In 1941, O. Abel established *Balaena belgica* based on a series of fused cervical vertebrae and citing other cranial fragments from the late Neogene of the Antwerp harbor (northern Belgium). Later, Plisnier-Ladame and Quinet (1969) added a neurocranium and other skeletal remains from the same area to this species. Recently, the neurocranium was re-assigned to the genus *Eubalaena* thanks to newer phylogenetic analyses. Here, a new description is provided of materials previously assigned to '*Balaena*' *belgica* together with taxonomic revisions. Our work suggests that the cervical complex originally designated as the type of '*Balaena*' *belgica* is too poorly preserved to be used as such and is assigned to Balaenidae gen. et sp. indet., thus making '*Balaena*' *belgica* a nomen dubium. In addition to the neurocranium, the other remains consist in a fragment of maxilla assigned to Balaenidae gen. et sp. indet. and in a humerus assigned to *Eubalaena* sp. Discovered in the Kruisschans Sands Member of the Lillo Formation (3.2-2.8 Ma, Piacenzian, Late Pliocene), the neurocranium is designated as the holotype of the new species *Eubalaena ianitrix*. Our phylogenetic analysis supports a sister-group relationship of *E. ianitrix* and *E. glacialis*, and helps constraining the ages of origin for balaenid clades. Ecological and phylogenetic data suggest that *E. ianitrix* may represent the direct ancestor of *E. glacialis*, the latter having evolved through phyletic transformation including body size increase during the temperature decline of the Late Pliocene.

15 **ABSTRACT**

16 In 1941, O. Abel established *Balaena belgica* based on a series of fused cervical vertebrae and
17 citing other cranial fragments from the late Neogene of the Antwerp harbor (northern Belgium).
18 Later, Plisnier-Ladame and Quinet (1969) added a neurocranium and other skeletal remains from
19 the same area to this species. Recently, the neurocranium was re-assigned to the genus *Eubalaena*
20 thanks to newer phylogenetic analyses. Here, a new description is provided of materials previously
21 assigned to '*Balaena*' *belgica* together with taxonomic revisions. Our work suggests that the
22 cervical complex originally designated as the type of '*Balaena*' *belgica* is too poorly preserved to
23 be used as such and is assigned to Balaenidae gen. et sp. indet., thus making '*Balaena*' *belgica* a
24 nomen dubium. In addition to the neurocranium, the other remains consist in a fragment of maxilla
25 assigned to Balaenidae gen. et sp. indet. and in a humerus assigned to *Eubalaena* sp. Discovered
26 in the Kruisschans Sands Member of the Lillo Formation (3.2-2.8 Ma, Piacenzian, Late Pliocene),
27 the neurocranium is designated as the holotype of the new species *Eubalaena ianitrix*. Our
28 phylogenetic analysis supports a sister-group relationship of *E. ianitrix* and *E. glacialis*, and helps
29 constraining the ages of origin for balaenid clades. Ecological and phylogenetic data suggest that
30 *E. ianitrix* may represent the direct ancestor of *E. glacialis*, the latter having evolved through
31 phyletic transformation including body size increase during the temperature decline of the Late
32 Pliocene.

34

35 Introduction

36

37 Living right whales include North Atlantic, southern and North Pacific right whales, all of them
38 grouped within the genus *Eubalaena* (Cetacea, Mysticeti, Balaenidae; Kenney, 2009; Rice, 2009).

39 The North Atlantic or northern right whale obviously inhabits the North Atlantic ocean, the
40 southern right whale is distributed in the waters around Antarctica, and the North Pacific right
41 whale is present in a portion of the Pacific that is limited in the south by southern Japan and the
42 southern portion of the California peninsula (Kenney, 2009). Recent studies have addressed
43 molecular taxonomy, population dynamics, and distribution patterns of these whales suggesting
44 that the genus *Eubalena* should include three species corresponding to the three groups mentioned
45 above (namely, *Eubalaena glacialis*, *E. australis* and *E. japonica*) (e.g., Rosenbaum et al., 2000).

46 Although a full agreement on this point has not been reached yet, it is largely acknowledged that
47 North Atlantic and North Pacific right whales are suffering high extinction risk (e.g., Clapham et
48 al., 1999). This is probably due to the catastrophic bottleneck effect induced into their populations
49 by human hunting activities during 19th and 20th centuries (e.g., Gaskin, 1986) that drastically
50 reduced the size of their populations in a brief period.

51 The assessment of the genetic diversity of the living right whale populations largely depends on
52 the reconstruction of the population size before the start of industrial whaling (Rooney et al., 2001;
53 Rosenbaum et al., 2000, Malik et al., 2000). Such a reconstruction depends on several factors
54 including the phylogenetic history of the genus and divergence time from the living species that is
55 phylogenetically closest to the living right whales (Rooney et al., 2001), namely the bowhead
56 whale *Balaena mysticetus*. The study of the fossil record may help determining the antiquity of the

57 genus *Eubalaena* and constraining the time of divergence of *Eubalaena* from the bowhead whale
58 (McLeod et al., 1993; Santangelo et al., 2005).

59 The fossil record of *Eubalaena* is scanty and scattered around the northern hemisphere. A right
60 whale skull from the Pleistocene of Japan was described by Nishiwaki & Hasegawa (1969) and
61 reviewed by Kimura (2009). Kimura (2009) also described *Eubalaena shinshuensis* from the latest
62 Miocene of the Gonda Formation, Nagano Prefecture, Japan. A partial skull of an indeterminate
63 species of *Eubalaena* was described by Bisconti (2002) from the Upper Pliocene of Tuscany,
64 Central Italy. Fragmentary tympanic bullae assigned to *Eubalaena* spp. were described by Morgan
65 (1994) from the Nashua Formation in Florida (latest Pliocene and earliest Pleistocene) and
66 Boessenecker (2013) from the Purisima Formation in Central California (Late Pliocene). Finally,
67 Field et al. (2017) described a fragmentary skull assigned to *Eubalaena* sp. from the Tjorres
68 Formation in Island (Early Pliocene).

69 A large-sized balaenid skull from the “Merxemien” of Antwerp, northern Belgium, was described
70 by Plisnier-Ladame & Quinet (1969) who assigned it to *Balaena belgica*, a taxon established by
71 Abel (1941) based on a described and illustrated cervical complex and the mention of other cranial
72 remains. Bisconti (2003) questioned Abel’s taxonomic decision and suggested that the skull should
73 be assigned to *Eubalaena*, a proposal supported by later phylogenetic analyses placing ‘*B.*’ *belgica*
74 as sister-group to *E. glacialis* (Bisconti, 2005a; Churchill et al., 2012) or as sister-group to the
75 extant *Eubalaena* species (Marx & Fordyce 2015). However, a formal re-description of the
76 specimen is currently necessary to make sound taxonomic decisions.

77 The specimens previously assigned to ‘*Balaena*’ *belgica* consist of:

78 (1) a cervical vertebrae complex discovered on March 6th, 1914 by G. Hasse in the docks of
79 the Antwerp harbor, figured by Abel (1941, pl. 2, fig. 9) and Plisnier-Ladame & Quinet

80 (1969, fig. 1, pls. 1 and 2), and bearings the inventory number of the Royal Belgian Institute
81 of Natural Sciences, Brussels (hereinafter RBINS) RBINS M. 881 (IG 8444);
82 (2) a partial neurocranium (RBINS M. 879a-f, IG 8652) discovered in 1921 in Oorderen (a
83 part of the Antwerp harbor) during the excavation of the first Kruisschans lock (Figs. 1 and
84 2), figured by Plisnier-Ladame & Quinet (1969, pls. 1-2);
85 (3) a large fragment of right maxilla (RBINS M. 880a-c, IG 8652) also discovered in 1921 in
86 Oorderen during the excavation of the first Kruisschans lock seemingly misidentified as a
87 fragment of mandible by Plisnier-Ladame & Quinet (1969), but never described or figured;
88 (4) a large isolated left humerus (RBINS M. 2280) without any locality data, most likely
89 corresponding to the specimen mentioned by Plisnier-Ladame & Quinet (1969), but never
90 described or figured.

91 In this paper, the material previously assigned to '*Balaena*' *belgica* Abel, 1941 is newly described
92 and compared with an extended sample of right, bowhead and pygmy right whales to get a
93 comprehensive analysis of anatomy and clear taxonomic assignments. The morphological
94 characters of the skull are then used in a new phylogenetic analysis of living and fossil right and
95 bowhead whales to (1) reveal the timing of the origin of the genus *Eubalaena* and the divergence
96 time from its closest living relative *Balaena mysticetus*, and (2) investigate whether the three living
97 right whale populations correspond to three different species confirming or not the results of
98 molecular analyses. Our results will hopefully provide molecular ecologists with useful
99 information for safer reconstructions of past population dynamics of these highly endangered
100 species.

110 *New species name*

111 The electronic version of this article in Portable Document Format (PDF) will represent a
112 published work according to the International Commission on Zoological Nomenclature (ICZN),
113 and hence the new names contained in the electronic version are effectively published under that
114 Code from the electronic edition alone. This published work and the nomenclatural acts it contains
115 have been registered in ZooBank, the online registration system for the ICZN. The ZooBank
116 LSIDs (Life Science Identifiers) can be resolved and the associated information viewed through
117 any standard web browser by appending the LSID to the prefix <http://zoobank.org/>. The LSID for
118 this publication is: urn:lsid:zoobank.org:pub:C8D3FE95-303E-4EF4-86DD-1B453E124981. The
119 online version of this work is archived and available from the following digital repositories: PeerJ,
120 PubMed Central and CLOCKSS.

121

122 *Anatomy*

123 Anatomical terms for skull osteology follow Mead and Fordyce (2009); terminology for humerus
124 and cervical vertebrae follows Schaller (1999).

125

126 *Comparative analyses*

127 Comparative analyses were made with an extended balaenoid sample including specimens from
128 museums MSNT, RBINS, AMNH, NBC and IZIKO (specimens are listed in Bisconti, 2011). In
129 addition, specimens described in literature were used to complement first-hand observations (True,
130 1904; Omura, 1958; Tomilin, 1967; Tsai & Fordyce, 2015).

131

132 *Body size estimate*

133 Three methods for body size estimate were followed. First, we used the regression equation
134 provided by Pyenson & Sponberg (2011) that allows the reconstruction of the total body length
135 based on a measure of the bizygomatic width of the skull. The equation is the following (data in
136 mm):

$$137 \quad (1) \log(\text{total body length}) = 0.92(\log(\text{bizygomatic width}) - 1.64) + 2.67$$

138 Pyenson & Sponberg (2011) used this equation to reconstruct total body lengths of living and fossil
139 cetaceans including mysticetes. Unfortunately, their study did not involve balaenid specimens,
140 therefore we cannot be sure that the equation (1) is well suited to provide an accurate reconstruction
141 of the total body length for Balaenidae. Moreover, results from equation (1) deviated from
142 observed values of intact specimens for amounts ranging from 47 to 37%. Bearing this in mind,
143 we corrected results generated by the equation (1) by reducing our results by 47 and 37%; in so
144 doing, we got two results from equation (1) corresponding to the range of estimates for the total
145 body length of RBINS M. 879a-f.

146 The second method used the occipital breadth as principal predictor as from the following
147 equation, provided by Evans et al. (2012) (measurements in mm):

$$148 \quad (2) \text{body mass} = 4.924 * 10^{-6}(\text{occipital breadth})^{3.858}$$

149 The equation (2) showed a high correlation coefficient in mammals ($R^2 = 0.9447$). Once a body
150 mass estimate was [obtained](#), we used equation (3) to obtain an estimate of skeletal length. Equation
151 (3) is the following, as developed by Silva & Downing (1995):

$$152 \quad (3) \log(\textit{body mass}) = 3.08(\log(\textit{skeletal length})) - 4.84$$

153 This equation was extensively used in the reconstructions of body masses and skeletal lengths of
154 living and fossil mammals in previously published papers. Unfortunately, in marine mammals,
155 body mass may change during the life cycle depending on different patterns of activity performed
156 in the year (e.g., foraging, migration, female lactation etc.) thus the body mass estimate provided
157 by equation (3) is to be intended as mean body mass for a whale of a given length (Churchill et al.
158 2014).

159 Unfortunately, none of these equations was tested on balaenid records and it is not known if they
160 are actually able to retrieve correct results in this family. For this reason, we used also the
161 regression equation provided by Bisconti (2002) to predict the total skull length of a balaenid whale
162 based on supraoccipital length. The equation is the following:

$$163 \quad (4) \textit{supraoccipital length} = 0.3937(\textit{skull length}) - 62.803$$

164 In this equation, [skull length corresponds to](#) condylobasal length. Unfortunately, the correlation
165 coefficient associated to this equation is rather low ($R^2 = 0.5967$) because the regression equation
166 is based on a limited and scattered dataset. Once a condylobasal length is [obtained](#), we inferred the
167 total body length by tripling or quadrupling the condylobasal length. In fact, following Tomilin
168 (1967), the skull length is about 25-to-30% of the total body length in extant Balaenidae. Presently
169 it is not possible to be sure that this proportion applies to [fossil](#) balaenids; however, given that
170 skull and body sizes have important adaptive functions in Balaenidae (Sanderson & Wassersug,
171 1993), and given that RBINS 879a-f represents an advanced balaenid species (as judged from its

172 placement in the phylogenetic hypothesis of relationships presented in this paper), there is no
173 reason to propose a fundamentally different skull/body ratio in this specimen.

174

175 *Phylogenetic analysis*

176 A total of 153 morphological characters were coded for 42 taxa including 3 archaeocetes used as
177 outgroups. The taxonomic sampling adopted here includes representative taxa from all the known
178 mysticete radiations. The family Balaenidae was represented by 11 taxa including *Morenocetus*
179 *parvus*; Neobalaenidae was represented by *Caperea marginata* and *Miocaperea pulchra*. [The](#)
180 [Pliocene *Eubalaena* sp. from Tuscany was included in a phylogenetic analysis for the first time.](#)

181 Characters were coded based on direct examination of specimens and on the literature listed in the
182 Supplementary Information file together with both character list and taxon x character matrix.
183 Only 2 characters were coded from baleen morphology; all the other characters were coded from
184 the analysis of the skeletal anatomy of mysticetes and archaeocetes. All characters were unordered
185 and unweighted and followed the outgroup polarization criterion.

186 Character choice was made bearing in mind the goal of maximum reduction of homoplasy in the
187 dataset. This goal was achieved by examining the homoplasy level shown by each character states
188 published by Bisconti (2008, 2011), Bisconti et al. (2013), Bisconti & Bosselaers (2016), Marx
189 (2011) and Boessenecker & Fordyce (2015). Bisconti et al. (2013) and Bisconti & Bosselaers
190 (2016) published the consistency index (hereinafter abbreviated as CI) of all the synapomorphies
191 supporting named nodes. Characters with $CI < 1$ were considered homoplastic and were excluded
192 from the present dataset. As far as characters from other papers are concerned, it was more difficult
193 to decide whether a character had a homoplastic distribution or not. To get decisions, character
194 states were mapped on published phylogenetic hypotheses and their distributions were assessed by

195 eye; in the case a character showed scattered distribution across the branches of the Mysticeti tree,
196 then the application of Fitch's (1971) parsimony allowed to decide if the character could be
197 considered homologous or not in those branches.

198 The taxon x character matrix was treated by TNT (Goloboff et al., 2008) with default parameters
199 for New Technology Search. The synapomorphies were mapped onto the resulting cladogram and
200 were listed through the dedicate commands in TNT. Number of steps added by each character was
201 calculated at relevant nodes to determine whether the character state constituted an ambiguous or
202 unambiguous synapomorphy at the node.

203

204 *Stratigraphic consistency index and determination of divergence dates*

205 The degree of agreement between the branching pattern and the stratigraphic occurrence of the
206 taxa was assessed by the calculation of the Stratigraphic Consistency Index (hereinafter, SCI)
207 following the method described by Huelsenbeck (1994; see also discussion in Bisconti, 2007).
208 Stratigraphic ages of the taxa were obtained from the Paleobiology Database available at
209 <https://paleobiodb.org> and mainly compiled by Mark D. Uhen. Adjustments to the ages of the
210 specimens provided by Marx & Fordyce (2015) were also included [where](#) necessary. Stratigraphic
211 ages of the taxa are provided in the Supplementary Information file published in the website of
212 this Journal. The stratigraphic intervals of occurrence of the taxa were used to constrain the
213 divergence dates of the branches included within Balaenoidea in order to get information about
214 the origin of the living right whale and bowhead whale species.

226 Family BALAENIDAE Gray, 1825

227

228 Balaenidae gen. et sp. indet.

229

230 *Material.* Cervical vertebrae complex RBINS M. 881 (IG 8444). This specimen was first figured
231 and described as the cotype of *Balaena belgica* by Abel (1941, p. 13; pl. 2, fig. 9), and later
232 commented and re-illustrated by Plisnier-Ladame & Quinet (1969, fig. 1; pl. 1 and 2, associated
233 to neurocranium RBINS M. 879).

234

235 *Locality and horizon information.* The specimen was found on March 6, 1914 by G. Hasse in the
236 docks of Antwerp harbor (northern Belgium), more precisely in the “darses I-II” (Fig. 1). Abel
237 (1941) mentions an origin in the “Scaldisien” for this specimen. Now disused, this
238 chronostratigraphic regional unit is roughly equivalent to the Lillo Formation, a latest early to
239 Late Pliocene lithostratigraphic unit (latest Zanclean to Piacenzian; Laga et al., 2006; De Schepper
240 et al., 2009; see Fig. 2).

241

242 *Description.* The specimen includes a complex formed by fused cervical vertebrae (Fig. 3).
243 Anteriorly, only the ventral portions of the articular facets of the atlas for the occipital condyles of
244 the skull are preserved. The articular surfaces of the facets are highly concave and wide
245 (measurements are provided in Table 1). The articular facets are separated dorsally by a wide
246 concavity that corresponds to the ventral border of the neural canal. Posteriorly, the articular facet
247 of the 7th cervical vertebra for the 1st thoracic vertebra is highly concave and shows a uniformly
248 convex lateral border. Laterally, the ventral apophysis of the atlas protrudes laterally and ventrally
249 and is separated from a small fragment of the ventral apophysis of the axis by a narrow,
250 dorsoventral groove that is slightly oblique in lateral view. The transverse grooves that are
251 sometimes observed in the cervical complexes of *Caperea marginata* and in balaenid species
252 (Bisconti, 2012) are not seen in this specimen. No additional characters can be described due to
253 the poor preservation of the specimen.

254 Moran et al. (2014) published a study on the ontogenetic fusion of the cervical vertebrae in the
255 extant bowhead whale *Balaena mysticetus*, observing that total fusion of the vertebral centra in the
256 cervical region occurs between 10 and 20 years after birth. In RBINS M. 881 the fusion appears
257 complete as the grooves observed at the dorsolateral and ventrolateral corners of the cervical
258 complex are not deep and do not allow to separate the centra. It is thus possible that RBINS M.
259 881 belonged to an individual of an age included between 10 and 20 years. However, this
260 hypothesis should be tested with comparisons to the fusion pattern of vertebral centra in the
261 cervical region of *Eubalaena* in a way to get a more accurate estimate of the individual age of this
262 specimen. Unfortunately, such a study is still lacking.

263

264 *Discussion and taxonomic decision.* The specimen represents a complex that presumably includes
265 all the cervical vertebrae of a balaenid whale. The morphology is consistent with that of Balaenidae
266 as in *Caperea marginata* the ventral apophysis projects much more ventrally and the outline of the
267 posterior articular surface of the 7th cervical vertebra is squared in posterior view. In other
268 mysticetes the cervical vertebrae are not fused; fusion may occasionally occur in the presence of
269 pathological processes, but the involvement of all the cervical vertebrae is extremely rare. It is
270 possible to distinguish the cervical vertebrae of the living species of *Eubalaena* from the extant
271 *Balaena mysticetus* based on: (1) shape of the neural apophysis, (2) shape of the neural canal, and
272 (3) size, shape and orientation of the ventral apophysis of the atlas. Unfortunately, the specimen
273 RBINS M. 881 is too poorly preserved to allow a safe identification; in fact, in this specimen the
274 neural apophyses are not preserved, the neural canal is only partly preserved, and the ventral
275 apophyses of the atlas are largely damaged and worn. For this reason, we assign RBINS M.881 to
276 Balaenidae gen. et sp. indet. Consequently, this decision implies that this specimen cannot be
277 designated as the holotype of the species *Eubalaena belgica*. Therefore, as Abel (1941) designated
278 RBINS M. 881 as the [cotype](#) of '*Balaena belgica* and now we assign it to gen. et sp. indet., it
279 follows that both '*Balaena belgica* and its recombination, *Eubalaena belgica*, are nomina dubia.

280

281 Balaenidae gen. et sp. indet.

282

283 *Material.* Fragment of right maxilla RBINS M. 880a-c (IG 8652), [mentioned as a fragment of](#)
284 [mandible by Plisnier-Ladame & Quinet \(1969, p. 2\), but never figured.](#)

285

286 *Locality and horizon information.* The specimen was found at Oorderen during the excavation of
287 the first Kruisschans lock of the Antwerp harbor at a depth of 7.80 m under the sea level (Fig. 1).
288 The specimen originates from the Lillo Formation (“Scaldisien”), in a level slightly lower than the
289 neurocranium RBINS M. 879 (see below). Its geological age falls in the range 3.7-2.8 Ma (latest
290 Zanclean-Piacenzian; De Schepper et al., 2009; Fig. 2).

291

292 *Description.* The specimen includes part of the proximal portion of the right maxilla of a balaenid
293 whale (measurements are provided in Table 1). The maxilla is transversely compressed and bears
294 an arched and thin lateral border (Fig. 4). Posteriorly, three infraorbital foramina are observed;
295 ventrally a long groove for the vasculature of the baleen-bearing tissue runs along the whole ventral
296 surface of the bone. Such a surface is lateromedially and anteroposteriorly concave. It is not clear
297 if the orientation of this fragment is more similar to *Eubalaena* and *Balaenula* (in these taxa the
298 posterior portion of the maxilla is nearly horizontal in lateral view) or to *Balaena mysticetus* (in
299 this species the posterior portion of the maxilla projects dorsally and anteriorly) or to *Balaenella*
300 *brachyrhynchus* (in this species the posterior portion of the maxilla distinctly projects
301 anteroventrally).

302

303 *Discussion and taxonomic decision.* The specimen RBINS M. 880a-c represents a balaenid
304 maxilla. In fact it shows a distinctive arch in lateral view, it is transversely compressed, and it
305 displays a longitudinally-developed groove for the vasculature of the baleen-bearing tissue.
306 Unfortunately, it is impossible to reconstruct the original orientation of this fragment in the skull;
307 this, together with the lack of the anterior portion of the rostrum and of the lateral process of the

308 maxilla, prevents a safe taxonomic assignment. For this reason, we assign RBINS M. 880a-c to
309 Balaenidae gen. et sp. indet.

310

311 Genus *Eubalaena* Gray, 1864

312

313 *Type species. Eubalaena australis* Desmoulins, 1822.

314

315 *Holotype.* An unnumbered skeleton housed at the Museum National d'Histoire Naturelle, Paris,
316 France.

317

318 *Diagnosis of genus.* Balaenid cetacean characterized by all the characters diagnostic of the
319 *Eubalaena* + *Balaenula* clade (i.e., rostrum and supraorbital process of the frontal form a right
320 angle in lateral view, nasal and proximal rostrum horizontal in lateral view, orbitotemporal crest
321 well developed on the dorsal surface of the supraorbital process of the frontal, and zygomatic
322 process of the squamosal directed anteriorly so that the posterior wall of the temporal fossa cannot
323 be observed in lateral view) and by the following, exclusively *Eubalaena* characters: vertically-
324 oriented squamosal, protruding lambdoid and temporal crests, convex and protruding
325 supramastoid crest, dome-bearing supraoccipital, wide and rounded anterior process of
326 supraoccipital, and pars cochlearis of petrosal protruded cranially.

327

328 *Discussion.* Bisconti (2003) provided the last diagnosis of *Eubalaena* published up to the present
329 work; diagnostic characters included: gigantic body size (maximum body length approaching 22
330 m), rostrum and supraorbital process of frontal form a right angle, nasal and proximal rostrum

331 horizontal, ascending temporal crest well developed on the dorsal surface of the supraorbital
332 process of the frontal, vertically-developed squamosal, zygomatic process of the squamosal
333 directed anteriorly so that the posterior wall of the temporal fossa cannot be observed in lateral
334 view, protruding lambdoidal and temporal crests, convex and protruding lateral squamosal crest,
335 exoccipital squared in lateral view, dome-bearing supraoccipital shield with sagittal crests, wide
336 anterior process of supraoccipital, pars cochlearis cranially-protruding, and superior process of
337 petrosal cranially-protruding. Bisconti's (2003) diagnosis is certainly useful to separate extant
338 *Eubalaena* from other living balaenids but it may be of limited help when trying to separate fossil
339 *Eubalaena* species from other living and fossil balaenids. In particular, the above diagnosis
340 includes characters that are shared with the extinct *Balaenula* lineage: rostrum and supraorbital
341 process form a right angle, nasal and proximal rostrum horizontal, ascending temporal crest
342 (orbitotemporal crest *sensu* Mead & Fordyce, 2009) well developed on the dorsal surface of the
343 supraorbital process of the frontal, and exoccipital squared in lateral view. All these characters can
344 be observed also in *Balaenula astensis* or in *Balaenula balaenopsis*. A more detailed diagnosis of
345 *Eubalaena* allowing to separate this genus from all the other living and extinct balaenid taxa
346 includes the characters listed in the Emended diagnosis of genus provided above.

347

348 *Eubalaena* sp. indet.

349

350 *Material*. Left humerus RBINS M. 2280, mentioned by Plisnier-Ladame & Quinet (1969, p. 2),
351 but never figured.

352

353 *Locality and horizon information.* Antwerp area. There is no precise locality data available for this
354 specimen. A stratigraphic assessment is currently impossible.

355

356 *Description.* This well-preserved, robust left humerus shows a highly rounded proximal articular
357 head that is anteriorly bounded by a protruding deltoid tuberosity; the latter is triangular in lateral
358 view (measurements are provided in Table 1). The diaphysis shows straight anterior and posterior
359 borders (Fig. 5); the posterior border is shorter than the anterior border, as it terminates more
360 proximally due to the development of the articular facet for the olecranon process of the ulna. Such
361 a facet protrudes posteriorly and occupies part of the posterior border of the humerus. The
362 anteroventral corner of the humerus protrudes anteriorly forming a kind of triangular tuberculum.
363 The articular facets for radius and ulna are separated by a transverse protrusion that is triangular
364 in lateral view.

365

366 *Discussion and taxonomic decision.* The morphology of the articular head of the humerus RBINS
367 M. 2280 is consistent with both *Eubalaena* and *Balaena*. In *Eubalaena glacialis* the external
368 border of the lateral surface of the articular head shows a posterior concavity that is not seen in
369 *Balaena mysticetus* (Benke, 1993). Unfortunately, RBINS M. 2280 is worn in that region thus
370 preventing a clear understanding of its morphology. More distally, the articular facet for the
371 olecranon is well developed as seen in the extant *Eubalaena* species while in *Balaena mysticetus*
372 it is largely reduced. Benke (1993) showed that the posterior border of the diaphysis in *Balaena*
373 *mysticetus* is uniformly concave and short and that the deltoid tuberosity is less protruding than in
374 *Eubalaena glacialis*. In the latter, the posterior border of the diaphysis is more elongated
375 (resembling that of RBINS M. 2280) and the deltoid tuberosity is triangular and protruding. In the

376 humerus RBINS M.2280 the deltoid tuberosity is triangular and protruding as in *E. glacialis*.
377 However, the posterior border of the diaphysis of RBINS M. 2280 is straighter than that observed
378 in *E. glacialis*.

379 Comparative analysis shows, thus, that the humerus RBINS M. 2280 is closer to *Eubalaena* than
380 to *Balaena*, as it shares with *E. glacialis* the presence of (1) well-developed and protruding
381 articular facet for the olecranon process, (2) triangular and protruding deltoid tuberosity and, (3)
382 comparatively long posterior border of the diaphysis. These shared characters allow inclusion of
383 RBINS M. 2280 within *Eubalaena*. However, the different shape of the posterior border of the
384 diaphysis and the lack of information about the shape of the lateral outline of the articular head do
385 not allow inclusion of this specimen within *E. glacialis* or other extant *Eubalaena* species. RBINS
386 M. 2280 is thus assigned to *Eubalaena* sp. indet.

387 When compared to the extant *Eubalaena* species, this humerus is particularly long suggesting that
388 it belonged to a [large](#) individual. The total proximodistal length of RBINS M. 2280 is 683 mm,
389 which is greater than the maximum humeral lengths published by Benke (1993) for *Balaena*
390 *mysticetus* (i.e., [605 mm](#)), *Eubalaena glacialis* ([555 mm](#)), and *E. australis* ([619 mm](#)), and by
391 Omura (1958) for *E. japonica* ([556 mm](#)). Based on this comparison, we suggest that the humerus
392 RBINS M. 2280 belonged to an individual that was longer than 16.5 m. This is the first report of
393 a gigantic right whale in the fossil record of the North Sea.

394

395 *Eubalaena ianitrix* sp. nov. LSID: urn:lsid:zoobank.org:act:F17C4DCA-FF1B-4EA4-9E6B-
396 6C1EED448745

397

398 *Derivation of name.* The specific name *ianitrix* derives from Ianus, the Roman God who was the
399 guardian of passages, gates and doors. This name is related to the discovery of the holotype in the
400 locks (or entrances) of the Antwerp harbor.

401

402 *Holotype.* The holotype is housed at the Royal Belgian Institute of Natural Sciences, Brussels,
403 Belgium, and bears the inventory number M. 879a-f, Reg. 4019, I.G. 8652 (all the numbers refer
404 to the same individual). It includes a partial skull (M. 879a), right squamosal and exoccipital (M.
405 879b), left squamosal and exoccipital (M. 879c), fragment of a maxilla (M. 879d), fragment of the
406 right supraorbital process of the frontal (M. 879e), fragment of the left supraorbital process of the
407 frontal (M. 879f). It was first figured and described as *Balaena belgica* by Plisnier-Ladame &
408 Quinet (1969, p. 2; pl. 1-2, associated to cervical complex RBINS M. 881).

409

410 *Type locality.* The neurocranium RBINS M. 879a-f was discovered in Oorderen (Fig. 1) during
411 the excavation of the first Kruisschans lock (*'première écluse du Kruisschans'*, now named Van
412 Cauwelaertsluis) of the Antwerp harbor (Plisnier-Ladame & Quinet, 1969). Geographic
413 coordinates: 51°16'32"N- 04°19'51"E. As mentioned above, the maxilla RBINS M. 880a-c was
414 found at the same site. However, based on labels associated to specimens, the neurocranium was
415 found at a depth of 3.70 m under the sea level, whereas the maxilla was found at a depth of 7.80
416 m under the sea level, therefore most likely not representing the same individual.

417

418 *Type horizon.* Based on data associated to the neurocranium RBINS M. 879a-f, Misonne (1958)
419 indicated an origin in the Kruisschans Sands (*'Sables du Kruisschans'*; Fig. 2) in the *'zone à*
420 *Cardium'*, and a Merkssemian (*'Merxemien'*) stage, a stage assignment later confirmed by Plisnier-

421 Ladame & Quinet (1969). Now disused, this regional stage was first introduced by Heinzelin
422 (1955a), including the Kruisschans Sands and Merksem Sands, together with an underlying gravel
423 layer (Laga & Louwye, 2006). Both the Kruisschans Sands Member and Merksem Sands Member
424 are now part of the Lillo Formation, constituting its two youngest members (Vandenberghe et al.,
425 1998; Laga et al., 2006).

426 In published sections of the Pliocene and Quaternary layers at the Kruisschans locks (including
427 sections in a new lock parallel to the ancient lock, 'Ecluse Baudouin'), a clayey sand layer
428 containing a high concentration of shells of the bivalve *Laevicardium* (first named *Cardium*)
429 *parkinsoni* and isolated cetacean bone fragments is reported at a depth of 5.5-7 m (Heinzelin, 1952,
430 1955b). This shell layer is located about 1 m above the base of the Kruisschans Sands. It is
431 therefore tempting to propose that the 'zone à *Cardium*' mentioned by Misonne (1958) for the
432 horizon of the skull RBINS M. 879a-f corresponds to this part of the Kruisschans Sands.

433 Dinoflagellate cysts from a section 4 km north to the Kruisschans locks give a Piacenzian (Late
434 Pliocene) age to both the Kruisschans Sands Member and the overlying Merksem Sands Member,
435 older than 2.6 Ma (as confirmed by pollens) and most likely somewhat younger than 3.7 Ma (age
436 of the base of the Lillo Formation), whereas sequence stratigraphy narrows even more their
437 temporal range to 3.2 to 2.8 Ma (De Schepper et al., 2009). RBINS M. 879a-f is therefore proposed
438 to date from that Piacenzian interval.

439 The record of fossil marine mammals in the Kruisschans Sands Member is relatively poor; only
440 the odobenid *Alachtherium antwerpiensis* and the stem phocoenid *Septemtriocetus bosselaersi* are
441 known to originate from that unit (Hasse, 1909; Lambert, 2008).

442

443 *Diagnosis.* *Eubalaena ianatrix* differs from *E. shinshuensis* in showing a distinctive anteroventral
444 corner in the parietal-frontal suture and in having an anterodorsally protruded squamosal-parietal
445 suture; it differs from the *Eubalaena* sp. from the early Late Pliocene of Tuscany (included in our
446 diagnosis considering that in our phylogenetic analysis it represents a true right whale species
447 needing a new species name) in having an anteriodorsally protruded squamosal-parietal suture; it
448 differs from *E. japonica* in having the pterygoid exposed in the temporal fossa, in having
449 posteromedially directed anterior borders of the palatine and in having anteriorly directed posterior
450 borders of the palatine; it differs from *E. australis* in having a less protruding anteroventral corner
451 in the parietal-frontal suture, in having an anterodorsally protruded squamosal-parietal suture, in
452 having the pterygoid exposed in the temporal fossa and in having anteriorly directed posterior
453 border of the palatine; it differs from *E. glacialis* in having a crest located at the squamosal-
454 parietal-supraoccipital suture and in having anteriorly directed posterior border of the palatine.
455 *Eubalaena ianatrix* does not possess any autapomorphy and may be distinguished from other
456 *Eubaena* species by the following combination of characters: bilateral bulge on supraoccipital with
457 presence of sagittal crest, alisphenoid exposed in the temporal fossa, and alisphenoid dorsally
458 bordered by a squamosal projection that prevents it to make contact with parietal.

459

460 **Comparative anatomy of the skull of *Eubalaena ianatrix***

461

462 The holotype specimen consists of a moderately well preserved partial skull. The skull is massive
463 and heavy and lacks part of the supraoccipital borders due to post-mortem erosion. It is subdivided
464 into six fragments that can be put together due to clear break surfaces. Measurements are provided
465 in Table 2.

466

467 *Rostrum*. Only a fragment of the right maxilla is preserved showing the typical transverse
468 compression present in Balaenidae.

469

470 *Frontal*. Due to the erosion of the anterior-most border of the supraoccipital, it is possible to
471 observe a tiny portion of the interorbital region of the frontal in dorsal view (Figs 6). Prior to the
472 erosion of the supraoccipital, that portion was superimposed by the anterior portion of the
473 supraoccipital and was not visible. Judging from what is preserved, the interorbital region of the
474 frontal was less bent than the supraoccipital suggesting that, in lateral view, the posterior portion
475 of the rostrum was nearly flat as seen in *Eubalaena glacialis*. The transverse diameter of the
476 interorbital region (measured along the inferred position of the nasofrontal suture) is *c.* 240 mm.

477 The supraorbital processes of the frontal are detached from the skull probably because post-
478 mortem damage. The supraorbital process of the frontal is anteroposteriorly narrow and bears an
479 evident but rounded orbitotemporal crest developed from the postorbital process to its
480 anteromedial border (Figs 6, 7 and 8). The orbitotemporal crest is sharper proximally and becomes
481 lower approaching the orbital rim. The right supraorbital process of the frontal is 650 mm in length
482 up to the center of the orbit. The left supraorbital process of the frontal is 712 mm in length. A
483 long groove for articulation with the maxilla is located at the anteromedial corner of the left
484 supraorbital process of the frontal (Fig. 9).

485 The optic canal is deep proximally (depth is *c.* 45 mm) and shallow distally (depth is *c.* 35 mm).

486 Proximally, the right optic canal is bordered by anterior and posterior crests whose distance is 50
487 mm proximally and *c.* 100 mm distally (Fig. 10). The anteroposterior diameter of the left optic

488 canal is 30 mm proximally at a distance of 400 mm from the orbital rim and 70 mm a few mm
489 from the orbital rim.

490 Approaching the orbit, the dorsal surface of the supraorbital process of the frontal flattens. The
491 right orbit is 170 mm in length (from the center of the postorbital process of the frontal to the
492 center of the antorbital process of the frontal) and 51 mm in height (measured from the center of
493 the orbital rim to an imaginary line joining antorbital and postorbital processes of the frontal). On
494 the right side, antorbital and postorbital processes are similar in size but on the left side, the
495 postorbital process is more robust than the antorbital process (Figs 7 and 8). The longitudinal axis
496 of the supraorbital process of the frontal is perpendicular to the imaginary line joining antorbital
497 and postorbital processes. This suggests that, in the living animal, the supraorbital process of the
498 frontal formed an approximately right angle with the lateral process of the maxilla and, thus,
499 resembling the condition observed in the right whale of the genus *Eubalaena* and the fossil
500 *Balaenula*.

501 The frontal of *Eubalaena ianatrix* shares the following characters with the living *Eubalaena* and
502 *Balaenula*: presence of an evident orbitotemporal crest developed from the postorbital process to
503 the anteromedial corner of the supraorbital process of the frontal, lack of dorsoventral compression
504 along most of the length of the supraorbital process of the frontal (as seen in *Morenocetus parvus*,
505 *Balaena mysticetus* and *Balaenella brachyrhynchus*), presence of a right angle between supraorbital
506 process of the frontal and the lateral process of the maxilla in lateral view, interorbital region of
507 the frontal clearly angled with respect to the dorsoventral inclination of the supraoccipital. The
508 articular groove for the maxilla combined with the short anteroposterior diameter of the proximal
509 portion of the supraorbital process suggests that the ascending process of the maxilla was short
510 and wide like that typically observed in the other Balaenoidea where this structure has been

511 described (Bisconti, 2012 and literature therein). The short exposure of the interorbital region of
512 the frontal on the dorsal surface of the skull and the exclusion of the parietal from exposure at
513 cranial vertex are typical characters of living and fossil Balaenoidea.

514

515 *Parietal*. The parietal is evident on the lateral sides of the skull and at the cranial vertex due to the
516 erosion of the anterior-most border of the supraoccipital (Fig. 6). Originally, the parietal was
517 covered by the anterior border of the supraoccipital forming the nuchal crest. The frontal border
518 of the parietal is superimposed on the interorbital region of the frontal obliterating it in dorsal view.
519 More laterally, the frontal border descends ventrally and posteriorly and borders the posterodorsal
520 portion of the supraorbital process of the frontal and forming an anteriorly convex coronal suture.
521 Posteriorly to the supraorbital process of the frontal, the coronal suture forms a curve with anterior
522 concavity and projects ventrally and posteriorly (Figs 7, 8).

523 The shape of the coronal suture is different in different balaenoid lineages. In the skull of *Caperea*
524 *marginata* as seen in lateral view, the frontal border of the parietal gently descends from an
525 anterodorsal point to a point located posteroventrally in a straight-to-slightly convex line located
526 dorsally to the supraorbital process of the frontal. This shape of the frontal border of the parietal
527 is shared also with *Balaena mysticetes*, *B. montalioni*, *B. ricei* and *Balaenella brachyrhynchus*. In
528 the fossil *Miocaperea pulchra*, the right parietal shows a slightly different condition; in this species
529 a distinctive anteroventral corner is located along the frontal border of the parietal (Bisconti, 2012).
530 The anteroventral corner is present also in the species belonging to *Balaenula* and *Eubalaena* and
531 in *Eubalaena ianatrix* (Figs 7, 8). In *Eubalaena australis*, posterior to the anteroventral corner, the
532 frontal border shows a strong ventral concavity and a rounded shape making it distinct from the
533 parietal of all the other balaenoid species.

534 The supraoccipital border of the parietal protrudes laterally and, together with the lateral border of
535 the supraoccipital, forms the temporal crest. The temporal crest protrudes laterally and forms a sort
536 of short roof of the temporal fossa in such a way that it prevents the medial wall of the temporal
537 fossa (formed by the external surface of the parietal) from being observed in dorsal view. The
538 external surface of the parietal is widely concave. Along the anteroposterior axis of the skull, the
539 parietal appears short and high. The dorsal portion of the squamous border is anteroposteriorly
540 elongated and bears a weak crest; the ventral portion of the squamous border forms a highly
541 interdigitated suture with the squamosal and projects ventrally.

542 Among Balaenidae, a crest along the squamous border has been detected as a synapomorphy of
543 *Balaena* and *Balaenella* by Bisconti (2005a) and Churchill et al. (2012) as it is absent from
544 *Balaenula* and *Eubalaena*. It is not clear whether this crest is present in *Morenocetus* and
545 *Peripolocetus*. The shape of the frontal border of the parietal differs from that observed in *Balaena*
546 and *Balaenella* as it shows an undulating development; in *Balaena* and *Balaenella* the frontal
547 border of the parietal proceeds posteroventrally as a straight line. A highly interdigitated ventral
548 portion of the squamous border of the parietal is also observed in a subadult individual of *E.*
549 *australis* (specimen NBC RGM 24757).

550 The squamous border of the parietal has distinctive characters in different balaenoid lineages. In
551 *Caperea marginata*, the dorsal portion of the squamous border projects posteriorly to meet the
552 supraoccipital (Bisconti, 2012). This character is also observed in *Balaena mysticetus* adult NBC
553 RGM 373 and foetal NBC RGM 31116; the character was also illustrated by Cuvier, 1823; see
554 Bisconti, 2003 for an image), *Eubalaena australis* adult IZIKO 2284, subadult NBC RGM 24757
555 and foetal IZIKO ZM 38950) and in the Pliocene *Eubalaena* sp. from Tuscany (Bisconti, 2002).
556 In *Miocaperea pulchra* and *Balaenella brachyrhynchus* the dorsal portion of the squamous border is

557 nearly vertical. In *Eubalaena glacialis*, *E. japonica*, *Balaenula astensis* and *Eubalaena ianatrix* the
558 dorsal portion of the squamous border projects anteriorly forming a finger-like structure that is
559 deeply wedged between the parietal and the supraoccipital.

560

561 *Supraoccipital*. The supraoccipital is strongly built and represents the largest bone of this skull
562 (Fig. 6). Parts of the anterior and lateral borders are missing due to post-mortem erosion of the
563 skull and to damage done during the collection and preparation of the skull. The supraoccipital is
564 wide and, as preserved, shows a convex lateral border and a widely rounded anterior border. The
565 anteroposterior length (from the anterior border to the inferred position of the dorsal edge of the
566 foramen magnum) is *c.* 531 mm; the transverse diameter is *c.* 350 mm anteriorly and *c.* 590 mm
567 at mid-length. The external occipital protuberance, located on the anterior surface of the
568 supraoccipital, is dorsally convex and forms a wide dome bordered by bilateral fossae located near
569 the lateral borders of the supraoccipital. The dome consists of relief posteriorly subdivided by the
570 interposition of a triangular, parasagittal fossa. There is a low sagittal crest located posteriorly to
571 the dome. In lateral view, the dome is clearly visible as it protrudes dorsally and is not obliterated
572 to view by the temporal crests. Before the post-mortem erosion of the skull, the supraoccipital
573 formed a dorsal roof to the temporal fossa preventing the parietal from being observed in dorsal
574 view.

575 In the genus *Eubalaena*, the supraoccipital is anteriorly wide and rounded and displays an external
576 occipital protuberance that is dome-shaped. These characteristics of the supraoccipital are
577 observed in all the living *Eubalaena* species, in the fossil *E. shinshuensis* and in the *Eubalaena* sp.
578 described by Bisconti (2002) from the Pliocene of Tuscany. Subtle differences in the characters of
579 the dome could be used for differentiating the species of *Eubalaena* but it is not completely clear

580 whether the differences are due to individual variation or have taxonomic value. Bisconti (2002)
581 described a sagittal crest on the external occipital protuberance and a series of five [parasagittal](#)
582 crests posterior to it in a Pliocene *Eubalaena* sp. The five [parasagittal](#) crests are not observed in
583 other *Eubalaena* species. A single sagittal crest is present in *Eubalaena australis* (NBC RGM
584 24757), *Eubalaena glacialis* (AMNH 42752, MSNT 264) *E. japonica* (Omura, 1958) and
585 *Eubalaena ianatrix*.

586 The external supraoccipital protuberance is formed by a bilateral bulge in *Eubalaena australis*
587 (NBC 24757), *E. glacialis* (AMNH 42752), *Eubalaena* sp. (Bisconti, 2002), and *E. ianatrix*, and
588 by a single axial bulge in *E. japonica* and *E. shinshuensis* (Kimura, 2009). The external
589 supraoccipital protuberance is a single bulge also in *Balaena mysticetus*, *Balaena montalioniis*,
590 *Balaena ricei* and *Balaenella brachyrhynchus* but in these species the anterior portion of the
591 supraoccipital is transversely constricted while in the species belonging to *Morenocetus*,
592 *Balaenula* and *Eubalaena* the anterior portion of the supraoccipital is transversely wide.

593 Observations on skulls belonging to living species suggest that the lateral borders of the
594 supraoccipital potentially undergo morphological change during ontogeny. In *Eubalaena*
595 *australis*, the lateral border of the supraoccipital is externally convex in fetal and subadult
596 individuals (ISAM ZM 38950, NBC RGM 24757). Omura (1958) observed that in adult
597 individuals of *Eubalaena glacialis* the lateral border of the supraoccipital is more concave than in
598 *E. japonica*. However, in the images provided by True (1904), an adult individual of *Eubalaena*
599 *glacialis* has a continuously convex lateral border of the supraoccipital. It is possible that Omura's
600 (1958) observation was related to differences in the point of view from which the skulls were
601 observed ([Yamada et al. 2006](#)).

602

603 *Vertex*. Based on Mead & Fordyce (2009, and literature therein) terminology, the vertex is the
604 highest portion of the skull. In mysticetes it is formed by a mosaic of bones including
605 supraoccipital, parietal, frontal and some posteromedial elements of the rostrum nasal and the
606 ascending process of the premaxilla and of the maxilla). In *E. ianatrix*, the supraoccipital overlaps
607 onto the parietal and prevents it from being observed in dorsal view (Fig. 6). The parietal is
608 superimposed onto the interorbital region of the frontal that is, thus, scarcely visible in dorsal view.
609 The only portion of the interorbital region of the frontal that can be observed is that that is
610 immediately posterior to the nasofrontal suture. Judging from the articular groove present on the
611 anteromedial surface of the supraorbital process of the frontal, the ascending process of the maxilla
612 had a limited posterior extension resembling other living and fossil Balaenoidea.

613 The supraoccipital superimposition on the parietal and the parietal superimposition on the
614 interorbital region of the frontal are synapomorphies of Balaenidae and Neobalaenidae and are not
615 shared with other mysticete taxa (Bisconti, 2012 and literature therein). The lack of parietal
616 exposure at the cranial vertex is another exclusive feature of Balaenidae and Neobalaenidae and is
617 observed in all the living and fossil taxa belonging to these groups (Churchill et al., 2012; Bisconti,
618 2003).

619

620 *Exoccipital*. The lateral portion of the exoccipital is a wide and flat surface with external border
621 squared (Fig. 11). Only the left paroccipital process is preserved and appears strong and rugose in
622 ventral view. A squared external border of the exoccipital is observed in *Eubalaena japonica* and,
623 at a lesser extent, in *Eubalaena australis*. In *E. glacialis* the external border has a rounder shape
624 than in those species. In *Balaena mysticetus* and *B. montalioni* the external border of the
625 exoccipital appears anterolaterally round with a distinctive lateroventral corner that is observed

626 also in *E. glacialis* but that seems absent in *E. japonica* (Omura, 1958). In lateral view, the
627 exoccipital has a squared shape in *E. glacialis*, *E. australis*, *E. japonica* and the species belonging
628 to *Balaenula* but it is not clear whether a squared shape is also present in *Eubalaena ianatrix*.

629 The occipital condyle is wide, **reniform** and its surface for articulation with the atlas is nearly flat
630 along both the dorsoventral and the lateromedial axes. The main axis of the occipital condyle is
631 **oriented** from a posteroventral point to an anterolateral point. There is a wide **intercondyloid fossa**
632 **located ventrally between** the condyles. The condyles are not in contact each other ventrally or
633 dorsally. The maximum anteroposterior diameter of the occipital condyle is 190 on the right side
634 and 170 on the left side; the maximum lateromedial diameter of the occipital condyle is 101 on the
635 right side and 107 on the left side. The condyles surround a wide foramen magnum whose dorsal
636 border is not preserved. The maximum transverse diameter of the foramen magnum is 145 mm and
637 its **dorsoventral** diameter is inferred to be *c.* 140 mm based on a nearly circular outline with a slight
638 dorsoventral compression as seen in other balaenid species. The distance between the external
639 borders of the occipital condyles is *c.* 350 mm.

640

641 *Squamosal*. Right and left squamosals are partly broken; breakage lines are straight enough to
642 allow an easy reconstruction of this part of the skull by putting the broken portions of the
643 squamosals in place through right connections (Figs 7, 8).

644 The parietal margin of the squamosal forms the squamosal-parietal suture. Dorsally, this suture
645 projects anteriorly making it possible for the squamosal to be deeply inserted between the
646 supraoccipital and the parietal. More ventrally, the squamosal-parietal suture is highly
647 interdigitated.

648 The squamosal plate is dorsoventrally and anteroposteriorly concave and, in lateral view, it is
649 hidden by the anterior and ventral development of an anteriorly convex supramastoid crest. The
650 supramastoid crest is protruding anterolaterally and shows a widely rounded anterior shape. The
651 supramastoid crest is separated from the zygomatic process of the squamosal by a wide anterior
652 concavity. The zygomatic process of the squamosal is short and stocky; [its main axis](#) projects
653 laterally and ventrally [in dorsal view](#).

654 The squamosal has a clear dorsoventral development as [typically](#) observed in Balaenidae. Its
655 dorsoventral diameter is 550 mm on the external surface (from the exoccipital-squamosal suture
656 to the anterior end of the zygomatic process of the squamosal) of the right squamosal. The glenoid
657 fossa of the squamosal is largely eroded; what remains suggests that it was flat or scarcely concave
658 as seen in other typical balaenid whales. The glenoid fossa of the right squamosal is 470 mm in
659 anteroposterior length.

660 Posterodorsally, [the site for the articulation with the posterior process of the petrotympanic](#) is
661 developed ventrally to the exoccipital-squamosal suture and is ventrally bordered by a crest that
662 separates it from the external acoustic meatus. Both [this site](#) and the external acoustic meatus are
663 represented by transverse and tube-like concavities developed along the dorsal and posterior
664 portion of the squamosal. [The posterior border of the foramen ovale is made of the squamosal and](#)
665 [the pterygoid](#).

666 The squamosal of *Eubalaena ianatrix* shows the following typical balaenid characters: dorsoventral
667 elongation, reduction of the zygomatic process of the squamosal, scarcely concave glenoid fossa
668 of the squamosal, widely rounded supramastoid crest [in lateral view](#). In *Balaenella* and in the
669 species of *Balaena* the squamosal is also posteroventrally oriented (Bisconti, 2000) but this
670 character is not observed in *E. ianatrix*. Rather, the squamosal of *E. ianatrix* appears more vertical

671 resembling *Morenocetus*, *Balaenula* and the living species of *Eubalaena*. In *Balaenella*
672 *brachyrhynchus*, *Balaena mysticetus*, *B. ricei*, and *B. montalioni* the zygomatic process of the
673 squamosal projects more laterally allowing the view of the posterior wall of the temporal fossa
674 formed by the squamosal plate. In *Eubalaena*, *Balaenula* and *E. ianatrix* this is not the case as the
675 zygomatic process of the squamosal projects anteriorly and prevents the posterior wall of the
676 temporal fossa from being observed in lateral view.

677

678 *Alisphenoid*. The alisphenoid is exposed in the temporal fossa. It has a triangular shape. It is
679 bordered anteriorly by the supraorbital process of the maxilla, ventrally by the palatine, and
680 dorsally and posteriorly by the squamosal.

681 The alisphenoid is exposed in the temporal fossa in *Eubalaena glacialis* and *E. japonica* but it is
682 not clear whether such an exposure occurs also in *E. australis*. In fetal specimen (IZIKO ZM
683 38950) the alisphenoid is observed in the temporal fossa but in subadult individual (NBC RGM
684 24757) the alisphenoid is only visible in ventral view and does not appear in the temporal fossa as
685 the ventral border of the squamosal superimposes onto it. In *Balaena mysticetus*, *B. brachyrhynchus*,
686 and in the genus *Balaenula* the alisphenoid is inferred to be exposed in the temporal fossa based
687 on the articular pattern of squamosal and parietal. The alisphenoid was originally bordered by the
688 squamosal dorsally and posteriorly and by the parietal dorsally and anteriorly, by the palatine
689 ventrally.

690

691 *Temporal fossa*. The temporal fossa of *E. ianatrix* is dorsally overhung by the lateral projection of
692 the temporal crest formed by the lateral border of the supraoccipital and the dorsal border of the
693 parietal (Fig. 6). The lateral extension of the temporal crest is difficult to assess because the lateral

694 edge of the supraoccipital and the dorsal border of the parietal are **damaged**. The medial wall of
695 the temporal fossa is formed by parietal, squamosal and alisphenoid. The alisphenoid is not in
696 contact with the parietal; the parietal-squamosal suture is highly interdigitated ventrally but,
697 dorsally, the squamosal forms a digit-like anterior protrusion that is deeply inserted between the
698 supraoccipital and the parietal. The medial wall of the temporal fossa is concave both
699 dorsoventrally and anteroposteriorly. The posterior wall of the temporal fossa is formed by the
700 squamosal and shows an anterior concavity. Lateral to the posterior wall of the temporal fossa, the
701 supramastoid crest protrudes anteriorly and forms the lateral border of the squamosal fossa.
702 The general features of the temporal fossa of *E. ianatrix* are also observed in *Eubalaena glacialis*
703 and *E. japonica*. *Eubalaena australis* differs in the lack of exposure of the alisphenoid in the
704 temporal fossa at adulthood. In the Pliocene *Eubalaena* sp. from Tuscany (Bisconti, 2002) and
705 *Eubalaena shinshuensis* (Kimura, 2009) the digit-like projection of the anterodorsal portion of the
706 squamosal is absent. In *Balaenula* the posterior apex of the lambdoid crest is located much more
707 anteriorly than in any species belonging to *Eubalaena*, *Balaena* and *Balaenella* and this makes its
708 temporal fossa anteroposteriorly smaller; moreover, in *Balaenula astensis* the posterior wall of the
709 temporal fossa is mainly flat along the dorsoventral axis (Bisconti, 2000, 2003).

710

711 *Palatine*. The palatine is almost rectangular in ventral view (Fig. 10). It is an elongated bone that
712 is anteriorly in contact with the maxilla and posteriorly with the pterygoid. As typically observed
713 in Balaenidae, the palatine is ventrally superimposed on the ventral lamina of the pterygoid that
714 appears, in ventral view, as a small stripe of bone close to the posterior limit of the skull. The
715 ventral surface of the palatine is almost flat. The longitudinal axis of the palatine diverges from
716 the anteroposterior axis of the skull posteriorly as the posterior ends of the palatines are not in

717 contact posteriorly. The lateral lamina of the palatine ascends and contacts the squamosal, the
718 alisphenoid and the frontal.

719 The relationships of the palatine observed in *E. ianatrix* are not different from those that can be
720 observed or inferred in other living and fossil Balaenidae for which information about this bone is
721 available.

722

723 *Pterygoid*. Following Churchill *et al.* (2012), Bisconti (2000, 2005a) and Fraser & Purves (1960),
724 in Balaenidae the pterygoid appears as a small stripe of bone in ventral view. This stripe of bone
725 represents the lateral lamina of the pterygoid that is transversely elongated and approaches the
726 posterior-most border of the skull in lateral view. The pterygoid is dorsally, anteriorly and
727 posteriorly bordered by the squamosal and anteroventrally by the palatine. The posterior border of
728 the pterygoid and the anterior border of the falciform process of the squamosal contribute to delimit
729 the shape of the foramen ovale (Fig. 10).

730 Apart from *Caperea marginata*, in which the foramen ovale is within the pterygoid, the foramen
731 ovale of other balaenoids is located between the squamosal and the pterygoid. In the living species
732 the foramen ovale extends into a tube formed almost entirely by the squamosal (= infundibulum
733 of Fraser and Purves, 1960). This condition is not observed in *E. ianatrix* where the foramen ovale
734 has an [elliptical](#) shape.

735

736 **Body size estimate**

737

738 Two of the chosen methods converge towards a total body length of *c.* 6-8 m. The application of
739 equation (1) based on a bizygomatic width of 1660 mm (Table 2) retrieved a total body length of

740 *c.* 13 m; this result is to be corrected by reducing it of 37-to-47%. After the correction, the resulting
741 values are respectively *c.* 8 m and *c.* 7 m.

742 The application of the regression equation (4) based on a supraoccipital length of 560 mm (Table
743 2) found a condylobasal length of *c.* 1.6 m. After having tripled and quadrupled this length, the
744 total body length was estimated between 4.74 and 6.37 m.

745 The application of the equation (2) based on an occipital breadth of 353 mm retrieved a body mass
746 of *c.* 33 t. This value is consistent with weight values obtained by Omura et al. (1958) for the North
747 Pacific right whale (*E. japonica*). We used this body mass estimate in the equation (3) and found
748 a total body length of *c.* 11 m, which is closer to the result obtained from the equation (1) before
749 the correction. It is not clear whether the results of the equation (3) need to be corrected but,
750 following the suggestions of Pyenson & Sponberg (2011), we hypothesize that a correction would
751 be necessary that should be around 40%. If we apply such a correction to the value obtained by
752 the equation (3), we find a total body length of *c.* 6.6 m that is very close to the higher results of
753 the equations (1) and (4). If we accept a total body length between 6 and 7 m then we need to apply
754 a roughly similar correction to the estimated body weight. If we reduce the estimated body weight
755 of 40% then we obtain an estimated body weight of 19.8 t.

756 We therefore estimate the total body length of [the holotype specimen of *Eubalaena ianatrix*](#)
757 between 5 and 7 m, with a body mass of *c.* 20 t.

758

759 **Phylogeny**

760

761 *Overview*

762 The phylogenetic analysis resulted in the single most parsimonious cladogram shown in Fig. 12 .
763 Tree statistics are provided in the corresponding caption. Our results confirm the monophyly of
764 Mysticeti, Chaemysticeti and Balaenomorpha. The sister-group of Balaenomorpha is the
765 monophyletic Eomysticetidae (here represented by *Eomysticetus whitmorei*, *Tokaraia kauaeroa*
766 and *Yamatocetus canaliculatus*). Balaenomorpha is then subdivided into two sister-groups:
767 Balaenoidea and Thalassotherii (including Balaenopteridae, Eschrichtiidae, Cetotheriidae and
768 basal thalassotherian taxa including *Cophocetus*, *Aglacetus*, *Parietobalaena*, *Isanacetus*,
769 *Uranocetus*, *Pelocetus* and *Diorocetus*). As such, the present results confirm the monophyly of
770 Balaenopteroidea (including Balaenopteridae and Eschrichtiidae) and Cetotheriidae (here
771 including *Mixocetus*, *Herentalia*, *Piscobalaena*, *Herpetocetus* and *Tranatocetus*). *Tranatocetus*
772 *argillarius* is nested here among Cetotheriidae. Although this may be due to our limited sample of
773 Cetotheriidae and related taxa, we are unable to support the monophyly of Tranatocetidae (as
774 proposed by Gol'din & Steeman, 2015), considering that *T. argillarius* (the only nominal
775 Tranatocetidae taxon included in our analysis) falls within Cetotheriidae.
776 Most surprising are the position of *Morenocetus parvus* (that will be discussed in the next
777 paragraph) and the sister-group relationships within Thalassotherii. Among Thalassotherii, four
778 monophyletic groups of family-level rank are recognized: Balaenopteridae, Eschrichtiidae,
779 Cetotheriidae and a clade including what Bisconti et al. (2013) called basal thalassotherian taxa.
780 Eschrichtiidae is the sister-group of Balaenopteridae and both form the monophyletic
781 Balaenopteroidea. Balaenopteroidea is the sister-group of a large clade including *Titanocetus*
782 *sammarinensis*, Cetotheriidae and basal thalassotherian taxa. *Ti. sammarinensis* is, in its turn, the
783 sister-group of Cetotheriidae and basal thalassotherian taxa.
784

785 *Relationships of Balaenoidea and morphological supports to nodes*

786 Our results support the monophyly of Balaenoidea with a noticeable difference with respect to
787 previously published literature (Cabrera, 1926; Bisconti, 2005; Churchill et al., 2012):
788 *Morenocetus parvus* falls outside Balaenidae + Neobalaenidae and represents the sister-group of
789 both families.

790 Nine synapomorphies support the monophyly of Balaenoidea. Three of them depends on the
791 structure of the skull: characters 37 (short exposure of interorbital region of the frontal because of
792 superimposition by the parietal), 54 (massive elongation of supraoccipital), and 55 (supraoccipital
793 is superimposed onto the interorbital region of the frontal). Moreover, character 47 (squamosal
794 dorsoventrally elongated) is also an exclusive synapomorphy of this clade.

795 Seventeen synapomorphies support the monophyly of Neobalaenidae + Balaenidae to the
796 exclusion of *Morenocetus parvus*. Three of them are unambiguous: characters 81 ([short](#)
797 [dorsoventral height of the tympanic cavity](#)), 82 (dorsoventrally compressed tympanic bulla), and
798 83 (enlargement of epitympanic hiatus). Characters 11 (rostrum highly arched), 84
799 (anteroposteriorly short anterolateral lobe of tympanic bulla), 92 (dorsal exposure of mandibular
800 condyle), 95 (dorsoventral arc of dentary along the whole length of the bone), and 101 (cervical
801 vertebrae fused) represent additional ambiguous synapomorphies of the clade. Neobalaenidae
802 (including *Caperea* and *Miocaperea*) is the sister-group of Balaenidae (here including *Balaena*,
803 *Balaenella*, *Balaenula* and *Eubalaena*). The monophyly of Neobalaenidae is supported by 4
804 synapomorphies including a reversal in character 122 (complete infundibulum). Characters 50
805 (presence of squamosal cleft) and 75 (exposure of posterior process of petrotympanics in the lateral
806 view of the skull) are ambiguous synapomorphies as these characters (in different ways) are
807 observed in Balaenopteridae and Cetotheriidae, presumably as a result of convergent evolution.

808 Four unambiguous synapomorphies support the monophyly of Balaenidae: characters 64 (massive
809 elongation of palatine posteriorly), 65 (posterior placement of pterygoid), 86 (sharply defined
810 groove for mylohyoidal muscle), and 122 (foramen ovale with incomplete infundibulum). Three
811 additional ambiguous synapomorphies are detected: characters 12 (transverse compression of
812 maxilla), 74 (long and thick roof of stylomastoid fossa), and 97 (strong anterior torsion of dentary).
813 Balaenidae is subdivided into two clades: one including *Balaena* and *Balaenella* and the other
814 including *Balaenula* and *Eubalaena*. The inclusion of *Balaenella brachyrhynchus* within *Balaena*
815 casts some taxonomic problems as it either makes *Balaena* paraphyletic or suggests inclusion of
816 *Balaenella* within *Balaena*. *Balaenella brachyrhynchus* and *Balaena montalionis* share an anteriorly
817 narrowed supraoccipital and a supraoccipital with transversely short anterior border; these
818 character states support their sister-group relationship. Unfortunately, a clear illustration of the
819 dorsal view of *Balaena ricei* is not available and it is difficult to understand whether this species
820 is really more closely related to *Balaena montalionis* and *Balaenella brachyrhynchus* or to *Balaena*
821 *mysticetus*. From our results, *B. mysticetus* represents a separate lineage that diverged before the
822 other *Balaena*-like taxa (*B. ricei*, *B. montalionis* and *Balaenella*). A low number of
823 synapomorphies support the monophyly of the clade including *Balaena* and *Balaenella*. These
824 include the following two unambiguous synapomorphies: characters 116 (transverse compression
825 of anterior supraoccipital) and 120 (lateral projection of zygomatic process of the squamosal).
826 Additionally, two ambiguous synapomorphies are also found to support this clade; these include
827 characters 126 (posterior orientation of dorsoventrally developed squamosal body) and 132 (crest
828 present at parietal-squamosal suture). The sister-group relationship of *Balaena montalionis* and
829 *Balaenella brachyrhynchus* is supported by one unambiguous synapomorphy (character 117: squared

830 anterior border of supraoccipital) and one ambiguous synapomorphy (character 118: short anterior
831 border of supraoccipital).

832

833 *Relationships of Eubalaena*

834 Confirming previously published hypotheses (Bisconti, 2000, 2005a; Churchill et al., 2012), our
835 analysis resulted in the monophyly of a clade including *Balaenula* and *Eubalaena* (Fig. 12). The
836 clade including *Eubalaena* and *Balaenula* is the sister-group to the *Balaena* + *Balaenella* clade.
837 *Balaenula* is the sister-group of *Eubalaena*. Three unambiguous and one ambiguous
838 synapomorphies support this clade. The unambiguous synapomorphies include characters 123
839 (transverse orientation of supraorbital process of the frontal in lateral view), 129 (curvature of
840 rostrum with horizontal proximal part), and 130 (concavity on the anterior border of nasal).
841 Character 118 (transversely wide anterior border of supraoccipital) was also found to support this
842 clade (ambiguous synapomorphy).

843 *Eubalaena shinshuensis* is the first *Eubalaena* species to branch; the *Eubalaena* sp. from the Late
844 Pliocene of Tuscany is the sister-group of the living *Eubalaena* species + *E. ianatrix* and its
845 inclusion on a separate ramus suggests that it could be a different *Eubalaena* species of its own.
846 *Eubalaena japonica* and *E. australis* branch before *E. ianatrix* and *E. glacialis*, the two latter being
847 sister-groups.

848 Only one unambiguous synapomorphy was found to support the monophyly of the right whale
849 genus *Eubalaena*; character 115 (presence of a dome on the supraoccipital). We think that this
850 reduced morphological support for the well-established *Eubalaena* genus is due to the fact that
851 most of the characters previously used to support its monophyly are shared with *Balaenula*.
852 *Eubalaena shinshuensis* from the Messinian of Japan was found to be the earliest-diverging right

853 whale species of the genus; the Pliocene *Eubalaena* sp. from Tuscany is the sister-group of the
854 living *Eubalaena* species + *E. ianatrix*. The monophyly of the *Eubalaena* sp. from Tuscany and
855 the crownward *Eubalaena* species was supported by one unambiguous synapomorphy (character
856 127: squared exoccipital in lateral view) and one ambiguous synapomorphy (character 126:
857 vertical orientation of squamosal body).

858 The clade including the living *Eubalaena* species and *E. ianatrix* is supported by 5 unambiguous
859 synapomorphies (125: parietal-frontal suture with distinctive anteroventral corner; 131: short
860 nasals; 133: parietal spreads on the supraorbital process of the frontal; 140: presence of vascular
861 groove on posterior part of pars cochlearis; and 141: evident pyramidal process posterior to
862 perilymphatic foramen) and 8 ambiguous synapomorphies (114: sagittal concavity on
863 supraoccipital; 134: anterior protrusion of parietal-squamosal suture; 135: prismatic posterior
864 process of petrosal; 138: transversely elongated pars cochlearis; 143: long transverse process of
865 the atlas; 146: highly concave anterior and posterior borders of humerus; 147: globular humeral
866 head; 150: superior corner of olecranon reduced-to-absent; and 151: reduced-to-absent coracoid
867 process in scapula) (Fig. 13).

868 *Eubalaena australis* was found to be more closely related to *E. ianatrix* + *E. glacialis* than *E.*
869 *japonica*. The sister-group relationship of *E. glacialis* with *E. ianatrix* + *E. glacialis* was supported
870 by two unambiguous synapomorphies: characters 139 (crista transversa exits from internal
871 acoustic meatus) and 152 (transverse orientation of thyrohyoid processes). It is noticeable that
872 none of these characters is preserved in the holotype of *E. ianatrix* and the placement of this species
873 in this precise position in the cladogram relies on ACCTRAN optimization of the morphological
874 transformations operated by TNT. The monophyly of the clade *Eubalaena ianatrix* + *E. glacialis*

875 is supported by a single ambiguous synapomorphy: character 121 (presence of pterygoid in
876 temporal fossa).

877

878 *Stratigraphic Consistency Index*

879 The calculation of the Stratigraphic Consistency Index shows that the degree of agreement of the
880 branching pattern with the stratigraphic occurrence of the taxa is exceptionally high. The SCI
881 depends on (1) the number of well-resolved nodes and (2) the number of stratigraphically
882 consistent nodes. In the hypothesis of phylogeny presented in this paper, the maximum number of
883 nodes is 40 (number of OTUs minus 2) and the number of stratigraphically consistent nodes is 33.
884 The SCI is thus 0.825.

885

886 *Divergence dates of balaenoid clades*

887 In Fig. 14 the hypothesis of phylogeny for Balaenoidea proposed in the present paper is plotted
888 against the stratigraphic age of the included OTUs. In the Figure, branch lengths are inferred from
889 the phylogenetic relationships of the taxa and from the stratigraphic ages of the representative
890 fossil record of each OTU.

891 The age of *Miocaperea pulchra* suggests that the origin of the clade including Balaenidae +
892 Neobalaenidae is older than Tortonian (early Late Miocene). Unfortunately, given that
893 *Morenocetus parvus* falls outside Neobalaenidae + Balaenidae, it is not possible to be sure about
894 the precise age of origin of these families. Indeed, as the stratigraphic occurrence of *M. parvus* is
895 limited to the Burdigalian (late Early Miocene), the age of origin of Neobalaenidae and Balaenidae
896 may be constrained to a time interval between Burdigalian and Tortonian.

897 The fossil record of *Balaena*-like species does not extend before Zanclean (Early Pliocene). The
898 stratigraphic occurrences of *Balena montalionis*, *B. ricei* and *Balaenella brachyrhynchus* suggest
899 that an expansion of the paleobiogeographic range of *Balaena*-like taxa was attained during the
900 earliest part of the Pliocene with invasion of Mediterranean, North Atlantic and North Sea. The
901 sister-group relationship of *Balaena mysticetus* and the other *Balaena*-like taxa suggest that the
902 direct ancestor of the living bowhead whale originated around the Zanclean or slightly earlier and
903 possibly quickly invaded the Arctic region, leaving us more limited possibilities to find fossil
904 records relevant for the morphological transition towards the extant species.

905 The stratigraphic age of *Eubalaena shinshuensis* is the most crucial point in the present
906 reconstruction of the divergence dates of balaenoid taxa. In fact, as the occurrence of this species
907 is from the Messinian, the origin of the whole *Balaenula* + *Eubalaena* clade must be traced back
908 to at least the latest Miocene. This means that the separation of the living right whales from their
909 closest living relative (i.e., *Balaena mysticetus*) is from 7-to-5.4 million years ago which
910 significantly increases the hypothesized divergence date based on McLeod et al. (1993) and
911 reduces to one-third of the hypothesized divergence date based on Bisconti (2005b) and Santangelo
912 et al. (2005). The impact of this new divergence date on the reconstruction of the demographic
913 history of the right whales based on genetic measures of diversity will be analysed elsewhere.

914 As far as the origins of the living *Eubalaena* species is concerned, the Messinian age of *E.*
915 *shinshuensis* suggests that the origin of the genus *Eubalaena* should be found at least in the latest
916 Miocene. The stratigraphic occurrences of the *Eubalaena* sp. from Tuscany and *E. ianatrix*
917 constrain the origin of the living right whale species to at least the Piacenzian. Therefore, we
918 estimate that the modern *Eubalaena* species originated in a period between 3.5 and 2.6 Ma. As we
919 will show in another paragraph, it is more difficult to determine a chronological placement for the

920 origin of the northern right whale *E. glacialis* because the origin of this species could be due to a
921 process of phyletic transformation from *E. ianatrix*, occurring in a time interval ranging from the
922 Piacenzian to the Pleistocene.

923 In summary, the stratigraphic distribution of the main evolutionary events of Balaenoidea are
924 presented in Fig. 13. Following our phylogenetic analysis and the computation of stratigraphic
925 ages of the included OTUs, the origin of Balaenoidea should be traced at least as far as the
926 Burdigalian (age of *Morenocetus parvus*). The origin of the living families (Neobalaenidae and
927 Balaenidae) occurred before the Tortonian (age of *Miocaperea pulchra*). The splitting between the
928 *Balaena*-like and the *Balaenula* + *Eubalaena* clades occurred before the Messinian (age of
929 *Eubalaena shinshuensis*). The origin of the modern *Eubalaena* radiation (including *E. ianatrix*)
930 dates at least from the Piacenzian. The separation between the living right whale species and their
931 extant relative (*Balaena*) dates at least from the earliest Messinian (*c.* 7 Ma).

932

933 **Discussion**

934

935 *Body size estimate*

936 The methods we used to estimate the size of *Eubalaena ianatrix* resulted in a total body length
937 included between 6 and 7 m and a body mass of *c.* 20 t. The statistical methods used have their
938 shortcomings in that most of them were not tested on species of the genus *Eubalaena*. The ratio
939 between skull length and body length is a general estimate of body proportions in Balaenidae used
940 by several authors based on observations of mounted skeletons, and killed and stranded animals
941 (Koshi et al., 1993; Tomilin, 1967; Omura, 1958). The ratio between supraoccipital length and
942 total skull length was used by Bisconti (2002) based on a small dataset of right whale

943 measurements and its correlation coefficient R^2 is rather low; therefore, the body size estimate
944 generated by this method must be considered as preliminary pending the inclusion of more
945 measurements in the dataset. However, all the methods used converge toward a total body length
946 of 6-to-7 m and we think that this result should be close to the true length of the living animal. At
947 present, we have no reason to suppose that a kind of systematic error occurred in a consistent
948 manner to provide a systematically wrong result based on all the methods used.

949 It is unclear whether this size represents the maximum length of *E. ianatrix* because nothing is
950 known about its individual variation. If compared with other balaenids, it represents a medium-
951 sized species (see Supplementary Table S2 and Supplementary Figure S1). More precisely, it is
952 the only medium-sized species within the *Eubalaena* clade (Supplementary Figure S2), suggesting
953 that its medium size is a derived condition. The origin of the size reduction in *E. ianatrix* may be
954 related to the warmer temperature of the southern portion of the North Sea during the deposition
955 of the Lillo Formation (latest Zanclean-early Piacenzian; Laga et al. 2006). In fact, the Kruisschans
956 Sands Member of the Lillo Formation (in which the holotype skull of *E. ianatrix* was found)
957 deposited in a shallow, low-energy environment, where molluscs indicate some degree of cooling,
958 but where the palynological assemblage suggests mild-temperate to warm marine conditions
959 (Marquet, 1993; Louwye et al., 2004; De Schepper et al., 2009). However, it is still unknown
960 whether *E. ianatrix* inhabited permanently the southern North Sea.

961 In the extant *Eubalaena glacialis* and *E. australis*, a total body length of less than 7 m corresponds
962 to the length of individuals less than one year old (George et al. 2016; Fortune et al. 2012). The
963 holotype skull of *Eubalaena ianatrix*, however, shows sutural morphologies and general robustness
964 inconsistent with the general osteological features of newborn and early juvenile individuals (e.g.,
965 occipital joints not closed, presence of spongy bone; see Walsh & Berta, 2011). Rather, its robust

966 muscular attachments on the supraoccipital and the degree of fusion at the frontoparietal (coronal)
967 and parietal-squamosal sutures suggests that its age was older than 1 year. It is impossible to assess
968 at which stage of its life cycle it died as nothing is known about intraspecific variation in skull and
969 body length in *E. ianatrix*. Future discoveries of new specimens from different age classes will help
970 providing an overview of the ontogenetic variation in body size in this newly discovered species.
971 The estimate of the body mass obtained in the present work is at odds with published records
972 regarding the relationships of body mass and total body length in extant Balaenidae. Fortune et al.
973 (2012) reported weights ranging from 0.7 to 11 t for 6-9 m long bowhead whales, while Trites &
974 Pauli (1998) estimated masses ranging from 19 to 24 t for 16-18 m long northern and southern
975 right whales. Our result of *c.* 20 for the 6-7 m long *Eubalaena ianatrix* appears overestimated,
976 suggesting that more research is needed to develop more accurate statistical methods for inferring
977 body size and body mass information in Balaenidae.

978

979 *Phylogeny: Relationships of Balaenidae*

980 Phylogenetic analyses of Balaenidae were published by several authors in the last 25 years.
981 McLeod et al. (1993) were the first to publish a phylogenetic tree based on manual manipulation
982 of morphological character states. They found a monophyletic Balaenoidea and a sister group
983 relationship between Neobalaenidae and a clade formed by Balaenidae and Eschrichtiidae. The
984 sister-group relationship of Balaenidae and Eschrichtiidae was not confirmed by subsequent
985 phylogenetic works.

986 Bisconti (2000) performed the first computer-assisted cladistic analysis of Balaenidae, retrieving
987 a monophyletic Balaenoidea and a monophyletic Balaenidae. Within Balaenidae, Bisconti (2000)
988 found two different clades: one including the genus *Balaena* and the other including *Eubalaena*,

989 *Balaenula* and *Morenocetus*. After a substantial re-discussion of the fossil record of Balaenidae
990 (Bisconti, 2003) and of previously published phylogenetic analyses, Bisconti (2005a) published a
991 new phylogenetic analysis resulting in a monophyletic Balaenoidea and a monophyletic
992 Balaenidae; two clades were recovered in Balaenidae: one included *Morenocetus*, *Balaenella* and
993 *Balaena* and the other included *Eubalaena* and *Balaenula*. These finds were substantially
994 confirmed by Churchill et al. (2012) after an extensive reanalysis of the morphological evidence
995 of the phylogeny of Balaenidae.

996 Numerous other works on the phylogeny of mysticetes were published in the last decades that
997 included balaenids, but not explicitly focused on Balaenidae. However, it is important to consider
998 these works as they provide information about the sister-group relationships of Balaenidae and
999 other mysticete taxa. While most of the morphology-based works agree that Balaenidae and
1000 Neobalaenidae are sister-groups (Bisconti, 2015 and literature therein; Boessenecker & Fordyce,
1001 2016), several recent papers did not support the monophyly of Balaenoidea with Neobalaenidae as
1002 sister group of Balaenopteroidea (see Gol'din et al., 2014 and literature therein) or as part of
1003 Cetotheriidae (e.g., Marx & Fordyce, 2015 and literature therein). The placement of *Caperea*
1004 *marginata* and *Miocaperea pulchra* within Cetotheriidae depended upon peculiar treatments of
1005 some characters related to the shape and orientation of the squamosal, the elongation of the
1006 supraoccipital and the reduction of the ascending process of the maxilla. Criticisms to this
1007 approach were published by El Adli et al. (2014) and Bisconti (2015) suggesting that the Marx &
1008 Fordyce (2015) dataset should be revised. Marx & Fordyce (2016) provided a subsequent version
1009 of such a dataset that shows substantially the same characteristics, as it does not include character
1010 states describing the topological relationships of the bones forming the skull vault in Balaenidae
1011 and Neobalaenidae. The proposed sister-group relationship of Neobalaenidae and

1012 Balaenopteroidea + Cetotheriidae depends on (1) inclusion of molecular data or (2) emphasis on
1013rorqual-like characters observed in *Caperea marginata* (i.e., long forelimb, presence of dorsal fin,
1014and presence of ventral throat grooves).

1015 The problem of using molecular data to infer the phylogenetic relationships of clades mainly
1016formed by fossil taxa (e.g., *Hominidae*, *Mysticeti*) has been addressed by several authors and this
1017is the precise case of mysticetes where most of the described species are now extinct and cannot
1018be used for DNA sequencing and analysis. Even if molecular analyses may include thousands of
1019character states (base pairs from DNA sequences), the lack of data from most of the taxa belonging
1020into the clade may be a serious problem as an enormous number of character states cannot be
1021scored and must be inferred by the computer program used for the analysis. The accuracy of
1022phylogenetic reconstructions based on molecular data for clades mainly formed by extinct taxa
1023tends to be lower than that based on morphological data (Heath et al., 2008; Wagner, 2000). This
1024suggests that emphasis should be given to morphological rather than molecular data in the
1025inference of the phylogeny of mysticetes.

1026 Aside from that, it must be said that taxonomic uncertainties, problems with character descriptions
1027and coding, and the discovery of large amounts of homoplasy in morphological datasets have
1028plagued morphological attempts to infer phylogenetic relationships in mysticetes in the last twenty
1029years (Deméré et al., 2005; Bisconti, 2007). Our effort to reduce dataset homoplasy was successful
1030only in part. In fact, after the exclusion of evident homoplastic characters from our morphological
1031dataset, the number of usable character states dropped down and our morphological evidence could
1032provide only strong support for only some clades. Most of the species-level sister group
1033relationships are thus supported by reduced numbers of synapomorphies. In this sense, what we
1034observe in balaenid phylogenetics resembles what was observed in complicated analyses of

1035 evolutionary radiations occurring in relatively recent times (e.g., cichlid fishes and hominins; e.g.,
1036 Seehausen, 2006; Haile-Selassie et al., 2016) with the important difference that the evolutionary
1037 radiation of Balaenidae occurred in a longer time interval. However, studies of DNA substitution
1038 rates interestingly showed that mysticete DNA evolves much more slowly than that of other
1039 mammals (Rooney et al., 2001); therefore, only limited morphological change should be expected
1040 to occur in this group in the last few million years. This expectation is somewhat confirmed by the
1041 substantial stasis detected in the last 10 million years of neobalaenid evolution (Tsai & Fordyce,
1042 2015; Bisconti, 2012) and by the small amount of morphological diversity observed in Balaenidae
1043 as discussed in this work. The reasons of the slow evolutionary pace in Balaenidae are not
1044 completely understood; one character that could be correlated is the evolution of increased
1045 individual longevity, demonstrated to be linked to DNA preservation (Jackson et al., 2009; Keane
1046 et al., 2015), which, in its turn, should reduce the accumulation of mutations preventing the
1047 evolution of phenotypic diversity.

1048

1049 *Phylogeny: intra-family relationships within Balaenidae*

1050 Published studies specifically directed at discovering phylogenetic relationships of Balaenidae
1051 recently converged towards the subdivision of this family into two sub-clades: a clade including
1052 *Balaena* and *Balaenella* and a clade including *Balaenula* and *Eubalaena*. These two groups are
1053 well supported by morphological characters and correspond to two different skull structures (as
1054 evidenced by Miller, 1923; Kellogg, 1928; McLeod et al., 1993; Bisconti, 2005a).

1055 The contribution of the postcranial skeleton to the support for these clades is rather scanty but, for
1056 the first time, we detected that: (1) the dorsal transverse process of the atlas is dorsoventrally
1057 enlarged in *Eubalaena* and reduced in *Balaena* (including *B. mysticetus* and *B. ricei*), (2) the

1058 ventral transverse process of the atlas is long and forms a ventral corner in *Balaena* but is short
1059 and squared in *Eubalaena*, (3) the humerus is long and slender in *Balaena* while in *Eubalaena* it
1060 is shorter and with a more globular head, and (4) the dorsal corner of the olecranon process of the
1061 ulna is conspicuous in *Balaena* but reduced to absent in *Eubalaena*.

1062 The four characters outlined above could be useful to suggest phylogenetic and taxonomic
1063 affinities of fossils of uncertain position because of their poor preservation. This is the case of a
1064 number of partial skeletons from the Pliocene of Italy (Bisconti, 2003; Chicchi & Bisconti, 2014;
1065 Cioppi, 2014; Bisconti & Francou, 2014; Manganelli & Benocci, 2014; Sarti & Lanzetti, 2014)
1066 that should be reassessed based on this new evidence.

1067 As mentioned above, the sister-group relationship of *Balaena montalionis* and *Balaenella*
1068 *brachyrhynchus* raises particular problems as the inclusion of *Balaenella* within *Balaena* would
1069 either make the latter paraphyletic, or would imply the assignment of *Balaenella* to *Balaena*.
1070 However, we feel that it is premature to choose one of the above options, as some morphological
1071 data from *Balaena ricei* were not available for this study (i.e., precise sutural pattern between
1072 parietal and frontal and between parietal and squamosal, and shape of the anterior end of the
1073 supraoccipital); this makes relationships within the *Balaena*-like subclade still biased by some
1074 uncertainty. However, the close relationship of *B. montalionis* and *B.lla brachyrhynchus* seems well
1075 supported by the shared squared anterior border of the supraoccipital and the transverse
1076 compression observed in the anterior half of the lateral borders of the supraoccipital. The point,
1077 here, consists in understanding if *Balaena ricei* is more closely related to *Balaena mysticetus* or to
1078 the *B. montalionis* + *B.lla brachyrhynchus* pair; more data are needed about the morphology of *B.*
1079 *ricei* to solve this question.

1080 Among right whales, *Eubalaena shinshuensis* is the first to branch off, due to the primitive sutural
1081 pattern observed in the skull of this Messinian species; the following branch is occupied by the
1082 Piacenzian *Eubalaena* sp. from Tuscany, due to the plesiomorphic parietal-squamosal suture and
1083 to a peculiar supraoccipital morphology. More interesting are the relationships of the living
1084 *Eubalaena* species and *E. ianatrix*. From our work, *E. japonica* is the earliest-diverging species
1085 among the living right whales, with *E. australis* and *E. glacialis* more closely related to each other.
1086 This result contradicts molecular studies that suggested that *E. australis* diverged earlier and that
1087 *E. glacialis* and *E. japonica* are sister-groups (e.g., Gaines et al., 2005; Rosenbaum et al., 2000).
1088 Also the DNA-based phylogeny of species of lice parasitizing living *Eubalaena* species lends
1089 support to the molecular hypothesis of relationships for right whales (e.g., Kaliszewska et al.,
1090 2005) thus suggesting that *E. glacialis* is the earliest-diverging *Eubalaena* species. However, these
1091 analyses did not include data from fossil right whales such as *E. shinshuensis*, *E. ianatrix*, and the
1092 *Eubalaena* sp. from Tuscany and did not take into account the fossil histories of the different lice
1093 species; therefore, they could be unable to retrieve correct results (in accordance with Heath et al.,
1094 2008; Wagner, 2000). Moreover, assuming an early branching of *E. glacialis* in the phylogeny of
1095 the living right whales implies that reticulate biogeographic histories have occurred between the
1096 southern and the North Pacific *Eubalaena* species to account for the peculiar genetic patterns
1097 observed in cyamid lice (Kaliszewska et al., 2005).

1098

1099 *Divergences of the living right whale species*

1100 Divergence ages of living balaenid species are important for the reconstructions of the
1101 demographic histories of these taxa in the context of conservation biology. Divergence dates are
1102 used in equations dealing with the genetic diversity of the living populations to assess whether

1103 living species suffered of genetic bottlenecks due to environmental change or human impact (e.g.,
1104 Rosenbaum et al., 2001). Fossil calibrations of divergence dates are necessary to constrain the pace
1105 of molecular clocks in order to get correct results in terms of assessments of genetic diversity and
1106 evolution (Quental & Marshall, 2010).

1107 Several works have provided estimates of divergence ages of balaenid species. McLeod et al.
1108 (1993) suggested a separation date between *Eubalaena* and *Balaena* of *c.* 4.5 Ma based on analysis
1109 of the balaenid fossil record. This assessment was used by Rosenbaum et al. (2001) to analyse the
1110 genetic diversity of the living bowhead whale, *Balaena mysticetus*, with the conclusion that this
1111 species did not suffer of population bottlenecks due to human whaling activities. Bisconti (2005b)
1112 and Santangelo et al. (2005) questioned this conclusion based on the phylogenetic analysis
1113 provided by Bisconti (2005a); the latter opened the possibility that the divergence between
1114 *Eubalaena* and *Balaena* occurred in the Early Miocene. This conclusion resulted from the
1115 placement of *Morenocetus parvus* as sister-group of the *Balaena*-like subclade to the exclusion of
1116 the *Balaenula* + *Eubalaena* subclade (Bisconti 2005a) thus providing a divergence date of *Balaena*
1117 and *Eubalaena* of more than 20 Ma.

1118 Subsequent analyses did not confirm this result as molecule-based and morphology-based works
1119 suggested later divergence dates (e.g., Sasaki et al., 2007; Churchill et al., 2012) and placed the
1120 divergence of *Balaena* and *Eubalaena* in a time interval ranging from *c.* 4 to *c.* 7 Ma. The
1121 phylogenetic analysis of *Cyamus* lice confirms a divergence at *c.* 6.6 Ma for the living right whale
1122 and bowhead whale species (Kaliszewska et al., 2005).

1123 The phylogenetic analysis of the present work (Figs 12 and 14) reinforces a minimum late Miocene
1124 divergence (Messinian: *c.* 7-5.4 Ma) based on the age of the earliest diverging *Eubalaena* species
1125 (i.e., *E. shinshuensis*). In fact, an earlier divergence age is not unlikely, considering that (1) based

1126 on the present work, the separation between Balaenidae and Neobalaenidae dates from at least the
1127 Tortonian (c. 10 Ma) and (2) the separation of the *Balaena*-like subclade from the *Balaenula* +
1128 *Eubalaena* subclade is deep in time and originates from the very origin of Balaenidae (Bisconti,
1129 2005a; Churchill et al., 2012; this work).

1130 How the reconstructions of the demographic histories of balaenids will be impacted by a Late
1131 Miocene age of divergence between *Eubalaena* and *Balaena* is outside the scope of the present
1132 paper. However, we suggest here that the past estimates of genetic diversity in right and bowhead
1133 whale populations should be considered with caution as those were based on underestimated
1134 (McLeod et al., 1993) or overestimated (Bisconti, 2005b; Santangelo et al., 2005) divergence ages.

1135

1136 *Possible ancestor-descendant relationships between Eubalaena ianatrix and Eubalaena glacialis*

1137 There is not a commonly accepted method to infer ancestor-descendant relationships (ADRs) in
1138 phylogenetics as it is supposed that only in exceptional cases such a relationship can be detected
1139 in the fossil record (Paul, 1992). The most usual recommendation to those who try to recover ADR
1140 from the fossil record consists in being sure that a reasonably complete sample is available for the
1141 past diversity of the investigated group. While it is certain that this is not the case for fossil
1142 cetaceans, some attempts to reconstruct ADRs in this order were attempted in the past with a
1143 diversified array of methods.

1144 Uhen & Gingerich (2001) provided an ADR for *Chrysocetus healyorum* and Neoceti (Mysticeti +
1145 Odontoceti). They used a stratocladistic approach in three steps: (1) they performed a traditional
1146 computer-assisted, morphology-based cladistics analysis retrieving a set of resulting cladograms;
1147 (2) they added a stratigraphic character and manipulated the initial hypothesis of relationships by
1148 hand in order to explore whether *C. healyorum* could be the direct ancestor of Neoceti; (3) they
1149 calculated a new set of cladograms via a computer-assisted algorithm. They found one most

1150 parsimonious tree in which *C. healyorum* was placed as direct ancestor of Neoceti. In the
1151 subsequent discussion, they suggested that newly discovered advanced [archaeocete](#) taxa could fit
1152 the ancestor position for Neoceti in a better way than *C. healyorum* thus giving this taxon a
1153 temporary ancestor status.

1154 More recently, Tsai & Fordyce (2015) suggested an ADR for *Miocaperea pulchra* and *Caperea*
1155 *marginata* based on a combination of cladistic analysis of traditional OTUs + juvenile individuals
1156 of *C. marginata* and by providing a discussion on the impact of the morphology of juvenile
1157 characters in phylogeny reconstruction. [Apart from cetaceans, ADR were also hypothesized for](#)
1158 [the fur seal *Callorhinus* \(Boessenecker 2011\), great white sharks \(Ehret et al. 2012\), and the](#)
1159 [dinosaur *Triceratops* \(Scannella et al. 2014\)](#)

1160 All of these methods have their own merits and [shortcomings](#); Uhen & Gingerich (2001) realized
1161 a systematized search for the most parsimonious solutions but their results were [limited](#) by
1162 uncertainties about the completeness of the relevant fossil record; Tsai & Fordyce (2015) used data
1163 from a hotly debated source of data (i.e., juvenile and embryonic specimens) (e.g., Hall, 1996 and
1164 literature therein). Apart from that, however, the search for ADRs is always worth doing, as it
1165 potentially gives information on natural evolutionary processes.

1166 Here, we suggest that an ADR should be proposed for the *Eubalaena ianatrix* and *Eubalaena*
1167 *glacialis* species pair. We support our hypothesis of relationships based on what follows:

1168 (1) *E. glacialis* and *E. ianatrix* are phylogenetically more closely related than all the other
1169 species belonging to *Eubalaena*; they share one peculiar synapomorphy that is not
1170 observed in any other *Eubalaena* species (i.e., presence of the pterygoid in the temporal
1171 fossa).

- 1172 (2) Molecular studies suggest that the branch of *E. glacialis* has been separated from the other
1173 living right whale species for a long time (up to 3 million years). This long time interval
1174 excludes the possibility of an arrival in the North Atlantic due to a [Pleistocene or Holocene](#)
1175 invasion from the North Pacific or the southern right whale species (Kaliszewska et al.,
1176 2005). Thus, it is highly likely that *E. glacialis* originated in that portion of the northern
1177 hemisphere that includes the North Atlantic and the North Sea.
- 1178 (3) *E. glacialis* and *E. ianatrix* share part of their geographic distribution. Even if only one
1179 specimen of *E. ianatrix* is known up to now, its geographic occurrence is included within
1180 the geographic range of *E. glacialis*.
- 1181 (4) The geographic area that encompasses the distribution of *E. ianatrix* and *E. glacialis*
1182 underwent extensive environmental change during the past 1.5 million years (Zachos et al.,
1183 2001), supporting the hypothesis that selective regimes could have been active there
1184 implying phenotypic evolution in previously established populations. In particular, the
1185 temperature decline observed in the whole northern hemisphere during the Pleistocene
1186 could have been the driver of organismal responses that can be described (in part, at least)
1187 by the Bergmann's rule (i.e., increasing body size).
- 1188 (5) Assuming a species longevity of 2 million years (Fordyce & de Muizon, 2001; Steeman et
1189 al., 2009), and hypothesizing that *Eubalaena glacialis* became a well-defined species
1190 around the Pliocene-Pleistocene boundary, there may be a time interval in which *E. ianatrix*
1191 and the earliest individuals of *E. glacialis* co-occurred in the same area where the
1192 morphological transition happened. [Unfortunately, the estimated species longevity](#)
1193 [mentioned above is only based on the observation that the fossil record of the living](#)
1194 [mysticete species does not exceed c. 2 million years \(Fordyce, 2002\). Based on molecular](#)

1195 data, alternative analyses suggest longer species durations (see Pastene et al. 2007 for
1196 *Balaenoptera acutorostrata* and Sasaki et al. 2005 for many species of baleen-bearing
1197 whales; these studies suggest divergence dates of some living species exceeding 2 million
1198 years). This does not contradict our proposed sympatry hypothesis for *E. glacialis* and *E.*
1199 *ianitrix*; rather, hypothesizing longer species duration would reinforce this hypothesis. To
1200 our knowledge, no molecule-based work supports a species duration shorter than 2 million
1201 years for extant baleen-bearing whales.

1202 (6) Bearing in mind the paleoenvironmental changes that occurred in the northern hemisphere
1203 from the earliest Pleistocene (*c.* 2.6 Ma) through most of [that](#) epoch, a transformation of a
1204 previously established population of right whale into a more [ecologically](#)-optimized
1205 species is a reasonable hypothesis.

1206 (7) From a skeletal morphology perspective, if a phyletic transformation of *E. ianitrix* into *E.*
1207 *glacialis* occurred, then it involved: (i) massive size increase at adulthood enabling the
1208 extant *E. glacialis* to reach more than 20 m in length at maturity (Tomilin, 1967) against
1209 the *c.* 7 m of *E. ianitrix* (consistent with Bergmann's rule in a colder environment), (ii)
1210 possible allometric adjustments of bone proportions (this is a direct consequence of point
1211 1), (iii) loss of the crest at the parietal-squamosal-supraoccipital suture, and (iv) change in
1212 the orientation of the posteromedial corner of the palatine. The crest at parietal-squamosal-
1213 supraoccipital suture appears to have been lost in the common ancestor of *E. glacialis* + *E.*
1214 *ianitrix* + *E. japonica* + *E. australis* clade and its presence in *E. ianitrix* is to be interpreted
1215 as a reversal to a plesiomorphic condition. The same applies to the protrusion of the
1216 posteromedial corner of the palatine. The recurrent evolution of these two characters
1217 suggests that some homoplasy occurred in the above clade in the last few million years.

1218 (8) Current genetic evidence supports the view that three distinct species of right whales
1219 inhabit three different ocean basins (Malik et al., 2000; Rosenbaum et al., 2001):
1220 *Eubalaena glacialis* in the North Atlantic and adjacent waters, *E. japonica* in the North
1221 Pacific, and *E. australis* in the Southern Ocean. Balaenoid whales perform a particular
1222 feeding behavior directed at capturing calanoid copepods; this feeding behavior is known
1223 as continuous ram feeding (Sanderson & Wassersug, 1993) or skim feeding (Pivorunas,
1224 1979). In the northern hemisphere, there is a geographic separation between the skim
1225 feeding species: the bowhead whale inhabits Arctic waters, while the right whales inhabit
1226 more temperate waters and the two right whale species of the northern hemisphere are
1227 separated by the Eurasia and thus do not compete for food or reproductive areas. In the
1228 southern hemisphere, the two skim feeding species are geographically separated as the
1229 southern right whale feeds around Antarctica while the pygmy right whale is restricted to
1230 more temperate waters; apparently, there is no competition between these species for food
1231 or reproductive areas. It appears, thus, that only one skim feeding species is “allowed” to
1232 live in a given ocean basin, and we may hypothesize that the pattern was not different in
1233 the past million years. For this reason, we may expect that only one or a few right whale
1234 species occupied a given geographic area in time intervals of *c.* 2 million years (mean
1235 duration of a marine mammal species; see above). This suggests that, paradoxically, the
1236 taxonomic sample of the right whale diversity in the Late Pliocene of the northern
1237 hemisphere is rather complete. This inference is also confirmed by the high value of the
1238 SCI obtained here, suggesting that most of the phylogenetic relationships presented here
1239 can be explained without the need for long ghost lineages. This inference fills the requests
1240 for a dense taxonomic sampling in the taxa under investigation and allows us to give further

1241 support to our hypothesis of ADR for *Eubalaena ianatrix* and *E. glacialis*. It must be said,
1242 however, that the current diversity of right and bowhead whales includes only large-sized
1243 species, whereas, in the Pliocene, large-sized and small-sized balaenid species are
1244 demonstrated to have been sympatric (Bisconti, 2003). Moreover, several studies have
1245 addressed the impact of shark predation on Pliocene right whales, suggesting some
1246 differences in the trophic webs of the Pliocene oceanic basins with respect to modern times.
1247 The ecological meanings of these differences are still not fully understood, potentially
1248 impacting our hypothesis regarding the taxonomic completeness of the balaenid fossil
1249 record.

1250 (9) In a way to test the ADR for *Eubalaena ianatrix* and *E. glacialis*, we followed the
1251 stratocladistic approach of Uhen & Gingerich (2001). The taxon x character matrix and the
1252 single most parsimonious tree were taken to MacClade (Maddison & Maddison, 2000).
1253 First, without the addition of a stratigraphic character, the ADR for *E. ianatrix* and *E.*
1254 *glacialis* was demonstrated to increase the tree length of two steps, as compared to the
1255 original tree length with a sister-group relationship. After addition of the stratigraphic
1256 character (see Supplementary Information) and without any other modification of the
1257 topology, the difference in tree length decreased from two steps to one step, meaning that
1258 the sister-group relationship was still the most parsimonious, but that stratigraphic data,
1259 namely the Piacenzian age of *E. ianatrix*, made the difference less significant. Swapping
1260 branches by hand, ADR for *E. ianatrix* and *E. glacialis* was found more parsimonious than
1261 a sister-group relationship only with (i) *E. shinshuensis* being more stemward than
1262 *Balaenula astensis*, and (ii) the three extant *Eubalaena* species forming a clade, with *E.*
1263 *ianatrix* as their last common ancestor. The need for such changes in topology may indicate

1264 that *E. ianitrix* is not the ancestor of *E. glacialis*. However, we think that such a pattern is
1265 strongly impacted by the scanty Pliocene balaenid fossil record in some areas (for example
1266 the North Pacific and the Southern Ocean). Pending the future discovery of fossil relatives
1267 of *E. australis* and *E. japonica*, stratocladistic analyses will most likely not be able to
1268 unambiguously discriminate ADR and sister-group relationships for *E. ianitrix* and *E.*
1269 *glacialis*.

1270

1271 **Conclusions**

1272

1273 We re-described specimens previously referred to '*Balaena*' *belgica* and found what follows.

1274 (1) The cervical complex RBINS M. 881 (IG 8444) that was originally designated as type of
1275 '*Balaena belgica* by Abel (1941) is poorly preserved and does not show diagnostic
1276 characters below the family level; therefore, we assign it to Balaenidae gen. et sp. indet.;
1277 this decision makes '*Balaena*' *belgica*, and its recombination nomina dubia.

1278 (2) The fragment of maxilla RBINS M. 880 lacks crucial diagnostic characters and cannot be
1279 assigned to any of the described balaenid genera and species; it is therefore assigned to
1280 Balaenidae gen. et sp. indet.

1281 (3) The morphology of the humerus RBINS M. 2280 is closer to that of *Eubalaena glacialis*
1282 as compared to *Balaena mysticetus* in the shape of the articular facet for the olecranon
1283 process of the ulna, in the overall shape of the deltoid tuberosity, and in the shape of the
1284 posterior border of the diaphysis. However, it differs from *E. glacialis* and other extant
1285 *Eubalaena* species in the elongation of the straight posterior border of the diaphysis; it is
1286 therefore assigned to *Eubalaena* sp. indet. This humerus corresponds to a large individual

1287 reaching a total body length over 16.5 m; it represents the first report of a gigantic right
1288 whale in the fossil record of the North Sea.

1289 (4) The neurocranium RBINS M. 879a-f represents the holotype of the new species *Eubalaena*
1290 *ianitrix*. This species is described and analysed into a phylogenetic context. From a
1291 morphological viewpoint, *E. ianitrix* is very close to the northern right whale *E. glacialis*
1292 in having the same sutural pattern in the skull vault and in sharing the presence of pterygoid
1293 in the temporal fossa. From a phylogenetic view, *E. ianitrix* is the sister-group of *E.*
1294 *glacialis*.

1295 (5) Our phylogenetic analysis also retrieved a monophyletic Balaenoidea, with *Morenocetus*
1296 *parvus* as the earliest stem balaenoid taxon, and with Neobalaenidae being the sister-group
1297 of Balaenidae. Two clades are observed within Balaenidae: one including *Balaena*-like
1298 taxa (genera *Balaena* and *Balaenella*) and the other including *Balaenula* and *Eubalaena*.
1299 The Messinian *E. shinshuensis* is the earliest diverging *Eubalaena* species; the *Eubalaena*
1300 sp. from Tuscany is the sister-group of a clade including all the living *Eubalaena* species
1301 and *E. ianitrix*.

1302 (6) The separation of *Eubalaena* from *Balaena* is estimated to have occurred around 7 Ma
1303 (minimum age). The origins of the living right whale species should be chronologically
1304 constrained to the Piacenzian (Late Pliocene: at least between 3.6 and 2.6 ma). Judging
1305 from supporting synapomorphies, stratigraphic ranges and ecological requirements, it is
1306 suggested that *Eubalaena ianitrix* is the direct ancestor of *E. glacialis*, the latter is proposed
1307 to have evolved via phyletic transformation, through body size increase and allometric
1308 adjustments during the temperature decline of the latest Pliocene and Pleistocene.

1309

1310 *Acknowledgments*

1311 The authors wish to thank Annelise Folie, Alain Drèze and Cécilia Cousin (all at RBINS, Brussels)
1312 for providing access to the specimens and for assisting in the transport of these heavy bones;
1313 Stéphane Berton and Marc Spolspoel (both at RBINS, Brussels) for their help when restoring the
1314 specimens studied here and when taking photos of part of the specimens illustrated here,
1315 respectively. Many thanks are due to Richard Monk, Eric Brothers, Eileen Westwig, Maria
1316 Dickson, and Nancy Simmons (all at AMNH, New York), Graham and Margaret Avery and
1317 Leonard Compagno (all at IZIKO, Cape Town), Reinier Van Zelst, John De Vos, Steven Van Der
1318 Mije and Wendy Van Bohemen (all at Naturalis, Rotterdam) for granting access to specimens
1319 under their care. Many thanks are due to Mark D. Uhen (George Mason University, Fairfax),
1320 Robert W. Boessenecker (College of Charleston) and J.G.M. Thewissen (PeerJ editor) for their
1321 reviews that highly enhanced the quality and the clarity of the manuscript.

1612 CAPTIONS TO TEXT-FIGURES AND TABLES

1613

1614 **Figure 1**

1615 Localities of the balaenids described in this paper. A, Localization of Antwerp in Belgium and its
1616 relationships with the North Sea. Grey whading represents marine Pliocene deposits. B, Detailed
1617 map of the Antwerp harbor showing the first Kruisschans lock, where the holotype of *Eubalaena*
1618 *ianitrix* sp. nov. (RBINS M. 879a-f) and the fragment of maxilla RBINS M. 880 were found. The
1619 cervical vertebrae RBINS M. 881 were discovered in the “Darses I-II” in Oorderen. Modified from
1620 De Schepper et al., 2009.

1621

1622 **Figure 2**

1623 Lithological units from the Pliocene of the Antwerp area. Formations, members and their ages are
1624 provided, including the Kruisschans Sands Member of the Lillo Formation in the Piacenzian (Late
1625 Pliocene), where the neurocranium RBINS M. 879, holotype of *Eubalaena ianitrix* sp. nov., was
1626 discovered. Positions along the local lithostratigraphic column of other balaenid specimens from
1627 the Antwerp area investigated in this work are also provided: right maxilla RBINS M. 880,
1628 Balaenidae gen. et sp. indet.; cervical complex RBINS M. 881, Balaenidae gen. et sp. indet.; left
1629 humerus RBINS M. 2280, *Eubalaena* sp. Modified from De Schepper et al., 2009.

1630

1631 **Figure 3**

1632 The cervical vertebrae RBINS M. 881 representing the cotype of ‘*Balaena*’ *belgica* by Abel (1941)
1633 and reassigned to Balaenidae gen. et sp. indet. in this work. A, anterior view. B, left lateral view.
1634 C, posterior view. D, right lateral view. E, ventral view. F, dorsal view. Scale bar equals 10 cm.

1635

1636

1637

1638 **Figure 4**

1639 The fragment of right maxilla RBINS M. 880 assigned to Balaenidae gen. et sp. indet. in this work.

1640 A, dorsolateral view. B, dorsomedial view. C, ventromedial view. Scale bar equals 30 cm.

1641

1642 **Figure 5**

1643 The left humerus RBINS M. 2280 assigned to *Eubalaena* sp. in this work. A, lateral view. B,

1644 anterior view. C, distal view of articular facets for radius and ulna. D, proximal view of articular

1645 head for scapula. E, posterior view. F, medial view. Scale bars equal 10 cm.

1646

1647 **Figure 6**

1648 *Eubalaena ianatrix* sp. nov. (holotype RBINS M. 879). Dorsal view of neurocranium. A,

1649 photographic representation. B, interpretation. Scale bar equals 50 cm. Anatomical abbreviations:

1650 fm, foramen magnum; fr, frontal; irfr, interorbital region of the frontal; oc, occipital condyles; smc,

1651 supramastoid crest; sq, squamosal; sop, supraorbital process of the frontal.

1652

1653 **Figure 7**

1654 *Eubalaena ianatrix* sp. nov. (holotype RBINS M. 879). Left lateral view of neurocranium. A,

1655 photographic representation. B, interpretation. Scale bar equals 50 cm. Anatomical abbreviations:

1656 fm, foramen magnum; fr, frontal; irfr, interorbital region of the frontal; oc, occipital condyle; orb,

1657 orbit; otc, orbitotemporal crest; par, parietal; pgl, postglenoid process of squamosal; p-fr, parietal-

1658 frontal suture; p-sq, parietal-squamosal suture; smc, supramastoid crest; soc, supraoccipital; sop,
1659 supraorbital process of frontal; sq, squamosal; vom, vomer; zyg, zygomatic process of squamosal;
1660 *, anterolateral corner of parietal-frontal suture.

1661

1662

1663

1664 **Figure 8**

1665 *Eubalaena ianatrix* sp. nov. (holotype RBINS M. 879). Right lateral view of neurocranium. A,
1666 photographic representation. B, interpretation. Scale bar equals 50 cm. Anatomical abbreviations:
1667 fm, foramen magnum; fr, frontal; irfr, interorbital region of the frontal; oc, occipital condyle; orb,
1668 orbit; otc, orbitotemporal crest; par, parietal; pgl, postglenoid process of squamosal; p-fr, parietal-
1669 frontal suture; p-sq, parietal-squamosal suture; smc, supramastoid crest; soc, supraoccipital; sop,
1670 supraorbital process of frontal; sq, squamosal; vom, vomer; zyg, zygomatic process of squamosal;
1671 *, anterolateral corner of parietal-frontal suture.

1672

1673 **Figure 9**

1674 *Eubalaena ianatrix* sp. nov. (holotype RBINS M. 879). Anterior view of neurocranium. A,
1675 photographic representation. B, interpretation. Scale bar equals 50 cm. Anatomical abbreviations:
1676 fr, frontal; irfr, interorbital region of the frontal; max-fr, grooves for articulation of maxilla and
1677 frontal; mes, mesethmoid; nas-fr, groove for articulation of nasal and frontal; pal, palatine; par,
1678 parietal; pgl, postglenoid process of squamosal; pm-fr, grooves for articulation of premaxilla and
1679 frontal; soc, supraoccipital; sop, supraorbital process of frontal; sq, squamosal; vom, vomer; zyg,
1680 zygomatic process of squamosal.

1681

1682 **Figure 10.**

1683 *Eubalaena ianatrix* sp. nov. (holotype RBINS M. 879). Ventral view of neurocranium. A,
1684 photographic representation. B, interpretation. Scale bar equals 50 cm. Anatomical abbreviations:
1685 exo, exoccipital; fm, foramen magnum; fr, frontal; sop, supraorbital process of frontal; oc, occipital
1686 condyle; och, optic channel; or, orbit; pgl, postglenoid process of squamosal; pt, pterygoid; sq,
1687 squamosal; vom, vomer; zyg, zygomatic process of squamosal.

1688

1689

1690 **Figure 11**

1691 *Eubalaena ianatrix* sp. nov. (holotype RBINS M. 879). Posterior view of neurocranium. A,
1692 photographic representation. B, interpretation. Scale bar equals 50 cm. Anatomical abbreviations:
1693 boc, basioccipital; bop, basioccipital protuberance; exo, exoccipital; fm, foramen magnum; fr,
1694 frontal; jn, jugular notch; oc, occipital condyle; pal, palatine; pgl, postglenoid process of
1695 squamosal; pt, pterygoid; ptf, pterygoid fossa; sop, supraorbital process of frontal; sq, squamosal;
1696 vom, vomer; zyg, zygomatic process of squamosal.

1697

1698 **Figure 12**

1699 Phylogenetic relationships of Mysticeti with focus on Balaenoidea. Single most-parsimonious
1700 cladogram with the following tree statistics: Consistency Index (CI), 0.508; Retention Index (RI),
1701 0.805; Rescaled CI, 0.40894; Homoplasy Index (HI), 0.492; Stratigraphic Consistency Index
1702 (SCI), 0.825.

1703

1704 **Figure 13**

1705 Schematic representation of diagnostic characters observed in the holotype skull of *Eubalaena*
1706 *ianitrix* in left lateral view. Not to scale.

1707

1708 **Figure 14**

1709 Phylogenetic relationships of Balaenidae plotted against a time scale in million years (Ma). Bold
1710 lines represent stratigraphic ages of taxa based on dated specimens; light lines represent inferred
1711 presence of taxa. Note that three time periods are highlighted: (1) separation of Balaenidae and
1712 Neobalaenidae inferred to have occurred *c.* 11 Ma (latest Serravallian-to-earliest Tortonian); (2)
1713 separation of the *Balaena* + *Balaenella* clade and the *Eubalaena* + *Balaenula* clade inferred to
1714 have occurred *c.* 7 Ma (latest Tortonian-to-earliest Messinian); and (3) origin of the extant
1715 *Eubalaena* species inferred to have occurred *c.* 2.5 Ma (latest Zanclean-to-earliest Piacenzian).

1716

1717

1718 **Table 1**

1719 Measurements (in mm) of RBINS M. 880 (cervical vertebrae complex, Balaenidae gen. et sp.
1720 indet.) and M. 2280 (left humerus, *Eubalaena* sp.). Characters are measured as preserved.

1721

1722 **Table 2**

1723 Measurements (in mm) of the neurocranium RBINS M. 879a-f (holotype of *Eubalaena ianitrix*
1724 sp. nov.). Characters are measured as preserved.

1725

Figure 1

Anatomical abbreviations: fm, foramen magnum; fr, frontal; irfr, interorbital region of the frontal; oc, occipital condyle; orb, orbit; otc, orbitotemporal crest; par, parietal; pgl, postglenoid process of squamosal; p-fr, parietal-frontal suture; p-sq, parietal-squamosal suture; smc, supramastoid crest; soc, supraoccipital; sop, supraorbital process of frontal; sq, squamosal; vom, vomer; zyg, zygomatic process of squamosal; *, anterolateral corner of parietal-frontal suture.

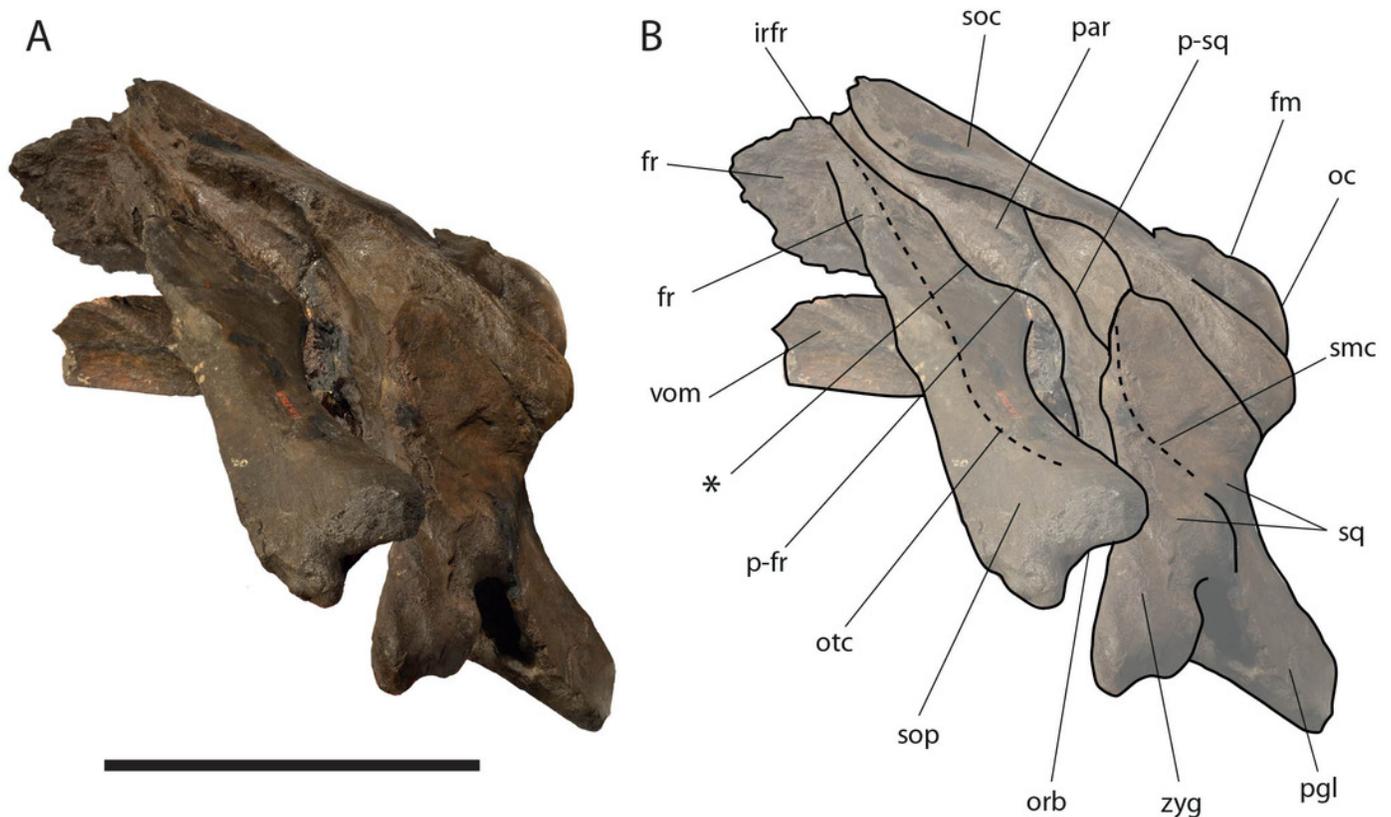

Figure 8

Fig. 8 - *Eubalaena ianatrix* sp. nov. (holotype RBINS M. 879). Right lateral view of neurocranium.

A, photographic representation. B, interpretation. Scale bar equals 50 cm. Anatomical abbreviations: fm, foramen magnum; fr, frontal; irfr, interorbital region of the frontal; oc, occipital condyle; orb, orbit; otc, orbitotemporal crest; par, parietal; pgl, postglenoid process of squamosal; p-fr, parietal-frontal suture; p-sq, parietal-squamosal suture; smc, supramastoid crest; soc, supraoccipital; sop, supraorbital process of frontal; sq, squamosal; vom, vomer; zyg, zygomatic process of squamosal; *, anterolateral corner of parietal-frontal suture.

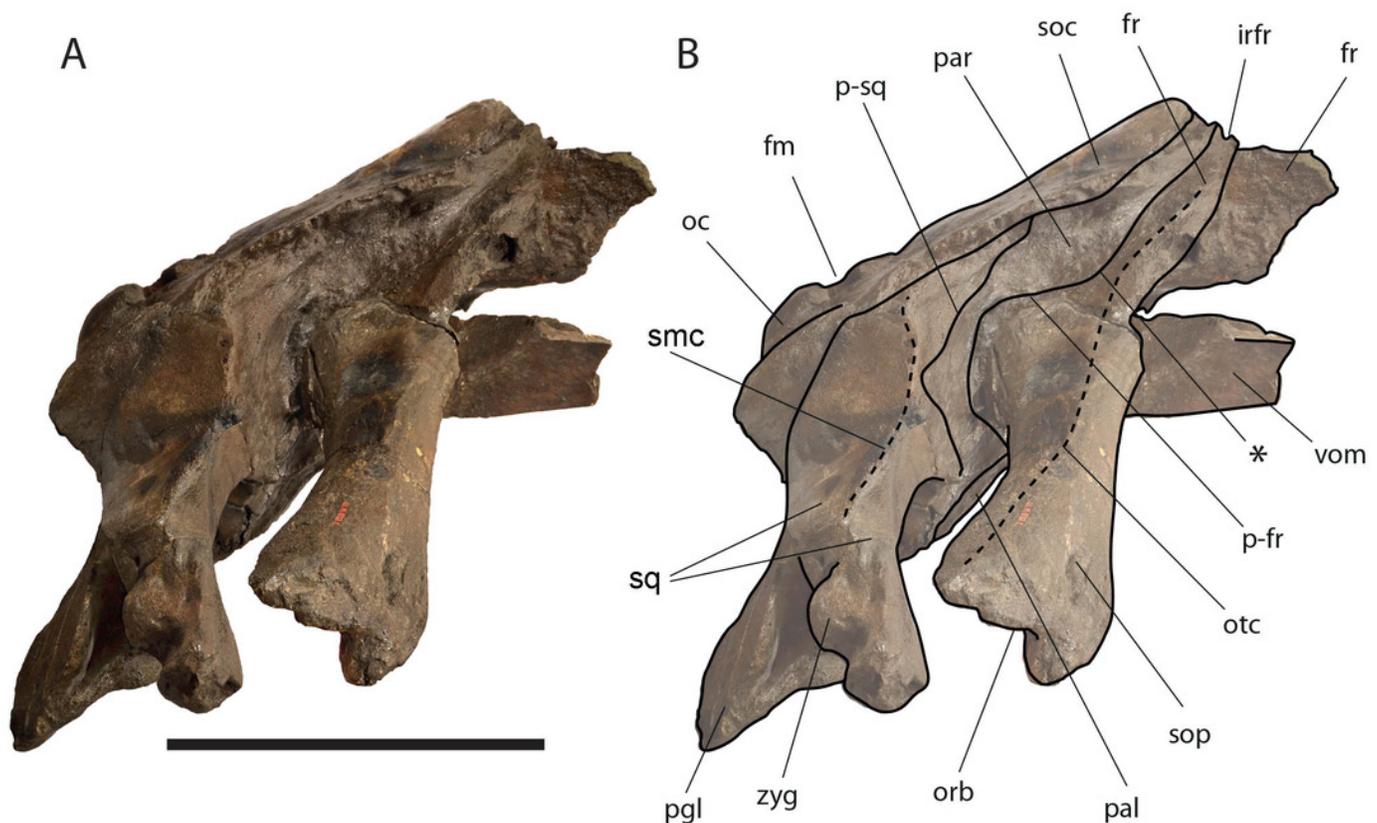

Figure 9

Fig. 9 - *Eubalaena ianatrix* sp. nov. (holotype RBINS M. 879). Anterior view of neurocranium.

A, photographic representation. B, interpretation. Scale bar equals 50 cm. Anatomical abbreviations: fr, frontal; irfr, interorbital region of the frontal; max-fr, grooves for articulation of maxilla and frontal; mes, mesethmoid; nas-fr, groove for articulation of nasal and frontal; pal, palatine; par, parietal; pgl, postglenoid process of squamosal; pm-fr, grooves for articulation of premaxilla and frontal; soc, supraoccipital; sop, supraorbital process of frontal; sq, squamosal; vom, vomer; zyg, zygomatic process of squamosal.

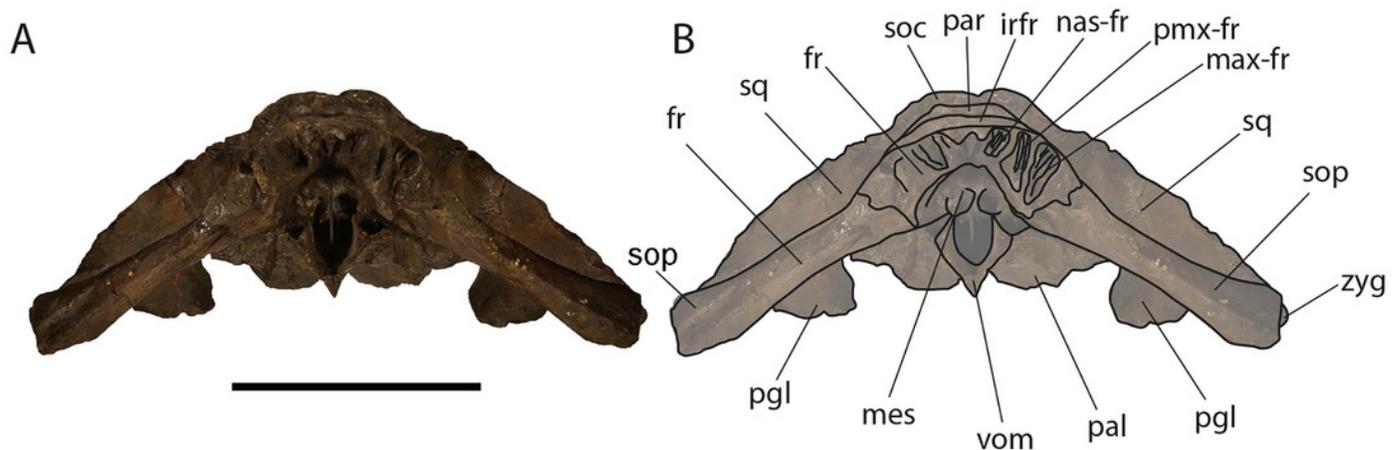

Figure 10

Fig. 10 - *Eubalaena ianatrix* sp. nov. (holotype RBINS M. 879). Ventral view of neurocranium.

A, photographic representation. B, interpretation. Scale bar equals 50 cm. Anatomical abbreviations: exo, exoccipital; fm, foramen magnum; fr, frontal; sop, supraorbital process of frontal; oc, occipital condyle; och, optic channel; or, orbit; pgl, postglenoid process of squamosal; pt, pterygoid; sq, squamosal; vom, vomer; zyg, zygomatic process of squamosal.

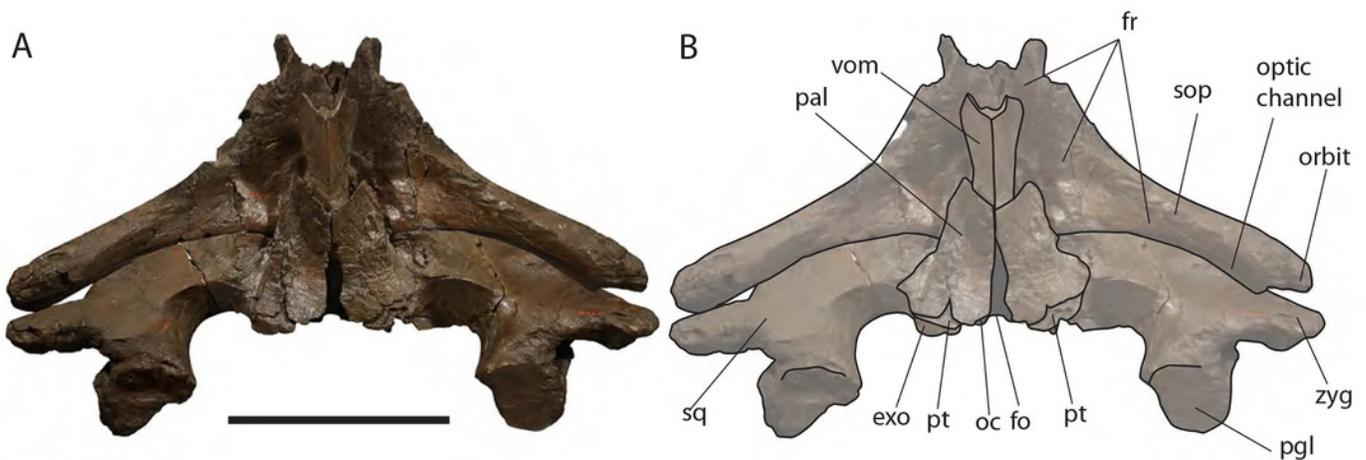

Figure 11

Fig. 11 - *Eubalaena ianatrix* sp. nov. (holotype RBINS M. 879). Posterior view of neurocranium.

A, photographic representation. B, interpretation. Scale bar equals 50 cm. Anatomical abbreviations: boc, basioccipital; bop, basioccipital protuberance; exo, exoccipital; fm, foramen magnum; fr, frontal; jn, jugular notch; oc, occipital condyle; pal, palatine; pgl, postglenoid process of squamosal; pt, pterygoid; ptf, pterygoid fossa; sop, supraorbital process of frontal; sq, squamosal; vom, vomer; zyg, zygomatic process of squamosal.

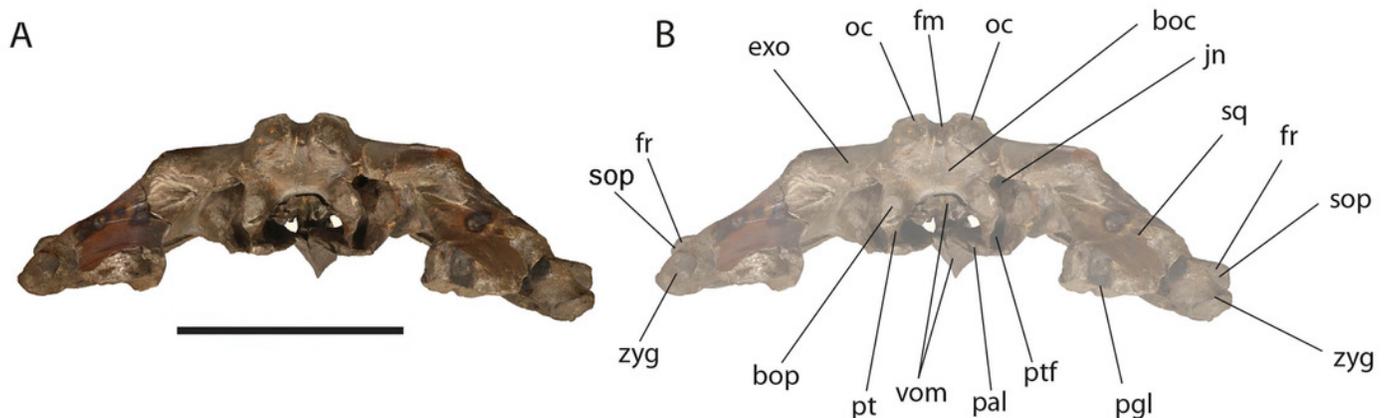

Figure 12

Fig. 12 - Phylogenetic relationships of Mysticeti with focus on Balaenoidea.

Single most-parsimonious cladogram with the following tree statistics: Consistency Index (CI), 0.508; Retention Index (RI), 0.805; Rescaled CI, 0.40894; Homoplasy Index (HI), 0.492; Stratigraphic Consistency Index (SCI), 0.825.

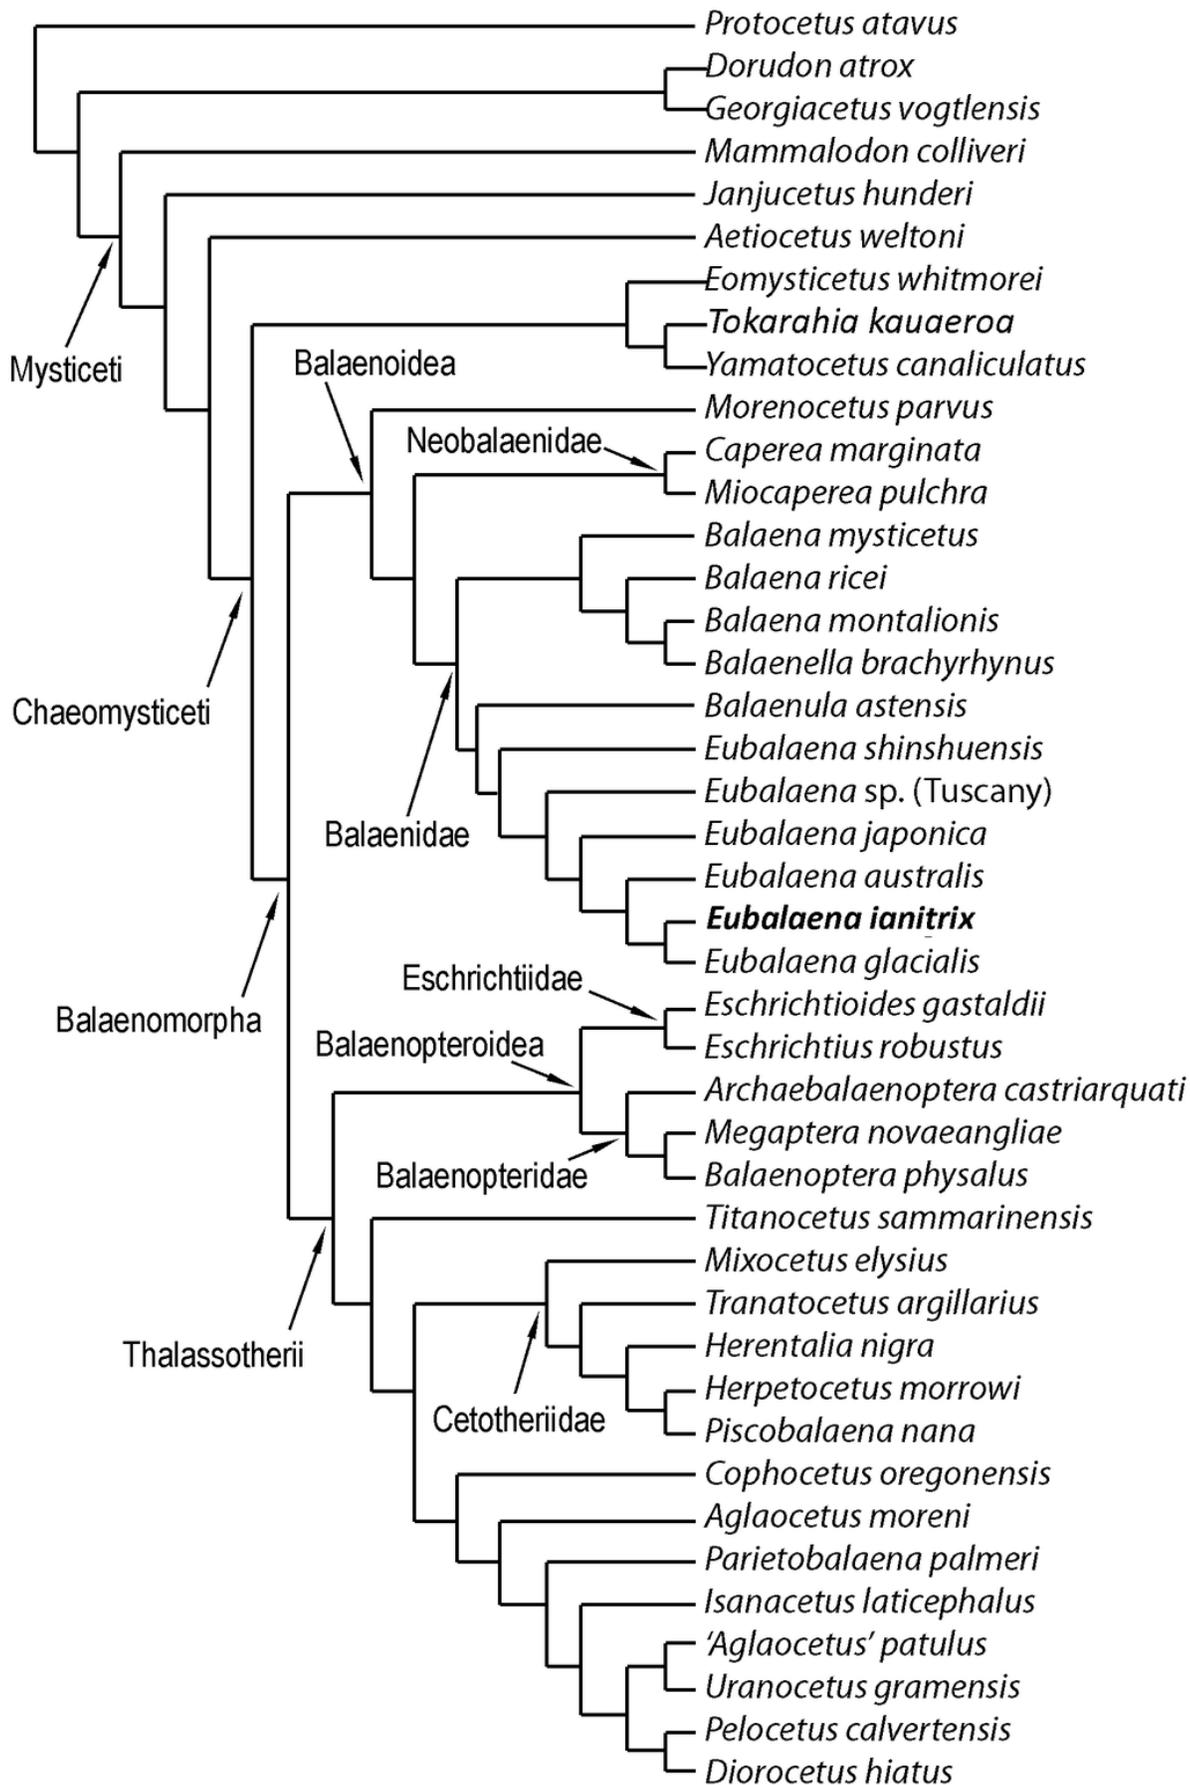

Figure 13

Fig. 13 - Schematic representation of diagnostic characters observed in the holotype skull of *Eubalaena ianatrix* in left lateral view.

Not to scale.

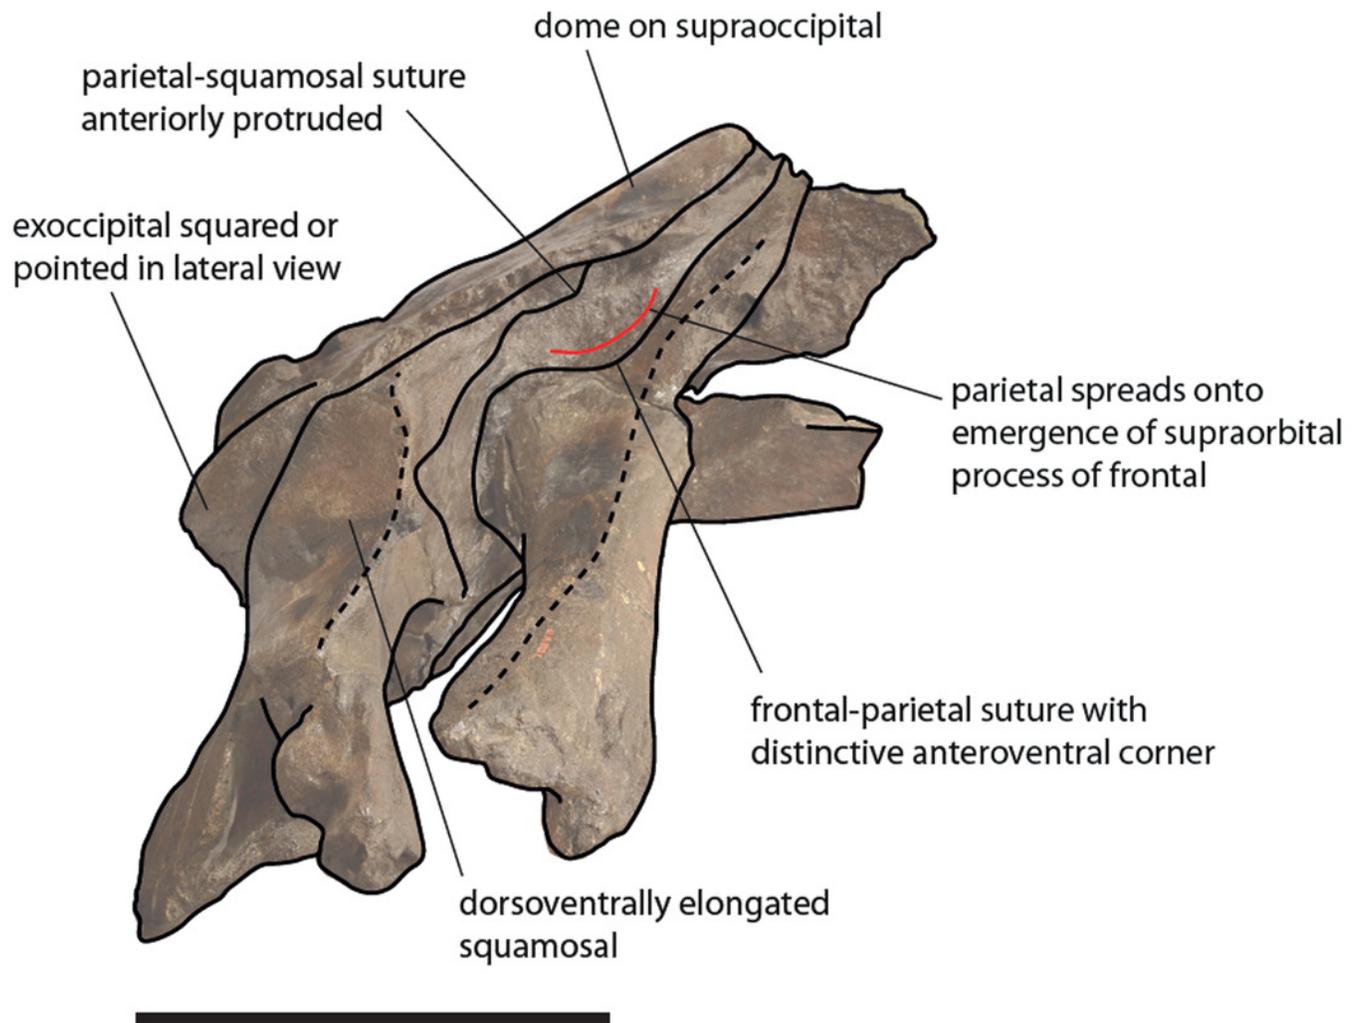

Figure 14

Phylogenetic relationships of Balaenidae plotted against temporal scale

Fig 14 - Phylogenetic relationships of Balaenidae plotted against a temporal scale showing that the separation of Balaenidae and Neobalaenidae occurred before Tortonian at least and that the separation of the *Balaena* + *Balaenella* clade from the *Eubalaena* + *Balaenula* clade occurred at the beginning or during the Messinian (latest Miocene). The origin of the modern *Eubalaena* (right whale) is inferred to be occurred at the beginning of the Piacenzian.

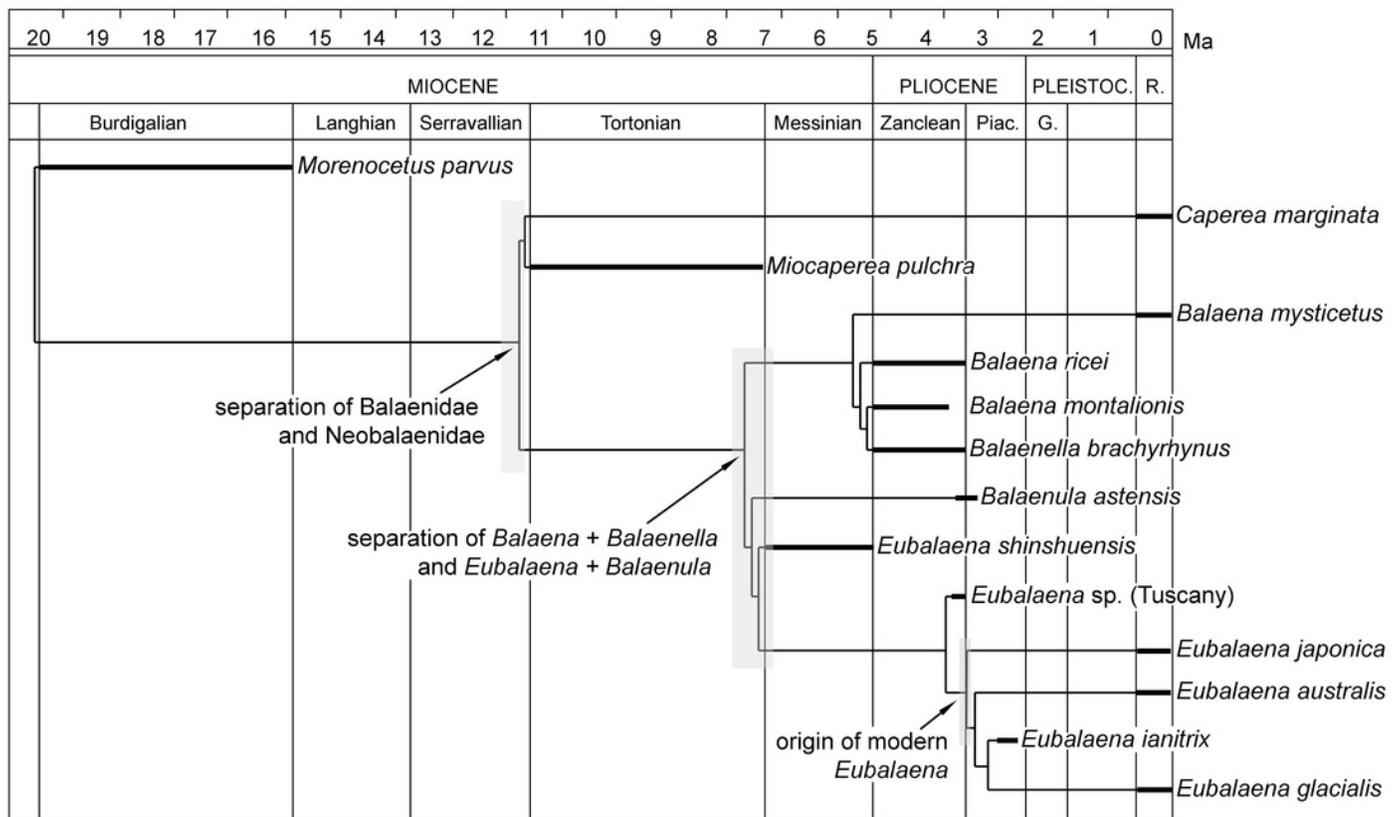

Table 1 (on next page)

Table 1 - Measurements (in mm) of RBINS M. 880 (cervical vertebrae complex, Balaenidae gen. et sp. indet.) and M. 2280 (left humerus, *Eubalaena* sp.).

Characters are measured as preserved.

- 1 Table 1
- 2 Measurements (in mm) of RBINS M. 880 (cervical vertebrae) and M. 2280 (left humerus).
- 3 Characters are measured as preserved.
- 4

Character	Measure
M. 880 (cervical vertebrae)	
maximum anteroposterior length of whole complex	280
maximum transverse width of whole complex	423
maximum width across articular facets of atlas	384
maximum height of articular facets of atlas	175
posterior width of centrum of last cervical	246
posterior height of centrum of last cervical	201
M. 2280 (left humerus)	
total length	683
maximum proximal mediolateral width	355
maximum proximal anteroposterior width	458
anteroposterior diameter of humeral head	345
mediolateral diameter of humeral head	343
minimum mediolateral width of diaphysis	222
minimum anteroposterior width of diaphysis	271
distal mediolateral width	249
maximum distal anteroposterior width	364
anteroposterior length of radial facet	239
anteroposterior length of ulnar facet (including facet for olecranon)	250

Table 2 (on next page)

Table 2 - Measurements (in mm) of the neurocranium RBINS M. 879a-f (holotype of *Eubalaena ianitrix* sp. nov.).

Characters are measured as preserved.

1 **Table 2**2 Measurements (in mm) of the neurocranium RBINS M. 879a-f (holotype of *Eubalaena ianitrix*

3 sp. nov.). Characters are measured as preserved.

4

Character	Measure
bizygomatic width	1660
estimated postorbital width	1760
width of occipital condyles	290
distance between lateral margins of exoccipitals	850
length of supraoccipital shield from foramen magnum to vertex	560
height between basicranium and vertex	71
transverse width of maxillae at vertex	290
