²) per quadrat (e.g., cover in 2010 – cover in 2009, or C₂₀₁₀-C₂₀₀₉). Proportional change was the relative difference in coral cover between time points compared to the original coral cover in 2009 (e.g., [C₂₀₁₀-C₂₀₀₉]/C₂₀₀₉). Tukey's post-hoc tests were used to determine potential differences among sites.

Because the same individual colony can appear in multiple years, analyses assessed the possible effect of independence of colonies through time. ANCOVA was used to determine interaction effects of year and site. Because 109 colonies were repeatedly assessed, data were randomly sampled using each colony only once. A binomial logistic regression was used to determine the effect of colony size on survivorship across years. Analyses were performed using R version 3.1.2 (R Development Core Team, www.r-project.org).

Results

The 2009 temperature rise impacted approximately 75% of the *Porites superfusa* population at Palmyra Atoll with bleaching and mortality observed island-wide. The initial size

of individual colonies was greater on average than in subsequent years. The number of colonies present in 2009 was also greater than in later time points. True recruit numbers in 2010 (after the bleaching event of 2009) were lower than in 2011 and 2012 (Supplementary Table 1).

All sites surveyed exhibited similar patterns of decline in *P. superfusa* from 2009 to 2010, followed by fluctuations of growth in 2011 and 2012 (Fig 4, 5). From 2009 to 2010, *P. superfusa* mortality was ubiquitous across sites, and the growth for this period was the lowest observed during the study (Fig 4). Mortality was divided into two categories: complete and partial mortality. These mechanisms contributed similarly to the reduction in cover observed (Fig 4, partial mortality: $-101.8[56.79]$ cm² per quadrat, mean [SE], complete mortality: $-105.7[39.10]$ cm² per quadrat, mean [SE]). Recruitment and growth were minimal initially, revealing no appreciable difference among growth mechanisms (Fig 4, Recruit: $4.99[1.31]$ cm², Growth: $4.56[0.69]$ cm² per quadrat). Across the study duration, the highest rates of growth were observed from 2010 to 2011. Resurrected recruits (i.e., apparent recruits that appear in a location where a colony had been recorded as suffering mortality in previous time points) made up a third of total “recruitment” ($12.45[4.45]$ cm²). Recruitment contributed less than colonial growth to the overall gain in cover (Fig 4, Recruit: $24.06[8.77]$ cm², Growth: $39.84[13.19]$ cm²). From 2011 to 2012, resurrected recruits played a decreased role ($2.702[0.49]$ cm²) in population growth. True recruitment and growth contributed similarly to overall growth (Recruit: $14.29[18.37]$ cm², Growth: $18.37[6.45]$ cm²).

In 2011, 83 of over 400 colonies (21%) reappeared (after being overgrown by turf and crustose coralline algae in 2010) and began to re-colonize the substrate 10 months later (resurrected recruits, Supplementary Table 1). Out of 1150 colonies tracked, approximately 100 fragmented into apparent daughter clones (due to partial mortality) and 79 fused. Of the 100

colonies that fragmented, 52 fused back with a remnant section of the original colony within 2 years.

This study found that *P. superfusa* colonies gained upwards of 80 cm² of new tissue area per year and lost up to 170 cm² of tissue area per year, with a mean tissue change of $|4.75[0.232]$ cm² per colony. During the time period that included the bleaching event from 2009 to 2010, *P. superfusa* declined an average of 8.3 cm² per quadrat (total quadrat size, 540cm²). From 2010 to 2011, the corals increased an average of 1.7 cm² per quadrat (Welch two sample t-test, $t = -3.74$, $p = 0.028$) and from 2011 to 2012 corals declined an average of 0.9 cm².

Average change in area, when normalized to initial coral size in 2009, was largely negative (Fig 4, 5) and inversely related to size. Smaller corals gained more proportional area relative to larger colonies. The year with the most negative growth was 2009-2010, with the following years slightly less negative (Fig 5). The overall change in *P. superfusa* cover from 2009 to 2010 ($C_{2010}-C_{2009}$) was negative (one sample t-test on $C_{2010}-C_{2009}$, $p < 0.001$) with no clear differences among sites (Tukey post-hoc). The change in cover from 2010 to 2011 ($C_{2011}-C_{2010}$) was minimal growth (one sample t-test on $C_{2011}-C_{2010}$, $p < 0.001$), followed by a slightly negative change from 2011 to 2012 (one sample t-test, $p = 0.09$, Fig 5). There was no statistical artifact associated with including repeatedly measured colonies, i.e., colonies with multiple transition data through time, in the ANCOVA analysis, as the results from bootstrapped subsampled data were comparable to those from the entire dataset (in only one iteration of the random resampling was a significant site effect was noted).

We recorded a significant relationship between initial size of a coral colony in 2009 and survival across time points (Fig 6). Larger corals had the greatest declines in area, but they were more likely to survive across time points. The size of the colony in 2009 predicted survival in

2012, with larger colonies showing a higher probability of survival (binary logistic regression, $p < 0.05$, for all time points). Figure 6 depicts the frequency of colony size classes and their survival from 2009 to 2012. The pattern is bimodal, with an increase in frequencies in the smaller corals, followed by a sharp decrease and then a slight increasing pattern of size. The size frequency between the two groups (survivors and non-survivors) was similar, however the largest size classes all survived to the end of the study, while the smaller size classes were more abundant across all years (Fig 6). The average size of colonies varied from approximately 5 cm² to 14 cm².

Discussion

The goal of this study was to quantify the population dynamics of a common encrusting coral during and after an ENSO event on a remote reef in the central Pacific. The effects of the ENSO warm-water event on the population of *Porites superfusa* on the forereef on Palmyra Atoll were dramatic and widespread. The ENSO event was associated with temperatures up to 30°C at the sites surveyed in 2009 (Maximum degree heating weeks 16, Williams et al., 2010), and in our results *P. superfusa* suffered high mortality rates for over a year after the bleaching event.

The fates of colonies tracked through time revealed that the mechanisms of growth and death changed in surprising ways. After the bleaching event in 2009, corals suffered widespread mortality. Although, clonal growth (colony expansion) was recorded in a subset of individuals, complete and partial mortality were sufficiently large so as to overcome the signal of minimal growth (Supplementary Table 1). Regrowth (from colony expansion and resurrected recruits) was an important driver of recovery and contributed to over 50% of the increase in cover of *P. superfusa*. Growth of corals in cryptic habitats, such as crevices or areas shaded by other corals,

may be responsible for some of this survival and growth. In 2010, after the mortality event, colony growth increased. This is consistent with other documented case studies, which suggest that corals may increase growth rates to heal after injury (e.g., Kramarsky-Winter & Loya 2000). However, the recorded increase in growth contradicts the idea that bleaching may decrease regeneration abilities of some corals (Meesters & Bak 1993).

Resurrected recruits played a surprising role in the coral's population growth (over 12% of total growth). The resurrected recruits could be a type of regrowth of cryptic tissue, beyond the observational scope of this study. Some of the regrowth appeared to be emerging out from underneath coral species that were shading the underlying benthos, such as *Pocillopora meandrina*, and this survival could indicate that partial mortality was induced from UV stress in exposed portions of the benthos (Baird & Marshall 2002). However, in many cases, the resurrected recruits appeared on a flat reef surface, emerging from benthic areas apparently covered in turf or crustose coralline algae. Unfortunately, the resolution of the photographs did not allow us to determine without question how the corals may have resurrected, for example, from a surviving piece of tissue in a small crevice or otherwise obscured from view. Alternatively, it is possible that these patterns represent true recruitment of larvae onto the exact same location as an adult colony had formerly occupied. Nonetheless, these observations hint at the modularity of coral colonies, and the spatial consistency among 'new' recruits is intriguing and warrants further investigation.

In certain cases the partial mortality of *P. superfusa* resulted in fragmentation (100 colonies) or clone fission (79 colonies). Fragmented coral colonies living in close proximity (groups of daughter clones) have a potentially higher rate of survival, as they are not as easily eliminated from disease or competition (Highsmith 1982). However, fragmentation in this study

was relatively low (<10%), and thus it is unclear if the “fused” colonies (<10%) were more likely to survive. While recruitment is important for some coral recovery, within-colony expansion and regrowth were of comparable quantitative importance regarding *P. superfusa* growth at Palmyra Atoll. Some *Porites* spp. have been found to have a limited capacity for recruitment (Potts et al., 1985), which may make regrowth a specifically useful recovery mechanism for this genus. A recent study by Roff and colleagues (2014) found that regrowth was an important contributor to the population-scale recovery of massive *Porites*. The ability of corals to regrow from remnant polyps may prove vital to recovery as climate change continues. If the regrowth of small fragments of remnant tissue can bring colonies back from apparent mortality, then colonies that appear dead in traditional coral surveys may actually have a chance at survival. As a result, traditional coral surveys may overemphasize mortality.

Coral colony size was an important predictor of the coral’s ultimate fate (Fig 6). Interestingly, *P. superfusa* seemed to have size-dependent growth and death. Growth decreased with increasing size, suggesting that this species may have determinate growth. This growth pattern could be due to high levels of partial mortality. In addition, as is consistent with the literature, smaller colonies of *P. superfusa* experienced higher rates of overall change, including mortality and recovery (Hughes & Jackson 1985). Large colonies are more likely to suffer partial mortality, which may be part of the declining growth with size phenomenon (Hughes & Jackson 1985). Probabilistically, larger colonies are more likely to suffer injury due to a larger surface area, and this may be a factor in the decline of overall growth. Smaller colonies tend to experience damage in a more binary way: either resisting disturbance entirely or dying completely, suffering less incidence of partial mortality (Connell 1973; Hughes & Jackson 1985).

While this study documents the potential for coral regrowth following anomalous temperature events, it is important to note that recovery did not exceed mortality over the course of this study. The decline in *P. superfusa* cover from 2009 to 2010 occurred more rapidly than the increase in coral cover from 2010 to 2011 and the decline from 2011 to 2012. Full population recovery is a slow process, and the longer-term trajectory of *P. superfusa* on Palmyra remains to be seen.

Understanding the effects of large-scale phenomena on community dynamics in relatively pristine reefs provides critical benchmarks for coral demography (Edmunds 2002). Further studies on this topic will help quantify the importance of fragmented or remnant corals for reef recovery processes. Examination of other species at these sites may provide important comparisons among morphologies and between species with different life history strategies, which combined may help infer the likelihood of community level recovery. The causes of bleaching, mortality, resistance, and recovery are clearly complex and species-specific. Thus, additional studies from remote Pacific island coral communities are important for understanding the capacity of these systems for recovery via different mechanisms; such studies will help to directly improve the policies for protection of reefs worldwide.

Conclusions

This study documented a bleaching event and subsequent change in areal cover of a common coral on a remote central Pacific atoll. Coral populations can change via four different dynamic processes: complete mortality, partial mortality, growth, and true larval recruitment. This study suggests a fifth dynamic, ‘resurrected’ recruits, as a mechanism contributing to coral

259 recovery. Additional research is needed to determine the source of this coral growth (e.g.,
260 exploitation of cryptic habitats, regrowth of remnant tissue),.

261 With increasing climate pressures, many coral reefs have experienced rapid decline. In
262 such cases, tissue loss due to mortality is faster and more obvious than tissue gain due to growth.
263 Coral growth is often slow and subtle, making it a difficult research and management target for
264 short time scales. Despite the challenges associated with quantification, regrowth is a critical
265 process in coral recovery, and it is vital we understand the mechanisms controlling it. The
266 implications from this study of colony-specific patterns of decline and recovery should be scaled
267 up to examine the role of regrowth and the future of remote Pacific islands' reef recovery.
