

Associations between the human intestinal microbiota, *Lactobacillus rhamnosus* GG and serum lipids indicated by integrated analysis of high-throughput profiling data

Accumulating evidence indicates that the intestinal microbiota regulates our physiology and metabolism. Bacteria marketed as probiotics confer health benefits that may arise from their ability to affect the microbiota. Here high-throughput screening of the intestinal microbiota was carried out and integrated with serum lipidomic profiling data to study the impact of probiotic intervention on the intestinal ecosystem and on host, and to explore the associations between the intestinal bacteria and serum lipids. We performed a comprehensive intestinal microbiota analysis using a phylogenetic microarray before and after *Lactobacillus rhamnosus* GG intervention. While a specific increase in the *L. rhamnosus*-related bacteria was observed during the intervention, no other changes in the composition or stability of the microbiota were detected. After the intervention, lactobacilli returned to their initial levels. As previously reported, also the serum lipid profiles remained unaltered during the intervention. The most prevailing association between the gut microbiota and lipid profiles was a strong positive correlation between uncultured phylotypes of *Ruminococcus gnavus*-group and polyunsaturated serum triglycerides of dietary origin. Moreover, a positive correlation was detected between serum cholesterol and *Collinsella* (*Coriobacteriaceae*). These associations identified with the spectrometric lipidome profiling were corroborated by enzymatically determined cholesterol and triglyceride levels. Actinomycetaceae correlated negatively with triglycerides of highly unsaturated fatty acids while a set of Proteobacteria showed negative correlation with ether phosphatidylcholines. Based on a high-resolution microbiota analysis, intake of *L. rhamnosus* GG did not modify the composition of the intestinal ecosystem in healthy adults, indicating that probiotics confer their health effects by other mechanisms. Our results suggest that several members of the Firmicutes, Actinobacteria and Proteobacteria may be involved in the metabolism of dietary and endogenous lipids, and provide a scientific rationale for further human studies to explore the role of intestinal microbes in host lipid metabolism.

21 Introduction

22 Over 90% of the cells in the human body constitute microbes, the majority of them living in the lower
23 part of the gastrointestinal (GI) tract. Hence, we are composite organisms programmed not only by the
24 inherited and stable human genome but also by the environmentally acquired and plastic microbiome.
25 The coding capacity of the microbiome vastly surpasses the human genome with more than three
26 million genes (Qin *et al.* 2010). While many of the microbial functions have not yet been characterized,
27 various mechanisms have been described by which the intestinal microbes impact our life, including
28 the metabolism of our food, exclusion of pathogens and many signaling functions that range from
29 modulation of the mucosal immune response to development of metabolic diseases (Holmes *et al.*
30 2011; Sekirov 2010). Bacterial metabolism of dietary and endogenous substances is known to generate
31 a wide repertoire of metabolites that may have beneficial or harmful effects on the host (O'Keefe 2008;
32 Blaut & Clavel 2007). Hence, the intestinal microbiota has a remarkable potential to influence the
33 physiology and biology of the host (Tremaroli & Bäckhed 2012), and unlike the human genome, its
34 gene pool can be modulated by changing the environmental conditions, such as food or drug intake,
35 affecting the composition and function of the intestinal microbiota (Zoetendal, Rajilić-Stojanović & de
36 Vos 2008).

37 Consumption of lactic acid bacteria marketed as probiotics is a common approach to maintain
38 health (Saxelin *et al.* 2005). *Lactobacillus rhamnosus* GG is one of the most widely used probiotic
39 bacteria that is assumed to interact with the host via binding to human mucus via its extracellular pili
40 (Kankainen *et al.* 2009). However, the further molecular details of the probiotic signaling are not yet
41 understood and it remains to be established whether the effect is direct, through metabolites or
42 structural components modulating for instance the immune responses of the host or indirect, via
43 alteration of the intestinal microbiota. From the ecological perspective, a single bacterial strain is not
44 likely to radically alter the established intestinal community, which in adults typically consists of

hundreds of different species-level phylotypes that represent approximately ten bacterial phyla, vastly dominated by Firmicutes, Bacteroidetes and Actinobacteria, followed by Proteobacteria, Fusobacteria and Verrucomicrobia (Zoetendal, Rajilić-Stojanović & de Vos 2008). Many of the currently characterized phylotypes are strict anaerobes, have not yet been cultured, and can only be recognized based on molecular methods (Zoetendal, Rajilić-Stojanović & de Vos 2008). The development of culture-independent molecular techniques has provided insights in the composition of the intestinal microbiota before and following probiotic intake. Targeted microbiota analyses as well as the more recent community-level profiling studies support the view that the effects of probiotic intake are limited and only affect bacteria related to the probiotics (Satokari *et al.* 2001; Vaughan, Mollet & deVos 1999; Palaria, Johnson-Kanda & O'Sullivan 2011; McNulty *et al.* 2011).

Animal and *in vitro* studies have shown that the intestinal microbiota can regulate host lipid metabolism via numerous microbial activities (Fava 2006; Martin *et al.* 2007). The best characterized mechanism is through the biotransformation of bile acids, which regulate the digestion and absorption of fats, and profoundly affects the cholesterol and other lipid metabolism in the body (Gérard P. 2010; Ridlon, Kang & Hylemon 2006). However, global monitoring of the serum and organ lipid profiles of germ-free and conventionally raised mice suggests an even more widespread and profound influence of the intestinal microbiota on host lipid metabolism, in particular on triglycerides and phosphatidylcholines (Velagapudi *et al.* 2010; Orešič, Hänninen & Vidal-Puig 2008).

In the present study, we characterized the impact of a probiotic intervention on the composition and stability of the intestinal microbiota and serum lipid profiles in healthy adults. A comprehensive intestinal microbiota profiling and phylogenetic analysis was carried out with the Human Intestinal Tract Chip (HITChip), a phylogenetic microarray that provides a robust and sensitive measurement platform to assessing the abundance of over 1000 microbial species-like phylotypes representing the

majority of the known bacterial diversity of the human intestinal tract (Rajilić-Stojanović *et al.* 2009). Stability of the microbiota was quantified by inter- and intra-individual correlations within and between time points. The study subjects were sampled prior and after three weeks consumption of dairy milks supplemented with either the probiotic *L. rhamnosus* GG or a placebo. Moreover, the microbiota composition was analyzed from additional follow-up samples collected three weeks after the intervention trial. With phylogenetic microarray analysis we could both deepen and expand the typical bacterial analysis in probiotic trials, often limited to specific bacterial groups, such as lactic acid bacteria, or to the dominant fraction of the microbiota. Previously, we have shown that the intake of *L. rhamnosus* GG did not elicit any significant changes in the serum lipids (Kekkonen *et al.* 2008b). The present study complements these results by providing longitudinal data and evidence that the probiotic intervention with *L. rhamnosus* GG does not affect the overall composition or stability of the intestinal microbiota. Furthermore, we have integrated the lipid profiling and global microbiota data sets to investigate the overall associations between the intestinal microbes and systemic metabolites, in particular serum lipids. Quantitative analyses suggest that the abundance of specific intestinal microbes is correlated to that of specific lipid species. We identified mainly uncultured members of the Firmicutes, Actinobacteria and Proteobacteria that seem to be involved in the absorption and metabolism of the dietary and endogenous lipids, providing a scientific rationale for further human studies designed to explore the role of intestinal microbes in lipid metabolism, and associations to health.

Materials and Methods

Ethics statement

The trial and its protocol have been approved by the Ethics Committee of the Hospital District of Helsinki and Uusimaa (Ethical protocol no HUS 3577E0/05). The subjects provided written informed

consent. The details of this trial have been published previously (Kekkonen *et al.* 2008a; Kekkonen *et al.* 2008b).

Subjects

The subjects were healthy Finnish adults (n=25, 18 females, 7 males) with a mean age of 42 years (23-55) and a mean BMI of 24 kg/m² (18-30) from Helsinki region, representing a subset of a larger cohort (Kekkonen *et al.* 2008a; Kekkonen *et al.* 2008b). The subject characteristics are provided in Supplementary Table S1.

Dietary Intervention

The subjects constituted two treatment groups in a randomized, double blind intervention study to receive either *L. rhamnosus* GG (probiotic; n=11) or placebo (n=14). During the intervention the subjects consumed daily a 250 mL milk-based fruit drink containing either *L. rhamnosus* GG (ATCC 53103, 6.2 x 10⁷ cfu/mL) or a similar placebo drink without probiotic bacteria for three weeks. No other probiotic-containing products were allowed three weeks prior or during the intervention; a list of fermented foods and commercial probiotic-containing products was given to the subjects. The subjects were not separately questioned about their abstinence from probiotic products, but they filled a study diary recording the daily intake of the study product.

Fecal samples and microbiota analysis with the HITChip and quantitative PCR

Three fecal samples per individual were collected three weeks before, during and three weeks after the intervention, as previously described (Kekkonen *et al.* 2008b). The fecal DNA extraction with modified Promega method, and quantification of the probiotic counts with a strain-specific quantitative PCR (qPCR) assay have been described previously (Ahluwalia & Tynkkynen 2009). The phylogenetic analysis

116 of the intestinal microbiota composition with the HITChip microarray was performed as previously
117 described (Rajilić-Stojanović *et al.* 2009; Salonen *et al.* 2010). The phylogenetic HITChip microarray
118 targets the V1 and V6 hypervariable regions of the 16S rRNA gene of over 1000 bacterial phylotypes
119 that present the majority of the so far detected phylotypes of the human intestine. Phylogenetic
120 organization of the microarray probes and data preprocessing have been explained in detail elsewhere
121 (Rajilić-Stojanović *et al.* 2009; Salonen *et al.* 2010; Jalanka-Tuovinen *et al.* 2011). Quantification of
122 the relative differences in the taxon abundance between samples was obtained by summarizing the
123 probe signals to phylotype (species-like), genus and phylum levels. Genus-level taxa with $\geq 90\%$
124 sequence similarity in the 16S rRNA gene are referred to as *Species* and relatives, the latter being
125 shortened in the text as “*et rel.*” (Rajilić-Stojanović *et al.* 2009).

126 Previously, HITChip-derived microbial profiles have been shown to correlate well with those
127 obtained with fluorescence in situ hybridization (FISH) (Rajilić-Stojanović *et al.* 2009) and
128 pyrosequencing (Claesson *et al.* 2009). Samples were also used for absolute quantification of total
129 bacteria, methanogenic Archaea, *Lactobacillus* group and *Bifidobacterium* spp. with previously
130 described qPCR primers and reaction conditions (Salonen *et al.* 2010).

131

132 *Blood samples and their biochemical analyses*

133 Of the 25 study subjects used for the microbiota analysis, 22 (8 from probiotic group and 14 from
134 placebo group) were available for the parallel analysis of serum lipid profiles before and after the
135 intervention (44 samples in total). Venous blood samples from the antecubital vein were taken at
136 baseline and after the three-week intervention. The blood samples were stored at -20°C for further
137 analyses. Total cholesterol, high-density lipoprotein (HDL) and low-density lipoprotein (LDL)
138 cholesterol as well as triglyceride levels were enzymatically determined from the serum as previously
139 described (Kekkonen *et al.* 2008a).

140

141 *Global lipid profiling: sample preparation and analysis by UPLC-MS*

142 Extraction of lipids from the serum samples, analysis of the lipid extracts with Waters Q-ToF Premier
143 mass spectrometer combined with an Acquity Ultra Performance LCTM (UPLC), data preprocessing and
144 identification of the lipid molecular species is described in detail elsewhere (Kekkonen *et al.* 2008a).
145 Lipids have been named according to Lipid Maps (<http://www.lipidmaps.org>) with the following
146 abbreviations: Cer: ceramide; ChoE: cholesteryl ester; lysoPC: lysophosphatidylcholine; PA:
147 phosphatidic acid; PG: phosphatidylglycerol; PC: phosphatidylcholine; PS: phosphatidylserine; SM:
148 sphingomyelin; TG: triglyceride. Where the fatty acid composition could not be determined, the total
149 number of carbons and double bonds is indicated. The first number indicates the amount of carbon
150 atoms in the fatty acid molecule, followed by the number of double bonds. For details, see (Kekkonen
151 *et al.* 2008a).

152

153 *Statistical analyses*

154 The effects of probiotic intervention on the intestinal microbiota were investigated with a combination
155 of linear models, sparse principal component analysis (PCA; Shen & Huang 2008; Lê Cao, González &
156 Dèjean 2009), unsupervised hierarchical clustering, and significance testing. The log-transformed
157 HITChip and lipid profiling values were approximately Gaussian distributed and fulfilled the general
158 statistical assumptions underlying the selected computational approaches. Background variables,
159 including age, body-mass index and gender were compared in the baseline samples to exclude
160 potentially confounding effects associated with these variables. The Wilcoxon test was used with
161 continuous variables and the Fisher exact test for categorical variables, followed by
162 Benjamini-Hochberg p-value correction for multiple testing. No significant differences between the
163 background variables were observed between the treatment groups ($p > 0.05$ in all comparisons). The

two-group comparisons between the time points and between the treatment groups were quantified based on a linear model with group-wise fixed effects and sample-specific random effects, as implemented in the limma R package (Smyth 2004), to identify bacterial taxa with significant changes induced by the probiotic intervention and to assess the magnitude and significance of the effects. The function lmFit was used to fit the linear model, followed by significance estimation by empirical Bayes as described in Smyth (2004). In addition, power calculation was carried out to assess statistical power of the current study. The original data was randomly permuted, one significant 2-fold alteration was inserted, and Gaussian noise was added using the same average standard deviation as in the original data. Empirical power calculation with 1000 random permutations showed that 2-fold and higher alterations that follow the noise levels in the original data were detected in > 99.8% of the cases with sample size of 8 or more, based on the same detection criteria than in the current study, confirming the high statistical power of the analysis at the present sample size. PCA is a linear dimension reduction method used to compress information in the high-dimensional phylogenetic (genus-level) and lipid profiles into few informative features that capture the main variation in the data and allow two-dimensional visualization of sample similarities. The temporal and inter-individual similarity of the microbiota and lipid profiles was assessed by average intra- and inter-individual Pearson correlations (r) between and within the time points, respectively. The differences in profile similarity between the probiotic and placebo groups were estimated with Wilcoxon test. The biweight midcorrelation, which is more robust to outliers than the standard Pearson correlation, was used to quantify correlation between the microbiota and lipid profiles across the individuals. High-throughput screening studies involve considerable multiple testing and the traditional multiple testing correction approaches are prohibitively conservative in this context due to their emphasis on estimating the probability of a single false positive finding. Hence, we have used q-values for multiple testing

187 correction in the high-throughput screening tests that include parallel comparisons of large numbers of
188 lipids and bacterial phylotypes.

189 *Correlation analysis of the intestinal microbiota and serum lipids*

190 The biweight midcorrelation measure was used to quantify associations between the microbiota and
191 lipid profiling data sets, and between the microbiota and biochemically determined lipids. The
192 correlations between genus-level bacterial groups and lipid species were calculated together with
193 significance estimates that were corrected for multiple testing. The significantly correlated ($q < 0.05$)
194 phylotypes and lipids were selected for further analysis. It is important to note, however, that while the
195 present sample size of 22 samples across 2 time points (before and during the probiotic intervention) is
196 sufficient for highlighting significant correlation patterns, the present experimental design cannot
197 uncover causal relationships and the observed correlations may be partly associated with diet or other
198 confounding variables that simultaneously affect both lipid and microbiota profiles. Two-way average
199 linkage hierarchical clustering of the bacterial taxa and lipids was applied to highlight and visualize
200 groups of phylotypes and lipids sharing similar correlation patterns. Analogous 'second-order'
201 correlations have previously been applied for instance in the context of gene expression studies
202 (Parmigiani *et al.* 2004; Lahti *et al.* 2012). A constant plaid model biclustering was used for systematic
203 detection of significantly correlated bacterial and lipid groups on the correlation heatmap (Lazzeroni &
204 Owen 2002). To interpret the detected biclusters, statistical enrichment (over-representation) of the
205 implicated bacteria was quantified. Moreover, enrichment analysis was carried out for lipids containing
206 even or odd number of carbon atoms, as well as the enrichment of lipids with zero, one or more double
207 bonds. The enrichment analyses were carried out with Fisher's exact test (Rivals *et al.* 2007). All
208 analyses were performed within the R statistical environment (R Development Core Team 2010).

209

210 Results

211 *Impact of the L. rhamnosus GG intervention in the intestinal microbiota*

212 This study characterized the impact of *L. rhamnosus* GG intervention on the stability and composition
213 of the intestinal microbiota. The subjects in the probiotic group consumed daily approximately 10^{10}
214 ($10.2 \log_{10}$) colony forming units (cfu) of *L. rhamnosus* GG. The compliance was verified with the
215 quantification of *L. rhamnosus* GG in the feces with strain-specific qPCR (Kekkonen *et al.* 2008b). The
216 average excretion of *L. rhamnosus* GG in the probiotic group was more than 1000-fold higher than that
217 in the placebo group (8.52 ; $sd\ 0.73 \log_{10}$ versus 5.20 ; $sd\ 1.09 \log_{10}$ genome copies per gram of feces,
218 respectively).

219 The stability of the microbiota during the trial was quantified by the similarity of the
220 microbiota profiles between the three time points with Pearson correlation (Table 1). The average
221 intra-individual correlations were high; 0.94 - 0.95 ($sd\ 0.02$ - 0.03). No significant difference in the
222 temporal stability of the microbiota between the probiotic and placebo groups was observed, indicating
223 that the probiotic intervention did not alter the overall microbial stability. Principal Component
224 Analysis (PCA) visualization of the relationships between the intestinal microbiota profiles
225 (Supplementary Fig. S1A) and hierarchical clustering (data not shown) further supported the
226 conclusion that there were no systematic differences in the microbiota between the intervention groups.
227 The average inter-individual microbiota correlation was 0.76 - 0.78 with no significant differences
228 between the probiotic and placebo groups (Table 1). The intra-individual microbiota correlations
229 ($r=0.94$ - 0.95) were notably higher than the inter-individual correlations ($r=0.76$ - 0.78), stressing the
230 subject-specificity of the microbiota.

231 Linear models were used to quantify the effects of the *L. rhamnosus* GG intervention on
232 individual taxa using genus- and phylotype-level microarray data. A specific and transient increase of

233 bacteria related to *L. rhamnosus* was detected in the probiotic group immediately after the intervention
234 (Fig. 1). There were no intervention-related effects in the other lactobacilli, Bifidobacteria or any other
235 taxa either in the probiotic or placebo group; however substantial individual variation was evident.

236 To complement the HITChip microarray analysis, we also determined the absolute counts of
237 total bacteria, methanogenic Archaea, *Lactobacillus* group and *Bifidobacterium* spp. using real-time
238 PCR. The ingestion of *L. rhamnosus* GG was reflected in the total lactobacilli that showed a highly
239 significant increase in the probiotic group after the intervention, returning to baseline levels in the
240 follow up ($q < 0.05$ in both comparisons). No other significant changes were observed in the amount of
241 targeted microbes neither in the probiotic or placebo group. We detected substantial inter- and
242 intra-individual variation in the methanogenic Archaea but that was independent of the time point or
243 the treatment group (data not shown). These observations support the conclusion that the *L. rhamnosus*
244 GG intervention did not change the overall microbiota composition.

246 *High-throughput profiling of serum lipids*

247 Global profiling of the serum lipids was performed using the UPLC-MS platform to assess the serum
248 lipid profiles at the molecular species level (Kekkonen et al. 2008a). In total, 407 lipid species from 11
249 different classes were identified. The lipid profiles were dominated with triglycerides (TG; 37%),
250 phosphatidylcholines (PC; 25%) and phosphatidylethanolamines (PE; 13%) while phosphatidic acids
251 (PA), phosphatidylglycerols (PG), sphingomyelins (SM), cholesteryl esters (CholE),
252 lysophosphatidylcholines (lysoPC), phosphatidylserines (PS), ceramides (Cer) and
253 lysophosphatidylethanolamines (lysoPE) each contributed with 7% to 0.3% to the total lipid pool.

254 The stability of the lipid profiles was quantified based on the same correlation analysis
255 approach than in the HITChip microbiota profiling analysis. No significant differences in the lipid

256 profile stability were observed between the treatment groups (average intra-individual $r=0.92$ and
257 $r=0.93$ for the probiotic and placebo groups, respectively; Table 1). In contrast to microbiota profiles,
258 the serum lipid profiles were remarkably similar, not only within the subjects but also between the
259 subjects (average inter-individual $r=0.89-0.91$; Table 1). No significant differences were seen between
260 the probiotic and placebo groups, or between the time points. The stability of the lipid and microbiota
261 profiles showed a weak positive correlation ($r=0.27$) across the subjects independent of a treatment
262 group. The global lipid profiles did not separate according to the treatment group in PCA visualization
263 (Supplementary Fig. S1B), and no statistically significant lipid alterations were detected between the
264 time points neither in the probiotic or placebo group (data not shown; Kekkonen *et al.* 2008b). The
265 fold-changes for each lipid species between the two time points followed normal distribution in both
266 intervention groups (data not shown), which further supports the conclusion that the intervention did
267 not induce systematic alterations on the lipid profiles.

269 *Associations between the intestinal microbiota and serum lipids*

270 In addition to studying the effects of probiotic *L. rhamnosus* GG intervention in the intestinal
271 microbiota, we investigated the co-variation of the microbiota and serum lipid profiles. As discussed
272 above, our results (Table 1, Supplementary Fig. S1) conclusively show that the probiotic intervention
273 did not affect the lipid profiles or the microbiota beyond the *L. rhamnosus* that was ingested. Hence,
274 the subjects from probiotic and placebo groups were pooled to increase the sample size and statistical
275 power in exploring the associations between the intestinal microbiota and serum lipids.

276 Heatmap visualization of the microbiota-lipid correlations across the 22 subjects from 2 time
277 points revealed intestinal bacteria and serum lipids with significantly correlated abundance patterns
278 (Fig. 2). In total, 86 bacterial group-lipid pairs with notable correlations (± 0.5 or higher) were

identified at $q < 0.05$ significance level (Fig. 2). Among the significant correlations, 23 of the 131
 genus-level taxa detectable by the HITChip were represented (Supplementary Table S3). Most of these
 taxa belonged to Proteobacteria (6) and Firmicutes within Clostridium cluster XIVa (5) and Bacilli (3).
 From the lipid side, the vast majority of the significant correlations were attributable to the most
 dominant lipids, TGs (62%) and PCs (30%). When analyzed at the genus-level, the significant
 correlations were strongly dominated by the positive correlations between bacteria related to
Ruminococcus gnavus and different TG species (31 of 40 significant positive correlations, average
 $r = 0.61$; Fig. 3A). Detailed analysis at the phylotype-level data indicated that within the *R. gnavus*
 group, two uncultured phylotypes, uncultured human gut bacterium JW1G3 and JW1H4a, dominated
 the correlations while the type species *R. gnavus* or related *R. torques* did not correlate significantly
 with TG or any other lipid species. Other representatives of the *Clostridium* cluster XIVa included
 bacteria related to *Dorea formicigenerans* that also correlated positively with four TG species (Fig. 2;
 average $r = 0.58$). The remaining TG correlations were negative and involved phylogenetically diverse
 bacteria (Supplementary Table S3). Also PCs correlated significantly with numerous taxa, most of
 which correlated negatively with ester- or ether linked PCs. Interestingly, a set of Proteobacteria
 (*Campylobacter*, *Helicobacter* and *Moraxellaceae*) with low signal intensities had a clear negative
 correlation with PC. Similarly, two *Lactobacillus* species (*L. rhamnosus* that was ingested during the
 trial and *L. salivarius*) together with another group of *Bacillus*, *Enterococcus* spp., also correlated
 negatively with PC while few Firmicutes exhibited a positive correlation with this lipid species. Among
 the less abundant lipids (<10% of the total lipid pool), a positive correlation was detected between
 cholesteryl ester and *Collinsella* ($r = 0.59$; Supplementary Table S3, Fig. 4A). On the phylotype level,
 the correlation was mainly attributable to an uncultured bacterium clone Eldhufec074 within genus
Collinsella. Another group of Actinobacteria, namely *Actinomycetaceae*, showed a significant negative
 correlation to TG and PA.

PeerJ Preprints

Hierarchical clustering and heatmap visualization of the significantly correlated lipid-bacteria pairs revealed groups of lipids and bacteria sharing similar correlation patterns. A constant plaid model biclustering approach was applied to detect coherent groups of significantly correlating microbe-lipid pairs (see Methods). The analysis revealed three major clusters of significantly correlated lipid-microbe pairs (Supplementary Table S2). One of the observed biclusters highlights the above discussed positive association between bacteria related to *R. gnavus* and TGs. Another TG cluster, containing highly unsaturated long-chain fatty acids, consisted of negatively correlating bacteria related to *Megamonas hypermegale* (family *Veillonellaceae*, Clostridium cluster IX) or belonging to the *Actinomycetaceae*. The third cluster contained a set of Proteobacteria (*Helicobacter*, *Oceanospirillum* and *Moraxellaceae* spp.) and bacteria related to *Eubacterium cylindroides* within the family *Erysipelotrichaceae*, which all correlated negatively with ether lipids.

To explore the nature of the identified lipid-microbe pairs, we quantified the enrichment of specific, functionally relevant lipid categories in the biclusters. In particular, we investigated the enrichment of lipids with even and odd number of carbon atoms and the degree of saturation (0, 1, or more double bonds). The origin of lipid can be inferred from its chemical composition: Polyunsaturated fatty acids (PUFAs; more than one double bond) and lipids that have uneven number of carbon atoms originating from plants, bacteria or marine organism as humans cannot synthesize them. Significant enrichment of long acyl chain polyunsaturated fatty acids (two or more hydrogen bonds; $p < 0.05$; Fisher exact test) was detected among the TG lipids that significantly correlated with bacteria related to *R. gnavus* (Fig. S2; Supplementary Table S2). Such a positive association suggests a role for these *R. gnavus*-related bacteria in the absorption of dietary lipids. In support of this interpretation, TGs containing fatty acids with odd number of carbons were also relatively common in this group ($p = 0.1$). In the other two biclusters, no significant enrichment of odd/even carbon count or saturation level was

326 detected but within the bicluster 2 (Supplementary Table S2), *Actinomycetaceae* correlated exclusively
327 with highly unsaturated PUFAs (Fig. 2).

328

329 *Associations between the intestinal microbiota and biochemically determined serum lipids*

330 The mean values (SD) for the major serum lipids were total cholesterol 5.10 (1.02), LDL cholesterol
331 3.00 (1.21), HDL cholesterol 1.50 (0.33) and TG 1.20 (0.71) mmol/L (Kekkonen *et al.* 2008a). No
332 significant changes were detected in the lipids of the probiotic or the placebo groups during the
333 intervention (Kekkonen *et al.* 2008b). Hence, we analyzed the potential associations of the
334 enzymatically determined major blood lipids with the intestinal microbiota (Table 2). A positive
335 correlation between bacteria related to *R. gnavus* and TG was observed ($q < 0.01$; $r = 0.60$; Fig. 3B),
336 corroborating the association identified within the global lipid analysis. In line with the spectroscopic
337 lipid analysis, representatives of Bacteroidetes and Uncultured *Clostridiales* correlated negatively and
338 other implicated Firmicutes positively with enzymatically determined TG (Table 2). Representatives of
339 Proteobacteria and Actinobacteria that correlated negatively with TG in the lipid profiling data did not
340 correlate significantly with enzymatically determined TG. Such inconsistency may partly arise from
341 methodological reasons as the enzymatic assay captures not only TG but also diacylglyceride,
342 monoacylglyceride and free glycerol, while lipid profiling captures TGs at the molecular level.

343 *Collinsella* spp. and *Eubacterium bifforme et rel.* showed statistically significant ($q < 0.05$) and
344 positive correlations to enzymatically determined total and LDL cholesterol (Fig. 4B; Supplementary
345 Table S2). No other significant correlations were identified for total or LDL cholesterol while HDL
346 cholesterol correlated significantly with numerous taxa. Eight different Firmicutes including taxa
347 related to *Ruminococcus obeum* and *D. formicigenerans* were found to correlate negatively with HDL,

348 while Uncultured *Clostridiales* I was the only taxon showing positive correlation to HDL
349 (Supplementary Table S2).

350

351 Discussion

352 In the present study, we analyzed the effect of probiotic intake on the stability and composition of the
353 intestinal microbiota and of the serum lipids, and the overall associations between the microbiota and
354 lipid profiles. The microbiota was analyzed using the HITChip, a phylogenetic microarray, providing
355 one of the first holistic and community-level microbiota assessments after a probiotic intervention. The
356 data published so far is largely dominated with targeted microbiota analyses that have reported a
357 generic increase of lactic acid bacteria after intake of individual lactobacilli strains (McNulty *et al.*
358 2011; Palaria, Johnson-Kanda & O'Sullivan 2011; Satokari *et al.* 2001; Savard *et al.* 2011; Vaughan,
359 Mollet & de Vos 1999; Yamano *et al.* 2006). Our community-level analysis showed that the probiotic
360 intake did not introduce any changes in the microbiota composition or stability except the specific
361 increase of *L. rhamnosus* and total lactobacilli, which likely reflected the excretion of the ingested
362 strain. Similarly, ingestion of a mixture of five different probiotic strains did not induce any significant
363 changes in the microbiota composition neither in adults nor in simplified model community in mice
364 (McNulty *et al.* 2011). Even when a combination of probiotic and prebiotic (synbiotic) food was
365 consumed, two studies based on microbiota profiling and qPCR did not identify any differences in the
366 microbiota composition between placebo and treatment besides the ingested strains (Palaria,
367 Johnson-Kanda & O'Sullivan 2011; Vitali *et al.* 2010).

368 We have shown previously using the same cohort that the ingestion of *L. rhamnosus* GG had
369 apparent effects on the host immunology (Kekkonen *et al.* 2008b). Hence, our results does not support
370 the hypothesis that probiotic bacteria would modulate the endogenous microbiota but rather points

371 towards direct signaling to host or altered gene expression of the resident microbiota as a mode of
372 probiotic action as recently proposed (McNulty *et al.* 2011).

373 Our study was carried out in healthy adults with seemingly well-established and balanced
374 microbial communities. In subjects whose intestinal ecosystem is unbalanced e.g. due to pathogen
375 overgrowth, gastrointestinal symptoms or recent intake of antibiotics, intake of probiotic bacteria may
376 modulate the microbiota. Similarly, the developing microbiota of children is potentially more
377 susceptible to environmental modulators including probiotics. Although substantial changes in infant
378 microbiota following daily intake of *L. rhamnosus* GG have indeed been reported (Cox *et al.* 2010),
379 these results must be interpreted with caution as the used phylogenetic microarray provided signals for
380 close to 50 phyla whereas the human intestinal ecosystem only contains a maximum of 10 phyla
381 (Rajilić-Stojanović, Smidt & de Vos 2007; Midgley *et al.* 2012).

382 To the best of our knowledge, this cohort is the first addressing the potential impact of
383 probiotics on global serum lipid profiles in adults. Daily intake of *L. rhamnosus* GG for three weeks
384 did not introduce any consistent alterations in the serum lipids or in the biochemically determined
385 cholesterol and triglyceride levels of the healthy, normolipidemic adults analyzed in this and previous
386 study (Kekkonen *et al.* 2008b). Probiotic bacteria have been suggested as a potential non-drug
387 treatment to lower serum cholesterol levels based on their *in vitro* described ability to deconjugate bile
388 acids and directly assimilate cholesterol. A recent meta-analysis implies that probiotic intake can lower
389 the total and LDL cholesterol (Guo *et al.* 2011), although numerous human studies have failed to
390 observe any effects on serum lipids after probiotic intake (see e.g. Sadrzadeh-Yeganeh *et al.* 2010;
391 Pereira & Gibson 2002). One explanation for the controversy is that similarly to the strain-specificity of
392 the immunomodulatory effects of probiotics (Kekkonen *et al.* 2008b), also their effects on lipid
393 metabolism are likely to vary between different strains. In atopic infants the consumption of *L.*

394 *rhannosus* GG supplemented formulas for several months resulted in a reduced proportion of
395 α -linolenic acid and of total n-3 PUFAs, leading to increased n-6 to n-3 PUFA ratio in sera of
396 probiotic-fed infants (Kankaanpää *et al.* 2002). Decrease of n-3 fatty acids has negative health
397 implication, underlining the need for more *in vivo* research to specify the bacterial strains and target
398 population where probiotics can have beneficial effects on the host lipid metabolism.

399 Our data indicates that the variation of the intestinal microbiota is considerably higher across
400 the individuals than the variation in serum lipid profiles, highlighting the tight homeostatic control of
401 systemically circulating lipids. The intestinal microbiota is known to play an important role in the
402 regulation of systemic lipid metabolism (Martin *et al.* 2007; Velagapudi *et al.* 2010). In this study, we
403 identified several novel associations between the human intestinal commensals and serum lipids. From
404 the lipid side, TGs (62%) and PCs (30%) dominated the significant lipid-microbe correlations. TGs are
405 used for energy storage while PCs are abundant constituents of cell membranes. Both of these abundant
406 lipid classes were affected upon colonization of germ-free mice (Velagapudi *et al.* 2010). The most
407 prominent correlation was between TGs and uncultured phylotypes related to *R. gnavus* that belong to
408 family *Ruminococcaceae* in Clostridium cluster XIVa. Two characterized species within the group, *R.*
409 *gnavus* and *R. torques*, have been implicated in intestinal disorders as they appeared to be
410 overrepresented both in IBS (Kassinen *et al.* 2007; Rajilić-Stojanović *et al.* 2011) and in IBD (Joossens
411 *et al.* 2011; Prindiville, Cantrell & Wilson. 2004). The TG lipids that were positively associated with *R.*
412 *gnavus*-related phylotypes were enriched with polyunsaturated and odd-chain fatty acids. Since the
413 odd-chain fatty acids are not synthesized in the body, these positive associations suggest that the
414 implicated bacteria facilitate the absorption of polyunsaturated dietary lipids. Moreover, it cannot be
415 excluded that these bacteria are even involved in their biosynthesis as related *R. obeum* together with
416 other Firmicutes are among the intestinal bacteria capable of producing isomers of conjugated linoleic
417 acids (CLA; McIntosh *et al.* 2009).

418 Triglycerides carry different types of fatty acids, and accordingly not all TGs displayed the
419 same pattern regarding microbial correlations. For example, bacteria related to *D. formicigenerans*
420 showed positive association to saturated triglycerides with a small carbon number, i.e. including
421 palmitic acid. These fatty acids are mainly produced *de novo* in the liver (Westerbacka *et al.* 2010;
422 Kotronen *et al.* 2009). *D. formicigenerans* produces formate and acetate that are precursors of hepatic
423 lipogenesis. Recent metaproteomic work verifies that the acetate kinases involved in acetate production
424 are highly expressed in the intestinal ecosystem (Kolmeder *et al.* 2012), suggesting that several
425 intestinal bacteria have potential to regulate lipogenesis. On the other hand, *Actinomycetaceae* were
426 inversely associated with TGs containing highly unsaturated triglycerides with a high carbon number.
427 Such TGs carry physiologically important fatty acids such as C22:6 (docosahexanoic acid) and C20:4
428 (arachidonic acid). Both are important cell membrane components, the former especially in visual and
429 neural tissues, and the latter is involved in inflammatory signaling. While not much is known about the
430 intestinal *Actinomycetaceae*, both commensal and pathogenic forms of these Actinobacteria are
431 abundant in the oral cavity.

432 We identified multiple taxa correlating negatively with normal or ether linked forms of PC.
433 Dietary PC was recently identified as compound that after conversion by the intestinal microbiota
434 promotes heart disease (Wang *et al.* 2011). Unfortunately, that study did not address the identity of
435 bacteria involved in the metabolism of dietary PC, but our data suggest that different Firmicutes,
436 Proteobacteria and Fusobacteria may participate in this metabolic conversion (Fig. 2). Remarkably, the
437 presence of serum ether PCs was negatively associated with various taxa, mainly with Gram-negative
438 genera that include pathogens and commensals, such as *Helicobacter*, *Moraxellaceae* and
439 *Campylobacter*. Among the ether lipids, plasmalogens, known as endogenous antioxidants (Wallner &
440 Schmitz 2011), are the most abundant. Their negative association with Proteobacteria could indicate
441 that the implicated bacteria may induce oxidative stress in host cells, leading to depletion of

442 plasmalogens. In support of this hypothesis, lipopolysaccharide (LPS), a ubiquitous and toxic surface
443 component of Gram-negative bacteria, induces oxidative stress in mammalian cell cultures (Aly,
444 Lightfoot & El-Shemy 2010).

445 Finally, we identified positive correlation between the abundance of serum cholesterol and
446 genus *Collinsella* (Actinobacteria, family *Coriobacteriaceae*). Biochemical lipid analysis indicated that
447 *Collinsella* spp. together with bacteria related to *E. biforme* correlated specifically with total cholesterol
448 and LDL but not HDL. To our knowledge, our work provides the first *in vivo* evidence about the
449 implication of *Coriobacteriaceae* in human lipid metabolism. Our present findings are supported by the
450 data generated with rodent models. In a hamster model, the proportion of *Coriobacteriaceae* showed
451 high positive correlation with non-HDL plasma cholesterol levels and reacted to the intake of dietary
452 lipids (Martinez *et al.* 2009). In a mouse model, a strong positive correlation between
453 *Coriobacteriaceae* and hepatic triglycerides was identified (Claus *et al.* 2011), providing cumulative
454 indication for the involvement of *Coriobacteriaceae* in mammalian lipid metabolism. While only one
455 taxon (*Collinsella*) correlated statistically significantly with cholesterol in the lipid profiling data,
456 numerous taxa showed significant correlation to enzymatically determined HDL cholesterol. This may
457 arise from technical differences, as the lipid profiling does not quantify free cholesterol but its
458 derivative cholesteryl ester, where cholesterol is esterified to long-chain fatty acids. All taxa that were
459 associated with both HDL cholesterol and TG had opposite correlation with these lipids
460 (Supplementary Table S2), in accordance with the fact that serum TG and HDL show strong inverse
461 relationship, and their ratio is used as an atherogenic index that predicts cardiovascular risk (Jeppesen
462 *et al.* 1997). Hence, identification of bacteria that potentially affect the atherogenic index may provide
463 important clinical implications for dyslipidemic individuals.

464 While good correspondence between the HITChip and pyrosequencing studies have been
465 previously demonstrated, the main advantage of the HITChip microarray compared to the

pyrosequencing studies is that the microarray technology provides very standardized and cost-efficient tools for deep and reproducible analysis of intestinal microbiota including phylotypes that are only present in low concentrations (Claesson et al., 2009; Salonen et al. 2012). We expect that our major findings, the associations between specific lipid species and bacteria related to *Collinsella* or *R. gnavus* could be detected also in a standard pyrosequencing study due to the relatively high abundance of these organisms. However, the associations involving less abundant taxa (Bacilli, Proteobacteria, Actinomycetaceae) would likely have been missed with conventional sequencing depth.

In summary, quantitative analysis of high-throughput profiling data identified several significant correlations between the intestinal microbiota and serum lipids. These results partly confirm and extend previous observations in animal studies, and provide hypotheses for follow-up studies in humans. It is important to note, however, that the present analysis is based on a Finnish cohort and only two time points, and does not consider causal relationships between these variables. Therefore it cannot be excluded that some of the observed correlations may be associated with the diet or other confounding variables that simultaneously affect both lipid and microbiota profiles. However, as all subjects ate their habitual diets, individual food components are not likely to cause systematic bias to the observed lipid-microbe correlations, which is further supported by the observation of distinct groups of correlated lipid-microbe pairs in the bicluster analysis. It can also be ruled out that the intervention would have caused the correlations as control measurements from the baseline were included, the ingested probiotics *L. rhamnosus* GG did not correlate significantly with any serum lipid, and the drink did not otherwise alter the microbiota. Confirmation of the findings in an independent cohort and a more thorough longitudinal analysis will be necessary to assess the effect of external variables on the microbiota-lipid correlations and their potential causal associations. None of the implicated bacterial taxa are functionally characterized, and thus the potential mechanisms of how human intestinal bacteria relate to the host lipid metabolism are currently unknown. Among the

490 potential mechanisms, bacterial modification of the bile acid pool is by far the best characterized.
491 *Collinsella* spp., *R. gnavus* as well as the genus *Eubacterium* are among the intestinal bacteria capable
492 of deconjugating bile acids (Lepercq *et al.* 2004). Bile acids are cholesterol-derived detergents that play
493 a central role in the absorption of fat in the intestine but also in signaling with systemic endocrine
494 functions (Swann *et al.* 2011). It has been known for long that intestinal bacteria can chemically
495 modify bile acids but recent work suggest that the microbiota may also control their production and
496 degradation (Antunes *et al.* 2011). In mice the intestinal bacteria profoundly affect the emulsification,
497 absorption and transport of dietary fat as well as their storage and peroxidation through the metabolic
498 and signaling properties of bile acids (Martin *et al.* 2007).

500 Conclusion

501 Our data supports the concept that the overall lipid content in human serum is a composite of host and
502 microbial metabolic activity, and the intestinal commensals are implicated in the metabolism of various
503 lipid species that human body utilizes for membranes, energy storage and signaling. Considering that a
504 single gene in an intestinal bacterium could alter host fatty acid composition (Rosberg-Cody *et al.*
505 2011), we can only envisage the metabolic capacity and the functional consequences from the million
506 genes in the intestinal microbiome. As epidemiological data do not support a link between dietary
507 cholesterol and serum cholesterol levels (Lecerf & de Lorgeril 2011), the role of genetic factors in the
508 individual variability of cholesterol levels is evident. Identification of the bacteria and their
509 mechanisms that regulate host fatty acid and lipid metabolism have considerable potential for clinical
510 implications due to the profound role of these molecules for instance in cardiovascular disease and
511 regulation of inflammatory cytokine signaling (Calder 2011). Future trials involving controlled diet and

512 dyslipidemic individuals will provide further insights on the role of intestinal microbes on human lipid
513 metabolism.

Table 1(on next page)

Stability of microbiota and lipid profiles in the probiotic and placebo groups

We determined the similarity (expressed as Pearson's correlation) both within and between the time points (TP) for the microbiota and lipid profiles by the average scatter r of the profiles. Lipid data is available for the first two time points (TP1 and TP2, three weeks before the intervention and during the intervention , respectively), and not available (-) for the third time point (TP3) measured three weeks after the intervention.

	Between subjects			Within subjects	
Microbiota	TP1	TP2	TP3	TP1 vs TP2	TP3 vs TP2
Probiotic	0.78	0.78	0.78	0.94	0.95
Placebo	0.76	0.77	0.77	0.94	0.95
Lipids					
Probiotic	0.90	0.89	-	0.92	-
Placebo	0.91	0.89	-	0.93	-

Table 2_(on next page)

Associations between genus-level bacterial groups and enzymatically determined lipids

Associations between the relative amounts of genus-level bacterial groups as determined by the HITChip analysis and the serum lipid concentrations are quantified with a biweight correlation. Only significant positive and negative correlations are shown ($q < 0.05$; otherwise '-'). Abbreviations: Total cholesterol (TC), high-density lipoprotein (HDL) and low-density lipoprotein (LDL) cholesterol, triglyceride (TG). Correlations between genus-level bacterial groups and mass spectrometry-determined lipids are provided in Supplementary Table S3.

Phyla/Firmicute order	Genus-level taxon	TC	LDL	HDL	TG
Actinobacteria	<i>Collinsella</i>	0.56	0.57	-	-
Bacilli	<i>Aneurinibacillus</i>	-	-	-0.58	0.50
Bacteroidetes	<i>Bacteroides plebeius</i> et rel.	-	-	-	-0.47
Bacteroidetes	<i>Bacteroides vulgatus</i> et rel.	-	-	-	-0.47
Bacteroidetes	<i>Tannerella</i> et rel.	-	-	-	-0.45
Clostridium cluster XI	<i>Anaerovorax odorimutans</i> et rel.	-	-	-0.48	0.49
Clostridium cluster XIVa	<i>Clostridium nexile</i> et rel.	-	-	-0.45	-
Clostridium cluster XIVa	<i>Clostridium sphenoides</i> et rel.	-	-	-	0.46
Clostridium cluster XIVa	<i>Dorea formicigenerans</i> et rel.	-	-	-0.56	0.57
Clostridium cluster XIVa	<i>Eubacterium hallii</i> et rel.	-	-	-	0.47
Clostridium cluster XIVa	<i>Ruminococcus gnavus</i> et rel.	-	-	-0.46	0.60
Clostridium cluster XIVa	<i>Ruminococcus obeum</i> et rel.	-	-	-0.48	0.51
Clostridium cluster XV	<i>Anaerofustis</i>	-	-	-0.45	-
Clostridium cluster XVI	<i>Eubacterium bifforme</i> et rel.	0.48	0.47	-	-
Clostridium cluster XVI	<i>Eubacterium cylindroides</i> et rel.	-	-	-0.45	-
Uncultured Clostridiales	Uncultured Clostridiales I	-	-	0.53	-0.45
Uncultured Clostridiales	Uncultured Clostridiales II	-	-	-	-0.54

Figure 1

Intervention effects on the abundance of *L. rhamnosus*.

Mean abundance of *L. rhamnosus* among the study subjects before, during and after the probiotic intervention (the time points 1-3, respectively) quantified by the HITChip hybridization signal. The error bars denote the Gaussian 95% confidence limits based on standard deviation of the mean.

Figure 2

Correlations between intestinal genus-level phylogenetic groups and serum lipids

The correlations between the intestinal bacteria and serum lipids are indicated by colors (red: positive; blue: negative). The significant correlations ($q < 0.05$) are indicated by '+'; only lipids and bacteria with at least one significant correlation are shown. Hierarchical clustering of the rows and columns highlights groups of significantly correlated bacteria and lipids. Lipids have been named according to Lipid Maps (<http://www.lipidmaps.org>) with the following abbreviations: Cer: ceramide; ChoE: cholesteryl ester; lysoPC: lysophosphatidylcholine; PA: phosphatidic acid; PG: phosphatidylglycerol; PC: phosphatidylcholine; PS: phosphatidylserine; SM: sphingomyelin; TG: triglyceride. Where the fatty acid composition could not be determined, the total number of carbons and double bonds is indicated. The first number indicates the amount of carbon atoms in the fatty acid molecule, followed by the number of double bonds. For further details, see the Methods section.

Figure 3

Association between *Ruminococcus gnavus et rel.* and serum triglyceride (TG) lipids

The relative amounts of *R. gnavus et rel.* were quantified by the HITChip analysis and the triglyceride concentration was determined based on two independent techniques: **A** the triglyceride TG(54:5) (see Fig. 2 for explanation) by mass spectrometry ($r=0.61$); **B** triglyceride by an enzymatic assay ($r=0.60$).

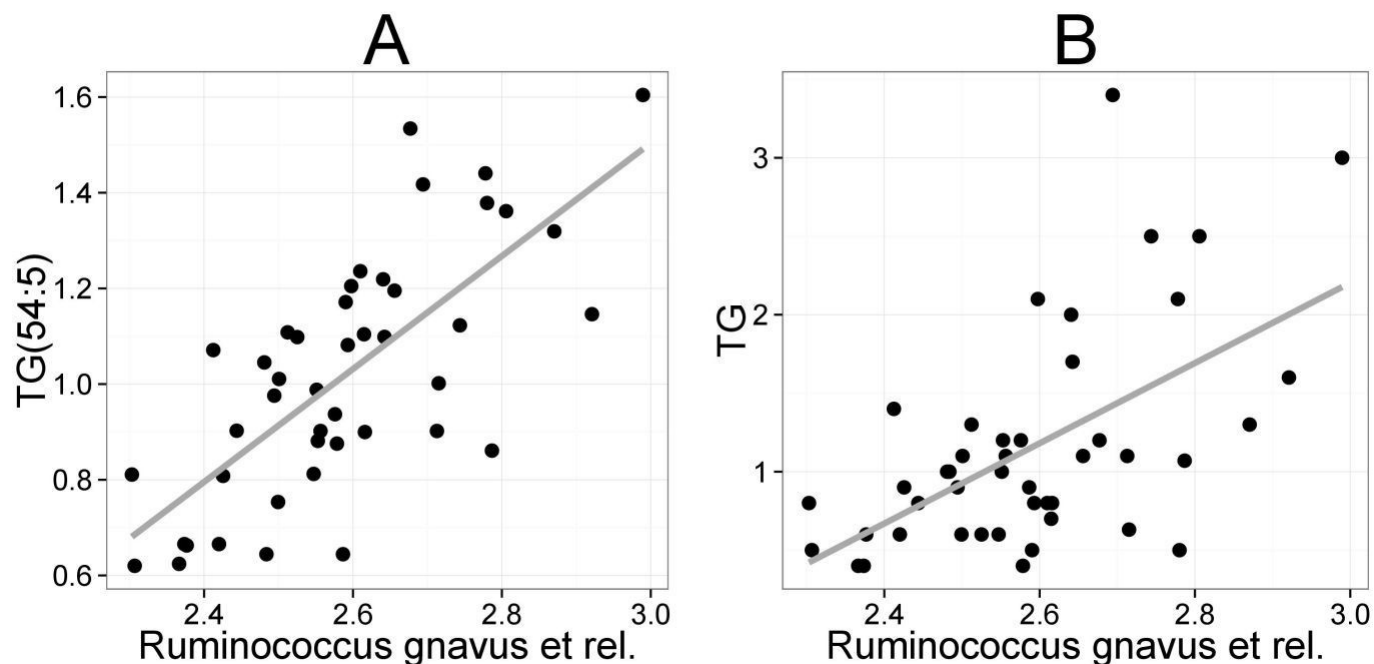

Figure 4

Association between *Collinsella spp.* and serum cholesterol

The relative amounts of *Collinsella spp.* were quantified by the HITChip analysis, and serum cholesterol levels were determined by two independent techniques: **A** Cholesterol ester ChoE(20:5) (see Fig. 2 for explanation) by mass spectrometry ($r=0.59$); **B** low-density lipoprotein (LDL) cholesterol by enzymatic assay ($r=0.57$).
