We characterize the diversity of nectar-living yeasts and measure the associations between yeasts and nectariferous plants assemblages and the effect of yeasts on nectar traits in a tropical environment. Using a series of hierarchically nested sampling units, we extracted nectar from an assemblage of host-plants representative of the diversity of life forms, flower shapes, and pollinator types occurring in the tropical area of Yucatan-Mexico. Yeasts were isolated from single nectar samples and DNA-identified, yeast-cell density was estimated, and sugar composition and concentration were quantified using HPLC. In contrast to previous studies from temperate region, diversity of nectar-living yeasts in the sampled plant community was characterized by a relatively high number of equally-common species with low dominance. Analyses predict highly diverse nectar yeast communities in the relatively narrow range of tropical vegetation. Significant associations between specific yeast species and specific host-plants were also detected and the impact of yeasts on nectar of different host-plants was related to yeast diversity and host-plant associations with flower visitors. This study provides an overall picture of the diversity of nectar-living yeasts in tropical host-plants and suggests that a key factor affecting community-wide patterns of nectar traits is not nectar chemistry, but rather the kind of yeasts associated to flower visitors.

Nectar-living yeasts of a tropical host-plant community: diversity and effects on
community-wide floral nectar traits

13 **ABSTRACT**

14 We characterize the diversity of nectar-living yeasts and measure the associations between yeasts
 15 and nectariferous plants assemblages and the effect of yeasts on nectar traits in a tropical
 16 environment. Using a series of hierarchically nested sampling units, we extracted nectar from an
 17 assemblage of host-plants representative of the diversity of life forms, flower shapes, and
 18 pollinator types occurring in the tropical area of Yucatan-Mexico. Yeasts were isolated from
 19 single nectar samples and DNA-identified, yeast-cell density was estimated, and sugar
 20 composition and concentration were quantified using HPLC. In contrast to previous studies from
 21 temperate region, diversity of nectar-living yeasts in the sampled plant community was
 22 characterized by a relatively high number of equally-common species with low dominance.
 23 Analyses predict highly diverse nectar yeast communities in the relatively narrow range of
 24 tropical vegetation. Significant associations between specific yeast species and specific host-
 25 plants were also detected and the impact of yeasts on nectar of different host-plants was related
 26 to yeast diversity and host-plant associations with flower visitors. This study provides an overall
 27 picture of the diversity of nectar-living yeasts in tropical host-plants and suggests that a key
 28 factor affecting community-wide patterns of nectar traits is not nectar chemistry, but rather the
 29 kind of yeasts associated to flower visitors.

INTRODUCTION

Floral nectars are sugar-rich environments that frequently harbor distinctive microbial communities. Studies on microbial diversity conducted, among other, by Brysch-Herzberg (2004), Pozo, Herrera & Bazaga (2011), Álvarez-Pérez & Herrera (2013), Jacquemyn et al. (2013) and Mittelbach et al. (2015), have revealed that floral nectar is frequently colonized by specialized sugar-consumer yeasts in the Ascomycota and Basidiomycota, along with several bacterial groups. However, most of the studies addressing questions about nectar-living microorganisms have been conducted in temperate areas, resulting in a still-poor knowledge of nectar microbial diversity in tropical habitats. Only three preliminary assessments of the frequency of microbial-cell density in floral nectars in several tropical environments have been conducted so far (Herrera et al., 2009; Canto & Herrera, 2012; Belisle et al., 2014). Altogether, these earlier studies showed that the incidence of microorganisms in tropical nectars was higher than in temperate areas, and provided a glimpse of the high diversity harbored in tropical host-plant communities. Diversity assessments in tropical nectars are still necessary to obtain a more complete view of microbial distribution linked to nectars across different environments and latitudes. Other aspect of the impact of nectar-microbial diversity is that microorganisms can account for a significant fraction of community-wide variance of nectar traits, since presence of yeast cells alters nectar sugar composition and concentration (the microbial imprint; Canto & Herrera, 2012). So far, the evidence indicates that differential yeast-effect on nectars is associated with characteristics inherent to plant (type of nectar) and pollinator type. For example, pollinators are the main source of inocula for the initial establishment of microbial communities in nectars as they introduce their mouthparts into the nectaries in their search for nectar rewards (Canto et al., 2008). The initial assemblage of microorganisms colonizing a flower will therefore largely depend on the type of pollinator visiting host-plants (Belisle, Peay & Fukami, 2012; de Vega & Herrera, 2013; Mittelbach et al., 2015). After initial colonization, however, nectar features will strongly influence the growth of arriving microorganisms and allow some species thriving but not others, with the consequence that the resulting microbial community consists of a cluster of phylogenetically related species (Herrera et al., 2010). It has been therefore hypothesized that, in a given community of nectariferous plants, nonrandom plant-microorganism associations can produce a mosaic of different qualities of floral nectars at the community level with potential effects on plant-pollinator interactions (Canto & Herrera 2012).

To characterize diversity of nectar-living microorganisms in a tropical environment and to gain insights on factors driving community-wide variance in nectar traits, we analyze in this paper the assemblage of yeast and yeast-like species (collectively termed ‘yeasts’ hereafter) occurring in the floral nectar of tropical plant environments of the Yucatan Peninsula, Mexico. By isolating and identifying culturable yeasts from the floral nectar from many species and individuals of animal-pollinated plants, quantifying their population densities in nectar, and estimating nectar sugar concentration and composition in the host-plant nectar, we will specifically assess (1) how diverse is the community of nectar-living yeasts in a tropical environment; (2) the existence of predictable associations between nectar yeasts and host-plants; and (3) the differential impact on nectar composition of yeast species associated with different host-plants. Yeast diversity is discussed in relation to the different nectars structuring the plant community sampled and the role of different host-plants and yeasts as sources of associations between plants and nectar-living yeasts, all of which will ultimately influence the plant-pollinator interactions. Our results predicts the existence of a relatively high diverse assemblage of nectar-living yeasts showing significant correspondence with the diversity of their host-plants, as well as significant differences between yeasts and host-plants in the effect that exert on floral nectars.

MATERIALS AND METHODS

Study area and species sampled

Field sampling was conducted from September 2008 to November 2009 in 28 sites located in a relatively narrow area of tropical vegetation (approx. 430 km²) in northwest Yucatan Peninsula, Mexico. This area includes a coastal dune portion, between Chuburna and Dzilam de Bravo towns, and the adjacent dry forest, between the Dzibichaltun Mayan Ruins and the Cuxtal Ecological Reserve. Elevation ranges between 1-10 m and climate is semi-arid at the coastal dune strip and subtropical at the dry forest, with a mean temperature of 26 °C in both types and annual rainfall of 370 mm and 1077 mm, respectively. The vegetation is a low, open scrub dominated by xerophytes, halophyte herbs, thorny bushes, palms and 1-3 m treelets growing on sandy, nutrient-poor soils in the dune strip. The dry forest is made up of cacti, thorny shrubs and deciduous medium-height trees (3-8 m tall) growing on limestone bedrock soil with a thick litter layer (Chan-Vermont, Rico-Gray & Flores, 2002; Canto & Herrera, 2012).

Sampling method

To provide an overall picture of the diversity of nectar-living yeasts in floral nectars of the studied area, nectar samples were obtained from an assemblage of 24 host-plant species belonging to 17 genera and 14 botanical families, representing the diversity of life forms, flower shapes, pollinator types and taxonomic categories occurring in the area (see Canto & Herrera 2012 for a complete list of species sampled). We adopted a five-tiered series of hierarchically nested sampling units for nectar collection, namely nectar drops (Drop), individual plants (Individual), plant species (Species), plant genus (Genus), and botanical family (Family). The criteria used for collecting nectar samples was that flowers were already open at the time of collection in the field, thus exposed to prior pollinator visitation and the nectar therefore susceptible to have been colonized by yeasts. Three nectar drops were obtained from each flower, and 3-6 flowers were sampled from each of 6-10 individuals per surveyed plant species. Each sample was extracted with sterile calibrated micropipettes and its volume was calculated following methods used by Herrera et al. (2009). Of the three nectar drops obtained from each flower, one was used for DNA-based identification of yeasts, another for quantification of yeast density and the other to estimate sugar concentration and composition, using in each case the methods described below.

Isolation and identification

Nectar drops were individually streaked onto YM agar plates (1.0 % glucose, 0.5 % peptone, 0.3 % malt extract, 0.3 % yeast extract, 2.0 % agar) with 0.01 % chloramphenicol, and incubated at 25 °C until microbial colonies were detectable (2-20 days). Colonies were observed at 10x - 40x magnification and phenotypically different colonies were purified by streak-plating. From 532 nectar drops collected, a total of 158 isolates were obtained from the resulting yeast colonies. The large-subunit (26S) ribosomal DNA gene (D1/D2 region) was two-way sequenced for each isolate using the primer combination NL1-NL4, according to Kurtzman & Robnett (1998) and Lachance et al. (1999). Raw sequences for each isolate were edited, assembled and consensus sequences were obtained using Geneious Pro 8.1.7 bioinformatics software (Biomatters Ltd, Auckland, New Zealand). Nucleotide collection databases at GenBank were queried with the Basic Local Alignment Search Tool (BLAST; Altschul et al., 1997) to look for named yeast species with DNA sequences matching those obtained for the isolates. All sequences queried

yielded significant alignments with named yeast accessions in GenBank databases, generally at 98–100 % of sequence coverage and identity. Resulting DNA-species and the associated sampling information (nectar drop, individual plant, host-species, genus and botanical family) was used in the analyses of yeast diversity. The strains studied are maintained in the Centro de Investigación Científica de Yucatán (CICY) and their corresponding DNA sequences have been deposited in GeneBank under the accessions listed in Table 1 along with their designation, frequency and respective host plants (botanical family).

Cell counts and nectar sugar composition and concentration

The density of yeast cells was estimated in each nectar drop using a Neubauer chamber and standard cell count procedures (Herrera et al., 2009). To do this, the initial volume of nectar drops was measured with calibrated micropipettes. Each nectar sample was diluted using a 0.5 % lactophenol cotton blue solution to obtain a final volume up to 1.5 – 6 times more than the initial volume. Diluted samples were loaded on the counting chamber and examined under a microscope (Olympus CX31) at 10x - 40 x magnifications. Cells were counted in each of 16 quadrants of the counting chamber and cell density was calculated using the formula: cells per μL = average number of cells counting in the quadrants multiplied by the dilution factor and for the fixed volume of the chamber.

The composition and concentration of nectar was measured following procedures described by Herrera et al. (2006) and Canto et al. (2011) and using ion-exchange high-performance liquid chromatography (HPLC). Nectar samples were blotted onto a 10 x 12 mm sterile Whatman 3MM paper wick and immediately after absorption, were placed into sterile envelopes and stored at 25-26 °C in silica gel. For analytical procedure, nectar-containing wicks were individually placed into Eppendorf tubes and 1mL of HPLC-grade water was added to each one. For each sample, 5 μL of solution was filtered using a 0.4 μm polyvinylidenedifluoride (PVDF) filter and injected into a Dionex DX 500 HPLC system (Dionex, Sunnyvale, CA, USA). The HPLC system was equipped with an effluent degas module, a GP 40 gradient pump, a CarboPac PA10 (4mm \times 50mm) guard column and a CarboPac PA10 (4mm \times 250mm) analytical column. It also had an ED 40 electrochemical detector for pulsed amperometric detection in integrated amperometric mode, with the normal preloaded wave form for sugar detection (Dionex Corp., 1994). The column was eluted (flow rate 1 mL min⁻¹) isocratically with 40mM NaOH (50%

solution; J.T. Baker, Deventer, The Netherlands) and kept at 24 °C during analysis. The concentrations of sucrose, glucose and fructose in each nectar sample (g of solute per 100 mL solution) were calculated by integrating the area under the corresponding chromatogram peaks, then using linear regression models fitted to the data of standard sugar-solutions, and then calculating the expected values of concentration corresponding with the integrated area of each type of sugar contained in the analyzed samples. Two independent HPLC measurements were done on each sample, and replicate results averaged for the analyses.

Data analysis

In order to characterize the species diversity of nectar yeasts and to compare diversity estimates across the different hierarchical sampling levels considered (i.e., drop, individual, species, genus, family), the analytical framework suggested by Chao et al. (2014) was performed with the R package iNEXT (Hsieh, Ma & Chao, 2016). This method generalizes the sample-size-based approach of Colwell et al. (2012) and the coverage-based approach of Chao & Jost (2012) to produce and expand rarefaction-extrapolation curves of species based on Hill numbers (Hill, 1973). Hill numbers are a mathematically unified family of diversity indices, differing among themselves only by an exponent q . These indices provide a suitable framework for measuring diversity because (1) they are expressed in units of effective numbers of species, (2) by using algebraic transformation, they are easily associated to key diversity indexes such as Shannon entropy and Gini-Simpson index, and (3) their estimations can be effectively generalized to incorporate hierarchical levels of diversity in a species assemblage (Chao et al., 2014). For each sampling level (drop, individual, species, genus, and family), an incidence matrix was built up by recording the presence-absence across sampling units of each of the 158 DNA-species identified. The first three Hill numbers (Hill, 1973), which are associated to estimators of species richness and species dominance, were calculated for each level and their corresponding rarefaction and extrapolation curves were constructed. The first Hill number ($q = 0$) used in the analysis estimates the expected yeast-species richness (number of species) in the assemblage of nectar host-plants. The second Hill number ($q = 1$) is the exponential of Shannon entropy index and estimates yeast diversity with respect to equally-common species and species richness (Shannon diversity). The third Hill number ($q = 2$) is the inverse Simpson concentration index and measures the dominance of yeast species in the species assemblage (Simpson diversity); see Hill

(1973) for further details of Hill numbers. To compare among hierarchical sampling levels, rarefaction and extrapolation sample-size-based were produced for each level to provide asymptotic estimators of diversity based on Hill numbers with their respective 95 % confidence intervals constructed by a bootstrap method (Chao et al., 2014). One potential issue in our sampling is that it included many different plant species each with a relatively low replication. To account for this as far as possible, firstly, all yeast species that occurred only once were excluded from the analysis, as they were likely to be allochthonous; secondly, an analysis of sampling completeness was conducted to estimate the sample size needed to achieve that the proportion of undetected autochthonous species remains unchanged even when the sample size increases; Chao & Jost, 2012). To this end, a sample completeness curve was constructed by combining the sample-size-based and the coverage-based estimations. Extrapolations were extended up to double the initial sample size for all sampling levels, which allow us to make predictions about the yeast diversity that can be detected in each sampling level using a similar sampling effort.

Correspondence analysis was conducted using the R package ca (Greenacre, Nemadic & Friendly, 2016) to obtain a statistical and graphical visualization of associations between nectar-living yeasts and host-plants. This analysis is a geometric technique for displaying the rows and the columns of a contingency table as points in a low-dimensional space such that the positions of the row and column points are consistent with their associations in the table. For yeasts and host plants data, contingency tables were produced using yeast species as column variables and plant species as row variables. All singletons were excluded from the analysis. The analysis produces correspondence-dimensions based on the profiles (relative frequency of yeast taxa corresponding with the respective host-plants), weighted average of profiles (centroid of the space representation), chi-square Euclidean-distances (proximity between points), and the total inertia (total contribution of yeast taxa and host-plant to correspondence precision). The first three dimensions obtained from the analysis were plotted to generate biplots representing correspondence between yeast taxa and host-plants.

To identify possible associations between yeasts and plant species in terms of yeast effects on nectar sugars, regression methods were applied using R software (R Development Core Team, 2016). Yeast-cell density (Log_{10} transformed) was used as predictor variable and sugar

concentration in nectar samples was used as response variable. To identify differences in nectar concentration due to the intrinsic traits of yeasts and plants species, yeast species (Yeast) and plant species (Plant) were treated as factors. Three interaction factors were added to test multiplicative effects of the interactions between the Yeast and Plant, between yeast-cell-density (Cell density) and Yeast, and between Cell density and Plant factors. Linear regressions were calculated separately for sucrose, glucose, and fructose to predict particular changes in sugar concentrations based on the effect of yeast-cell density on nectar (Canto & Herrera, 2012).

RESULTS

Yeast diversity

A total of 39 species of yeasts were identified, comprising 48 % ascomycetous and 52 % basidiomycetous species (Table 1). The most frequent ascomycetous yeasts were *Metschnikowia koreensis* ($n = 13$), *Metschnikowia ipomoeae* ($n = 12$), and *Kurtzmaniella cleridarum* ($n = 12$), and for basidiomycetous yeasts were *Ustilago* species ($n = 14$) *Cryptococcus laurentii* ($n = 12$), and *Sympodiomyopsis paphiopedili* ($n = 8$). Analysis of diversity predicts that the overall species richness of yeasts in the sampled nectar community (Hill number $q = 0$) was between 25-34 species, which was in the same order of magnitude as the number of equally-common species ($q = 1$, 22-34 species) or dominant species ($q = 2$, 19-33 species). Rarefaction and extrapolation curves were consistent in showing that there remained a number of unrecorded yeasts at Genus and Family sampling levels of the plant community surveyed. None of the three diversity estimates used reached an asymptote at these levels in the sampling hierarchy. At the Species level, species richness reached an asymptote at sample size doubling initial sampling effort, i.e., $n = 34$. In contrast, species diversity estimates obtained with Hill numbers $q = 1$ and $q = 2$ did not reach an asymptote at that level. Analyses also showed that the number of species harbored at Drop and Plant levels was nearly complete sampled. At those levels, the three estimators of diversity reached an asymptote at approximately 100 and 50 sampling units, respectively. The maximum predicted values were 25 yeast species for species richness Hill number $q = 0$, and 22 and 19 species for estimates of equally-common ($q = 1$) and dominant ($q = 2$) species, respectively. Again, estimated species richness was roughly comparable to higher-order diversity estimates incorporating information on dominance.

Rarefaction and extrapolation curves also allow to identify two predictions of Hill numbers for equally-common species ($q = 1$) and dominance ($q = 2$) of yeasts in the host-plant community. In one scenario, Drop and Individual sampling categories for nectar collection reach an asymptote and harbor a relatively low yeast diversity. In other scenario, Species, Genus and Family categories do not reach an asymptote, even when extrapolations double initial sample size. Those categories have the highest predicted diversity of yeasts (Fig. 1, $q = 0$, $q = 1$, $q = 2$). Completeness curves show that sample completeness was nearly achieved at the Drop and Individual levels (1 and 0.99 respectively) with the current sample size in the survey. At Species level sampled completeness was close to one (0.89) and at higher-order diversity estimates, the maximum sample completeness was 0.76 and 0.65 for Genus and Family respectively (Fig. 1, sampling completeness).

Yeast-plant association

Correspondence analysis revealed a significant number of associations between yeasts and host plants (Fig. 2). The most extreme correspondence was observed between *Kurtzmaniella cleridarum* with *Opuntia dillenii*. The other closest associations include *Starmerella* sp. and *Metschnikowia ipomoeae* corresponding to the host-plant *Ipomoea crinicalyx*; *Clavispora lusitaniae* with *Agave angustifolia* and *M. koreensis* with *Tecoma stans*. Looser associations include *Candida sorbosivorans* with *Passiflora foetida*, *Metschnikowia* sp. with *Lonchocarpus longistylus*, *Sporidiobolus ruineniae* with *Merremia dissecta*, *Papilotrema flavescens* with *Bravaisia berlandieriana*, and *Kwoniella mangrovensis* with *Operculina pinnatifida*. The weakest associations were observed between two groups of species, including *Saitozyma flava*, *Ustilago sparsa*, and *Ustilago* sp. with *Ipomoea hederifolia* and *Ipomoea triloba*, and *Vishniacozyma taibaiensis*, and *Naganishia liquefaciens* with *Piscidia piscipula* (Fig. 2).

Yeast effects on nectar sugars

Significant regressions were found for the overall effect of yeast-cell density on nectar sugars. In general, concentrations of sucrose, glucose and fructose decreased with increasing density of yeast cells (sucrose: $R^2 = 0.85$, $F_{1, 180} = 47.84$, $p < 0.0001$; glucose: $R^2 = 0.70$, $F_{1, 180} = 96.12$, $p < 0.0001$; and fructose: $R^2 = 0.67$, $F_{1, 180} = 93.20$, $p < 0.0001$). The analysis also showed that the effect of yeasts on sugars was influenced by inherent differences due to yeast species (Yeast) and

plant species (Plant) (Table 2). Significant Plant x Yeast and Plant x Cell density interactions were observed for sucrose concentration but not for glucose and fructose concentrations. The Yeast x Cell density interaction effect on concentration was not significant for any sugar (Table 2). To illustrate how the effect of yeast cells density on sugar concentration in nectar can be modified by Yeast and Plant factors, separate regressions for four representative yeasts species were plotted. Figure 3 shows that the overall negative effect of yeast cells density on nectar sugars did not remain consistent across yeast and plant species. For example, *M. ipomoeae* showed no effect on concentration of any nectar sugars of *I. crinicalyx*, while *Cry. laurentii* had negative effect on concentration of sucrose and fructose in *M. dissecta* and *O. pinnatifida*, but no statistically significant effect on the nectar of *I. hederifolia*. Moreover, *Metschnikowia lochheadii* showed overall negative effects on sugar concentrations in *O. pinnatifida* while *Ustilago sparsa* had not significant effect on any nectar sugars.

DISCUSSION

No other studies on nectar-living yeasts have been conducted in tropical nectariferous plants so far, excepting Herrera et al. (2009) and Canto & Herrera (2012), where frequency of yeasts in floral nectar samples was assessed in three regions, two at Southern Spain and one in Southern Mexico. Diversity of nectar yeasts, however, was not explicitly addressed in these two previous studies, although their results did suggest differences between temperate and tropical regions. Another similar study was conducted by Mittelbach et al. (2015) in a subtropical environment of the Canary Islands. We will first discuss diversity patterns found in the present study and then compare them with previous findings. Then we will discuss on the association between yeast species and host-plants and on the implications of differential yeast effects on nectar sugars.

Yeast diversity

Our results indicate that the assemblage of yeasts in the plant community surveyed was made up of a relatively high number of species at the highest sampling levels (plant genera and botanical families), along with a substantial number of equally-common species and relatively low species dominance at all sampling levels considered. Low dominance in the assemblage is pointing a bias inherent in the diversity estimates due to under-sampling at higher sampling levels and oversampling at lower levels (Chao & Jost, 2015). This tropical plant community harbored a

higher diversity of nectar yeasts than our sampling design was able to detect. While the expected yeast diversity at the drop- and individual-based levels was acceptably estimated with the sample size set in this study, the analysis predicted that diversity remarkably increased at higher levels in the sampling hierarchy. Reducing the number of nectar drops replicates per plant, as well as the number of individual plants per species, while increasing the number of plant species by genera and families, will probably achieve a more encompassing picture of diversity of nectar-living yeasts in the tropical plant assemblage studied.

In temperate communities, Herzberg, Fischer & Titze (2002) studied microfungal diversity in the nectars of native plants of Germany, reporting a species richness of 20 yeasts in a total of 25 different plant species. Pozo, Herrera & Bazaga (2011) found 12 yeast taxa in 24 plant species in Southern Spain, later Álvarez-Pérez & Herrera (2013) in a large plant assemblage from Southern Spain found 20 yeasts in nectar of 30 plant species. Most recently, Mittelbach et al. (2015) reported nectar fungal diversity from a subtropical plant community in the Canary Islands. A total of 34 yeasts species were found in 8 native plant species. Belisle et al. (2014) reported 38 microfungi species, associated to mouthparts of 21 hummingbirds and 6 bats species of Costa Rica. In this work, corresponding to a tropical environment, 18 nectariferous plants were surveyed, finding a total of 41 yeast taxa. Yeast species richness seems therefore to steadily decrease from tropical community of Yucatan and subtropical community in the Canary Islands to temperate plant communities of Southern Spain and Germany. One frequent diversity patterns of animal and plant diversity is the latitudinal gradient of species richness (Pianka, 1966; Hillebrand, 2004). The well-known latitudinal gradient of species richness is discernible in several groups of marine bacterioplankton and phytoplankton microorganisms (e.g. Fuhrman et al., 2008; Schattenhofer et al., 2009; Barton et al., 2010). Although more studies are necessary, our results altogether with those of the studies mentioned above reveal a possible tendency of lower latitudes to support more nectar yeast species than higher latitudes.

Yeast-plant associations

The diversity of nectar-living yeasts in our sample was also shaped by associations between yeast, host-plants and flower visitors. This pattern creates a mosaic of nectar-environments at community level where habitat features are filters that influence the probability that the taxa with their specified traits are able to join and persist as members of a local community (Soininen,

2012; Hillebrand & Blenckner, 2002). According to our results and previous evidence (e.g., Lachance et al., 2001; Lachance et al., 2008; Lachance et al., 2016), two kinds of non-exclusive filters may have an effect on nectar-yeast interactions. First, floral nectar may act as a yeast community filter owing to its physicochemical and nutritional factors such as availability of nutrients, water activity and presence of yeast limiting/enhancing solutes, which altogether can lead to physiological specialization in nectar-living yeasts (Lievens et al., 2015). Our results show the existence of frequent yeast and host-plant correspondences, which is compatible with the existence of nectar filters that ‘sieve’ yeasts arriving to nectar and drive yeast distribution across host-plants. However, experimental evidence culturing yeasts under different nectar environments are necessary in order to test the existence of this kind of filter. Second, flower visitors can be also seen as ecological filter as they show particular associations with yeasts. Different plant species have different pollinators that can transport different yeast species to floral nectars. In a preliminary nectar-yeast assessment from South African plants, de Vega, Herrera & Johnson (2009) observed that differences among plant species in yeast incidence were related to variations in pollinator types. Mittelbach et al. (2015) also found that differences in pollinator types partly explained variation in nectar yeast composition between the Canary Islands plants. Pollinators of plants sampled for this study included solitary bees, stingless bees, hummingbirds, beetles, and bats. It thus seems reasonable to postulate that these different groups will carry different yeast species, and the closest yeast-plant correspondences are also resulted from particular flower visitors carrying particular yeasts to flowers. For example, correspondence between *K. cleridarum* and the cactus *O. dillenii* is explained by the association of this yeast with beetles of genus *Carpophilus*, which arrive to cactus flowers to feed on nectar and pollen and release yeast cells to this environment (Lachance & Starmer, 2008). Correspondence showed by *Starmerella* sp. and *M. ipomoeae* with *I. crinita* denote that the flower visitors are bees and nitidulid beetles (Rosa et al., 2003; Lachance et al., 2001). The strong association of *M. ipomoeae* and *M. lochheadii* with *Ipomoea* species is resulted from the association of these yeasts with *Conotelus* beetles (Lachance et al., 2001). In contrast, looser yeast-plant correspondences involved mostly basidiomycetous yeasts (except *C. sorbosivorans*) that have been isolated in non-flower, non-nectar substrates and probably arrive to nectar through accidental contamination or air dispersal (Lachance et al., 2001; Valério, Gadanho & Sampaio, 2002; Fell & Tallman, 1980; Yang et al., 2010). Additionally, plant-yeast species

correspondences mostly involved ascomycetous yeasts. In fact, ascomycetous yeasts showing correspondence with plants all belong to the same class Saccharomycetes (subphylum Saccharomycotina), while basidiomycetous taxa isolated from nectar belong to several classes such as Tremellomycetes, Ustilaginomycetes, Microbotryomycetes, and Hyphomycetes (subphyla Agaricomycotina, Pucciniomycotina, and Ustilaginomycotina).

Yeast effects on nectar

Our results confirm that the overall effect of yeasts (ascomycetous and basidiomycetous taxa) on nectar generally involves changes in the composition of nectar sugars that denote not only a chemical signature of yeast metabolism, but also a nectar quality-impoverishment, since sugar concentration decreases with increasing yeast-cell density. This phenomenon has been previously reported by Herrera, García & Pérez (2008) and de Vega & Herrera (2013). By reducing the nutritional value of nectar, foraging behavior of pollinators is affected and nectar-living yeasts become a factor that drives plant-pollinator interactions (Herrera, Pozo & Medrano, 2013; see also Vannette, Gauthier & Fukami, 2012; Good et al., 2014). Although more data from additional tropical communities are needed, it is reasonable to expect that nectar-living yeasts will have ecologically significant implications in plant-pollinator interactions at the community level because of their effects on community-wide floral nectar traits and foraging behavior of flower visitors. Results in this study also show that nectar alteration by yeasts is not a rare phenomenon in the community of host-plants surveyed and probably, is more frequent in tropical plant communities than currently acknowledged.

Different yeast species were found to have different impacts on nectar traits. One possible explanation is that initial conditions in nectar can match or mismatch with traits of arriving yeast (e.g. physiologic requirements of yeasts). Floral nectars frequently contain plant metabolites (Adler, 2000; Thornburg et al., 2003) or high sugar concentrations that prevent for yeast degradation of nectar (Herrera et al., 2010; Heil, 2011; Nepi, 2012); and nectar-living yeasts differ in their relative ability to grow in different nectars of different plants (Herrera, Pozo & Bazaga, 2014). In this study the close-related yeasts, *M. ipomoeae* and *M. lochheadii* (Lachance, 2011) and the far-related basidiomycetous yeasts *Cry. laurentii* and *Ustilago* sp., exemplify the diversity of yeast effects across nectar types resulting from different yeast species matching and mismatching with different floral nectars. The four yeasts partly overlapped each other across

different types of nectars, occur in the same plant community and showed different effects, from negative to no effects, on the same type of nectar.

The observed diversity of nectar-living yeasts in the assemblage of host-plants surveyed most likely represent only a small portion of actual species numbers occurring in floral nectar in the area, suggesting that tropical communities of nectars harbor an impressive, so far undiscovered diversity of yeast taxa associated to flower-nectar environments. The diversity of this type of yeasts is not only characterized by an important number of equally-common species with low dominance, but also by significant species correspondences between yeasts and nectariferous plants. Finally, the different effects that yeasts exert on floral nectars observed in this study, provide evidences for the existence of a nectar filtering process that sieves the initial assemblage of yeast species arriving to nectar from pollinators mouthparts, thus opening the opportunity to yeast specialization.

FUNDING

This work was supported by the Consejo Nacional de Ciencia y Tecnología through CB-2007-01 program [grant number 80031], the Ministerio de Educación y Ciencia [grant number CGL2010-15964] and the Junta de Andalucía [grant number P09-RNM-4517].

ACKNOWLEDGEMENTS

Permission to collect in natural areas of Yucatan was granted by Secretaría del Medio Ambiente y Recursos Naturales, Delegación Yucatán-Subsecretaría de Gestion para la Protección Ambiental: Dirección General de Vida Silvestre (oficio 00837/09). We thank Pilar Bazaga and Esmeralda López for assistance with DNA sequencing of yeasts; Atzelby López, Blanca Lizama, Cesar Canché and Raymundo González for assistance in the field and laboratory; Marina García for chemical analyses; Paulino Simá, Filogonio May and Alfredo Dorantes for host-plant identification.

Figure 1(on next page)

Diversity of nectar-living yeast

Diversity of nectar-living yeasts at the different hierarchically nested sampling levels used in nectar collection: nectar drops (Drop), individual plants (Individual), plant species (Species), plant genus (Genus), and botanical family (Family). Plots show species richness (Hill number for $q = 0$), diversity in terms of equally-abundant species (Hill numbers for $q = 1$ and $q = 2$), and sample completeness curve. Diversity curves were constructed using rarefied (solid lines) and extrapolated nectar samples (dashed lines) with sample-size-based (left panels) estimations. Each curve was extrapolated up to double the base reference sample size. Observed reference size for each category curve is denoted by a different symbol. The 95 % confidence intervals (color-shaded regions) were obtained by a bootstrap method based on 200 replications

Categories of sampling in host plants

Method of estimation

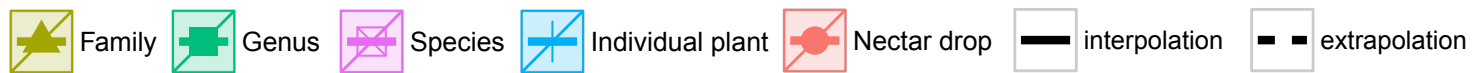

Figure 2 (on next page)

Correspondence analysis for nectar-living yeasts

Correspondence analysis for yeasts isolated from floral nectar samples. Plots show the associations between yeasts and host plants. Yeasts are depicted by filled triangles and letters and Host-plants by filled circles and numbers. Distances among points depict the similarity between member of the same yeast group or of the same plant group. Whiting dashed-line ellipses are the significant correspondences between yeasts and host-plants. Percentage of contribution of each dimension to total variation is shown in parenthesis in the respective dimension. The points depicting the extreme correspondence of *Kurtzmaniella cleridarum* with *Opuntia dillenii* were extracted from the graphic analysis so that the remained correspondences are better observed. Yeasts: (a) *Starmerella* sp. , (b) *Wickerhamiella occidentalis*, (c) *Candida sorbosivorans*, (e) *Clavispora lusitaniae*, (f) *Metschnikowia ipomoeae*, (g) *Metschnikowia lochheadii* (h) *Metschnikowia* sp., (i) *Metschnikowia koreensis*, (k) *Vishniacozyma taibaiensis*, (l) *Saitozyma flava* (m) *Cryptococcus* sp.1, (n) *Cryptococcus laurentii* var. *laurentii*, (o) *Papilotrema flavescens*, (p) *Cryptococcus* sp.2, (q) *Naganishia liquefaciens*, (r) *Hannaella siamensis*, (s) *Kwoniella mangrovensis*, (t) *Rhodotorula paludigena*, (u) *Sporidiobolus ruineniae*, (v) *Sympodiomyopsis paphiopedili*, (w) *Ustilago sparsa*, (x) *Ustilago* sp. Host-plants: (1) *Agave angustifolia*, (2) *Bravaisia berlandieriana*, (3) *Gymnopodium floribundum*, (4) *Ipomoea crinicalyx*, (5) *Ipomoea hederifolia*, (6) *Ipomoea nil*, (7) *Ipomoea triloba*, (8) *Lonchocarpus longistylus*, (9) *Merremia dissecta*, (10) *Operculina pinnatifida*, (12) *Passiflora foetida*, (13) *Piscidia piscipula*, (14) *Tecoma stans*.

Figure 3(on next page)

Differential effects of nectar-living yeasts

Differential effects of four representative yeasts species (yeast cell density) on nectar sugars of floral nectar of their respective host plants. Statistical significance is shown for the p-values in each panel.

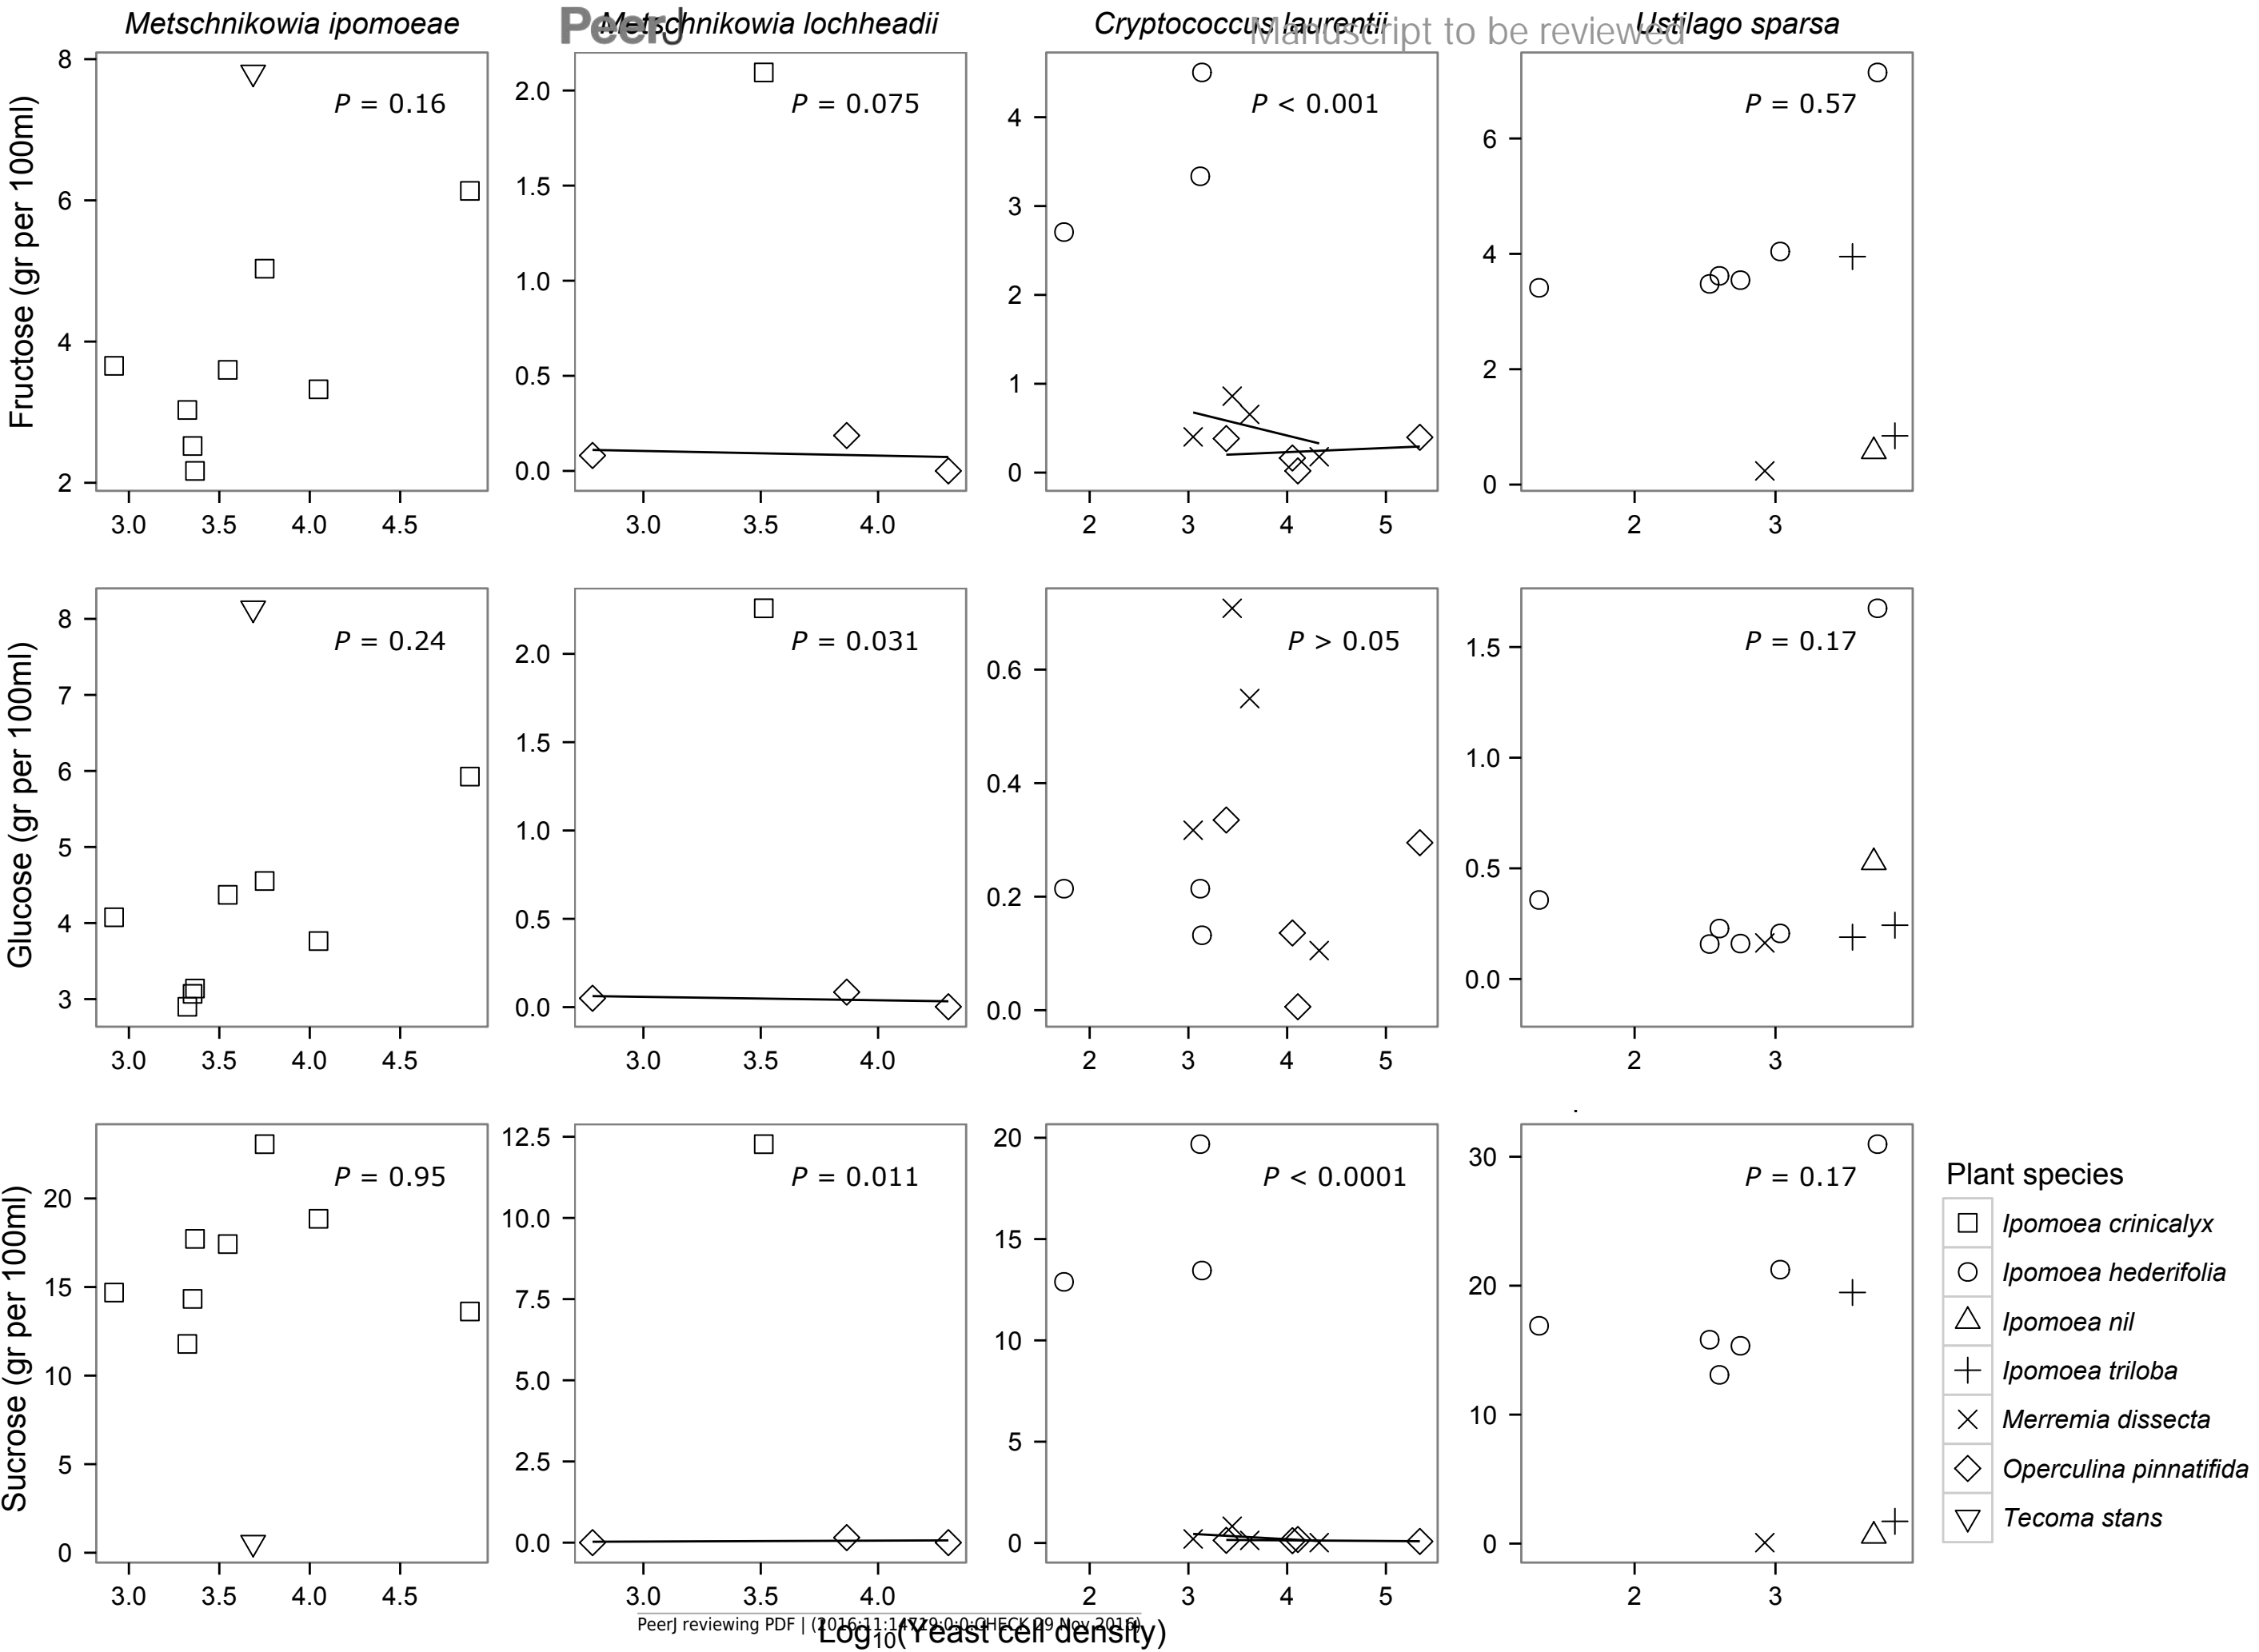

Table 1(on next page)

Yeasts isolated from floral nectar of tropical plants

Yeast species isolated from floral nectar in a tropical community of host-plants. Frequency of each yeast species in nectar samples is showed along with accession numbers.
