Long-term field studies are critical for our understanding of animal life history and the processes driving changes in demography. Here, we present long-term demographic data for the northernmost population of mantled howler monkeys (Alouatta palliata) residing in a highly anthropogenically fragmented landscape in Los Tuxtlas, Mexico. We carried out 454 monthly group visits to 10 groups of mantled howler monkeys between 2000 and 2011. The population remained relatively stable over the 11-year study period, with an overall increase in the total number of individuals. Birth rates and inter-birth intervals were comparable to those of howler monkeys at non-fragmented sites, suggesting that living in a fragmented landscape did not affect the reproductive output of our study population. Moreover, despite the landscape, dispersal events were commonplace, including many secondary dispersals (individuals emigrating from groups that they had previously immigrated into). Finally, we found a marked effect of seasonality on the dynamics of our study population. In particular, the period of lowest temperatures and resource scarcity between November and March was associated with higher mortality and reproductive inhibition, while the period of resource abundance between April and May was associated with the majority of conceptions and weaning of offspring. This, in turn, could be influencing dispersal patterns in our study area, as male howler monkeys seem to time some of their immigrations into new groups to coincide with the start of the period of higher fertility, while females preferentially joined new groups several months before the onset of this period. These data have important implications for the conservation and management of howler monkeys in fragmented landscapes, as well as for our understanding of the effect of seasonality over howler monkey dispersal, reproduction and survival.

#### 25 ABSTRACT

Long-term field studies are critical for our understanding of animal life history and the processes 26 27 driving changes in demography. Here, we present long-term demographic data for the 28 northernmost population of mantled howler monkeys (*Alouatta palliata*) residing in a highly 29 anthropogenically fragmented landscape in Los Tuxtlas, Mexico. We carried out 454 monthly 30 group visits to 10 groups of mantled howler monkeys between 2000 and 2011. The population 31 remained relatively stable over the 11-year study period, with an overall increase in the total 32 number of individuals. Birth rates and inter-birth intervals were comparable to those of howler 33 monkeys at non-fragmented sites, suggesting that living in a fragmented landscape did not affect 34 the reproductive output of our study population. Moreover, despite the landscape, dispersal 35 events were commonplace, including many secondary dispersals (individuals emigrating from groups that they had previously immigrated into). Finally, we found a marked effect of 36 37 seasonality on the dynamics of our study population. In particular, the period of lowest 38 temperatures and resource scarcity between November and March was associated with higher 39 mortality and reproductive inhibition, while the period of resource abundance between April and 40 May was associated with the majority of conceptions and weaning of offspring. This, in turn, 41 could be influencing dispersal patterns in our study area, as male howler monkeys seem to time 42 some of their immigrations into new groups to coincide with the start of the period of higher 43 fertility, while females preferentially joined new groups several months before the onset of this 44 period. These data have important implications for the conservation and management of howler 45 monkeys in fragmented landscapes, as well as for our understanding of the effect of seasonality 46 over howler monkey dispersal, reproduction and survival.

### 49 INTRODUCTION

50

51 Long-term field studies of primates, i.e., studies that cover at least an important proportion of 52 individual life cycles, are critical for our understanding of life history and the processes driving 53 changes in demography (Kappeler & Watts, 2012). However, field studies that have lasted long 54 enough to provide data spanning several generations have only been carried out on a very small 55 number of primate species (Kappeler & Watts, 2012), and the long-term studies that do exist are 56 usually limited to one or a handful of sites across the species' distribution. Given that 57 demographic patterns are contingent on local climate and vegetation, a comprehensive 58 understanding of the factors determining dispersal processes, mortality and fertility of primates 59 requires long-term studies to be conducted not only in different taxa, but also in different 60 landscapes and locations. Such studies are particularly important in modified habitats, where 61 monitoring demographic parameters in threatened populations may be critical for primate 62 conservation.

Long-term data on howler monkey (*Alouatta* spp.) demography is limited to studies of
red howler monkeys in Venezuela (*A. arctoidea*) (Crockett & Rudran, 1987; Rudran &
Fernandez-Duque, 2003), mantled howler monkeys in Panama (*A. palliata aequatorialis*)
(Milton, 1982, 1990, 1996) and Costa Rica (*A. p. palliata*) (Glander, 1992; Clarke et al., 2002;
Zucker & Clarke, 2003; Clarke & Glander, 2010), black and gold howler monkeys (*A. caraya*) in
Argentina (Kowalewski & Zunino, 2004; Zunino et al., 2007), and Central American black
howler monkeys (*A. pigra*) in Mexico (Dias et al., 2015).

70 Here, we present eleven years of demographic data from ten groups of mantled howler 71 monkeys (Alouatta palliata mexicana) residing in a highly fragmented landscape in the Los Tuxtlas Biosphere Reserve, Mexico. Despite howler monkeys having been studied since the 72 73 1980s in Los Tuxtlas (Cristóbal-Azkarate & Dunn, 2013), our knowledge of reproduction, 74 mortality and migration in this subspecies is very limited, and what data are available are mostly 75 based on indirect evidence from single population censuses and anecdotal observations (Estrada 76 & Coates-Estrada, 1996; Cristóbal-Azkarate, Dias & Veà, 2004; Cristóbal-Azkarate et al., 2005). 77 The motivation for this study was twofold. Firstly, we wanted to analyse population size, 78 dispersal patterns and reproductive parameters such as birth rates and inter-birth intervals in 79 order to understand the consequences of living in anthropogenically fragmented landscapes in 80 this taxon. Long-term data, from several groups, is essential in order to obtain reliable data on 81 such measures, as variation might be expected across both years and groups, and reproductive 82 parameters require observations over several consecutive years. Owing to widespread habitat 83 loss and fragmentation throughout its range, the remaining population of A. p. mexicana is now 84 restricted to highly fragmented forested areas which has led it to be listed as critically 85 endangered by the IUCN (Cuarón et al., 2008). Information generated by this study will be 86 useful to understand the capacity of these primates to adapt to transformed landscapes and help 87 develop informed projections of the conservation risk of this subspecies. 88 Secondly, we wanted to analyse the relationship between seasonality and howler monkey 89 dispersal patterns, reproduction and survival. Los Tuxtlas represents the northernmost limit of 90 mantled howler monkey distribution, and is near the northern limit of the distribution of the 91 genus (Cortés-Ortiz, Rylands & Mittermeier, 2015; Rylands et al., 2006). Previous studies 92 indicate that winter is a period of energetic stress due to the combined effect of increased

93	thermoregulatory demands and lower food availability (Cristóbal-Azkarate et al. in prep; Dunn et
94	al., 2013), but whether this has any impact over the fitness of this howler monkey population is
95	yet to be studied. Establishing correlates between climate and life history parameters will allow
96	us to better understand the challenges howler monkeys face at the extreme limits of their
97	distribution, and the responses they develop to cope with them.
98	
99	METHODS
100	
101	Ethics statement
102	This study is based on observational data and there was no direct interaction with the study
103	subjects. We were granted access to the study site by local communities, landowners, and the
104	Los Tuxtlas Biosphere Reserve, part of the National Commission of Natural Protected Areas of
105	Mexico (CONANP). All research adhered to the American Society of Primatologists Principles
106	for the Ethical Treatment of Non-Human Primates and to the legal requirements of Mexico.
107	
108	Study species
109	Five subspecies of mantled howler monkeys (Alouatta palliata) are currently recognised: A. p.
110	mexicana, A. p. palliata and A. p. aequatorialis, A. p. coibensis, and A. p. trabeata. These
111	subspecies are distributed from south-east Mexico to northwest Peru (Cortés-Ortiz, Rylands &
112	Mittermeier, 2015).
113	Mantled howler monkeys are seasonally folivorous, with leaves contributing over $80\%$
114	of food intake when fruit is scarce (Milton, 1980; Glander, 1981; Cristóbal-Azkarate & Arroyo-
115	Rodríguez, 2007; Dunn, Cristóbal-azkarate & Veà, 2010). This degree of folivory has been

116 associated with their small home range size compared to other more frugivorous species (Milton

117 & May, 1976) and primates living in small home ranges are considered to be more resistant to

118 habitat fragmentation (Cowlishaw & Dunbar, 2000).

119 Gestation lasts 6 months in mantled howler monkeys (Glander, 1980) and weaning 120 occurs at approximately 18-20 months of age (Carpenter, 1934; Clarke, 1990; Domingo-Balcells 121 & Veà-Baró, 2009). Age of first reproduction for females is approximately 41-43 months and 122 males reach maturity at approximately 48 months of age (Glander, 1980b; Domingo-Balcells et al., 2009). This species is characterized by bisexual emigration of juveniles; males typically 123 124 emigrate at around 22 months of age and females typically emigrate at around 33 months of age 125 (Glander, 1992). However, it has been suggested that in Los Tuxtlas juveniles may occasionally 126 emigrate as early as 14 months of age (Domingo-Balcells & Veà-Baró, 2009). Accordingly, the 127 11-year duration of our study covers an important proportion of a howler monkey's life cycle. 128 Recent evidence indicates that secondary dispersal (individuals emigrating from groups that they 129 have previously immigrated into) also exists in mantled howler monkeys and that this can be 130 driven by the sex ratio of groups (Clarke & Glander, 2010). Dispersal patterns can be disturbed 131 by relatively low levels of fragmentation (Chiarello & de Melo, 2001), as howler monkeys are 132 highly arboreal and spend almost all of their time in the upper canopy, very rarely coming to the 133 ground (Mendel, 1976).

134

#### 135 Study site

136 The Los Tuxtlas Biosphere Reserve represents the northernmost limit of tropical rainforest

137 distribution in the Americas (Guevara-Sada, Laborde & Sánchez-Ríos, 2004). Our study site (18°

138 39' 21"  $- 18^{\circ}$  31' 20" N and 95° 9' 14"  $- 95^{\circ}$  1' 45" W; elevation 0 - 400 m a.s.l) covers

140from extensive forest loss, transformation, and fragmentation, principally as a result of cattle141farming (Fig. 1). This occurred predominantly between 1976-1986, and the great majority of the142actual forest fragments were created during this time (Cristóbal-Azkarate, 2004). Nevertheless,143compared to many other fragmented landscapes, it retains a relatively high level of connectivity,144with live fences (i.e., several strands of barbed wire held up by a line of trees), riparian145vegetation and isolated trees found between many fragments, and a mean distance to nearest146fragment of 103 ± 172 m (Arroyo-Rodríguez, Mandujano & Benítez-Malvido, 2008). It also147contains areas of continuous forest in close proximity (less than 500m) to the fragments (Fig. 1).148The climate in Los Tuxtlas is warm and humid with a mean annual temperature of 25 °C149and rainfall of 4,900 mm (Soto, 2004). There is a dry season between March and May and a wet150season from June to February. During the wet season there is also a period of strong winds and a151considerable reduction in temperature between October and February (Fig. 2a). Long-term152records of phenological data in the region show that there are two distinet peaks in fruit153production: a primary peak at the end of the dry season -beginning of the rainy season (April-154June), and a shorter, less intense secondary peak in the wet season (August–October), while fruit155production abruptly falls to very low levels between November and March (Fig. 2b). The howler156monkeys in Los Tuxtlas respond to the reduction in temper	139	approximately 7, 500 hectares, and like many other regions throughout the tropics, it has suffered
142actual forest fragments were created during this time (Cristóbal-Azkarate, 2004). Nevertheless,143compared to many other fragmented landscapes, it retains a relatively high level of connectivity,144with live fences (i.e., several strands of barbed wire held up by a line of trees), riparian145vegetation and isolated trees found between many fragments, and a mean distance to nearest146fragment of 103 ± 172 m (Arroyo-Rodríguez, Mandujano & Benitez-Malvido, 2008). It also147contains areas of continuous forest in close proximity (less than 500m) to the fragments (Fig. 1).148The climate in Los Tuxtlas is warm and humid with a mean annual temperature of 25 °C149and rainfall of 4,900 mm (Soto, 2004). There is a dry season between March and May and a wet150season from June to February. During the wet season there is also a period of strong winds and a151production: in temperature between October and February (Fig. 2a). Long-term152records of phenological data in the region show that there are two distinct peaks in fruit153production: a primary peak at the end of the dry season-beginning of the rainy season (April-154June), and a shorter, less intense secondary peak in the wet season (August–October), while fruit155production abruptly falls to very low levels between November and March (Fig. 2b). The howler156monkeys in Los Tuxtlas respond to the reduction in temperature and fruit availability between157November and March by increasing their consumption of leaves and their foraging effort (Dunn,158Cristóbal-Azkarate & Veà, 2010), which, in turn, has been associated to h	140	from extensive forest loss, transformation, and fragmentation, principally as a result of cattle

161

#### 162 Study groups

163 We carried out the first census of our study site in 2000. Of the 55 forest fragments that are 164 found in our study site, we found 21 to be inhabited with at least one howler monkey and 165 recorded a population of 316 individuals living in 43 groups (Cristóbal-Azkarate et al., 2005). 166 We began studying four of these groups intensively in 2000. Over the following 10 years, we 167 studied six more groups as part of a programme of interdisciplinary research, for a total of 10 168 groups, which provided the data for our analyses (e.g. Cristóbal-Azkarate et al., 2006, 2007; 169 Dunn, Cristóbal-azkarate & Veà, 2010; Dunn et al., 2013). Despite the wide-ranging nature of 170 the research, we gathered basic demographic data, such as the number of individuals, age-sex 171 composition, births, deaths and migrations, over the 11-year period.

172

#### 173 Data collection

We present demographic data from 10 groups of howler monkeys, representing 454 monthly group visits, which were carried out between 2000 and 2011 (Table 1). Given that the data has been pooled across several different studies, there is some discontinuity, with certain groups being studied for longer and/or more frequently than others (mean  $\pm$  SD = 45.1  $\pm$  29.7 monthly visits per group; Table 1). The study groups inhabited eight different forest fragments, which varied in size, shape and connectivity (Fig. 1).

We identified group members by the distinguishing colour patterns on their feet and tails, which are characteristic of this subspecies. We created an identity sheet for each individual as a reference in the field, drawing and making notes on the distinctive features (Fig S1). Each time we recorded a new individual in a group, we assigned it an age and sex using the classification

#### PeerJ reviewing PDF | (2015:01:3824:2:1:NEW 31 May 2017)

184	system developed by Balcells and Vea (Domingo-Balcells & Veà-Baró, 2009), which allows an
185	age range to be estimated on the basis of morphological and behavioural characteristics.
186	
187	Demographic events
188	Throughout the study, we registered all demographic events in the groups, including: emigration,
189	immigration, birth and death. However, given the low probability of observing these events
190	directly, some of the events were also assumed to have occurred on the basis of changes in group
191	composition and supporting evidence.
192	
193	Birth
194	We assumed a new individual had been born in a group when a new dependent infant, which was
195	strongly associated with one of the group females, was observed in a group.
196	To calculate the mean annual birth rate for each group, we determined the number of
197	births that had taken place per year for the mean number of adult females in the group. This
198	allowed us to control for the effect of the number of females on birth rate. We defined the inter-
199	birth interval (IBI) as the time that occurred between births for any given female.
200	
201	Emigration
202	We assumed an individual had emigrated from a group when all of the following criteria were
203	met: 1) we had not observed the individual in the group for more than one month; 2) the last time
204	we observed the individual it showed no sign of disease or injury; and 3) the last time we
205	observed the individual it was fully weaned (unless emigrating with its mother). We also

206	classified an individual as having emigrated if it was observed in a new group or as a solitary
207	individual.
208	When an individual emigrated from the group it was born in, we defined this as `natal
209	emigration'. When an individual emigrated from a group that it had previously immigrated into,
210	we defined this as `secondary emigration'.
211	
212	Immigration
213	We assumed a new individual had immigrated into a group when, on first sighting, its estimated
214	age was greater than the time passed since our last visit to the group (e.g., a new individual with
215	an estimated age of 12 months was observed for the first time in a group, but the group was last
216	visited 2 months ago).
217	
218	Death
219	We assumed an individual had died when at least one of the following criteria was met: 1) we
220	found the body; 2) the individual went missing while still dependent on its mother's milk and its
221	mother remained in the group; or 3) the individual went missing fully weaned, but was showing
222	serious signs of injury or disease the last time it was observed.
223	
224	Disappeared
225	For some individuals it was not possible to determine with any confidence whether they had
226	emigrated or died. Therefore, we recorded these individuals as disappeared.
227	

228 Statistical analyses

229 For the calculation of the seasonality of demographic events, IBI and birth rates, we considered 230 only those events that were registered during periods in which the study groups were observed continuously and that could be assigned to a date with a maximum error of one month. In order 231 232 to control for the effect that our slightly unbalanced sampling effort could have on the 233 seasonality data, we weighted the original data by dividing the frequency of events per month by 234 the number of different visits to the same group within a month (mean  $\pm$  SD average visits per 235 month =  $37.6 \pm 3.1$ , range = 35 - 42; Table 1). We used these weighted values to calculate the 236 percentage of demographic events in each month.

237 We used ANOVAs to analyse the differences in annual birth rate and IBI among groups, 238 and reported eta squared ( $\eta^2$ ) as a measure of effect size (which is analogous to R<sup>2</sup> in regression 239 analyses). Values of  $\eta^2$  vary from 0 to 1 and values of 0.02, 0.13, and 0.26, and can be, as a rule 240 of thumb, considered as small, medium and large effects, respectively (Cohen, 1973). We also 241 used a Student's T test to test the hypothesis that the death of a suckling offspring,  $\leq 14$  months 242 of age (Domingo-Balcells & Veà-Baró, 2009), shortens the IBI by comparing the mean IBI of 243 females with surviving and non-surviving offspring, and reported Cohen's d (Cohen, 1977) as a 244 measure of effect size. For Cohen's d effect sizes of 0.2, 0.5, and 0.8, can be thought of as small, 245 medium and large, respectively (Cohen, 1977).

To test for differences in the frequency of demographic events between the season of energetic stress (November – March, see above) and the rest of the year, as well as to test for statistically significant differences between peaks in demographic events at certain times of year compared to the rest of the year, we conducted Chi-squared ( $X^2$ ) goodness of fit tests, with expected values being proportionally calculated according to the number of months used in the analysis. We calculated effect sizes for Chi-square tests using Cramer's phi coefficient ( $\varphi$ ),

252 whereby 0.1, 0.3, and 0.5 can be interpreted as small, medium and large effects (Cramer, 1999). 253 Furthermore, in order to account for the underlying continuity of the time variable, we also used 254 circular statistics to test for seasonality of demographic events (Batschelet, 1981). This approach 255 has several advantages over those traditionally used by primatologists to test for seasonality 256 (Janson & Verdolin, 2005; Gogarten et al., 2014). The mean vector length (r) obtained from 257 circular statistics is well suited as an index of seasonality, as it provides a measure of how evenly 258 events are distributed throughout the year. When events are spread evenly across months (not 259 seasonal), r is close to zero and when events are highly clustered at the same time of year (highly 260 seasonal), r is close to one. We tested the statistical significance of the r statistic using the 261 Rayleigh test (Batschelet, 1981), which compares the data with the null hypothesis that 262 demographic events have a random distribution across months. As we used monthly data for 263 demographic events, rather than specific dates, we also used a correction factor (c = 1.0115) 264 when calculating the r statistic (Batschelet, 1981). To test for bimodal distribution in the data, we also calculated r by doubling the angle calculated for each demographic event (Batschelet, 1981; 265 266 Janson & Verdolin, 2005; Gogarten et al., 2014). 267 We carried out analyses in R 2.13.1 (Team Development Core, 2008), testing for

268 normality in the data and considering p < 0.05 as significant.

269

#### 270 RESULTS

271

272 Overall, we observed an increase in the number of individuals in our population between 2000

and 2011. Most of the study groups showed little change in the number of individuals and in the

number of adult individuals from the start to the end of the eleven-year study period. However,

two groups showed a substantial increase in number (Table 2). Migration was the principal cause of change in group size and composition, followed by births, then deaths. An overview of the demographic events for which we were able to determine the date with a maximum error of one month is given in Table 1.

279

280 Births

We registered 75 births and at least two births were observed in all 10 of our groups (Tables 1 &
282 2). Of these, we were able to determine the date of birth to within one month on 49 occasions.

The mean birth rate per group was  $0.42 \pm 0.32$  births per female per year (N = 39 births; Table 3). There were groups with no births in some years, while other groups had a birth rate as high as 1 in some years (indicating that all females of reproductive age gave birth in that year). Although mean birth rate ranged from  $0.18 \pm 0.24$  to  $0.56 \pm 0.40$  births per female per year across groups (Table 3), we found no statistically significant differences in mean birth rate among groups (F<sub>9.29</sub> = 0.57, p = 0.81,  $\eta^2$  = 0.15).

289 The mean IBI was  $21.6 \pm 13.3$  months (N = 18; Table 3). Although mean IBI varied from 290  $11.0 \pm 4.2$  months to  $39.5 \pm 24.7$  months across groups (Table 3), we found no statistically significant difference among groups ( $F_{4,13} = 1.68$ , p = 0.22,  $\eta^2 = 0.34$ ). We observed 12 IBIs in 291 292 which the offspring from the first birth had survived until weaning (mean =  $26.1 \pm 14.1$  months) 293 and six IBIs in which the offspring from the first birth had died before weaning (mean =  $12.7 \pm$ 294 4.5 months), and found a significant reduction in IBI when the first offspring had died before 295 weaning (mean difference = 13.42, 95% CI = 3.89 - 22.95, t = 3.01, df = 16, p = 0.009, d = 296 1.28).

### Manuscript to be reviewed

297 Although we observed births throughout the whole year, births were clearly seasonal. 298 Seventy-four per cent of births occurred between October and March, with a main peak in 299 November and a smaller second peak in February (Fig. 3a & Table 1). Accordingly, the bimodal 300 r statistic was highly significant (unimodal r = 0.20, p = 0.14; bimodal r = 0.43, p < 0.001). As 301 the gestation time of howler monkeys is 6 months, and weaning occurs at approximately 18-20 302 months, these data indicate that conceptions leading to births and weaning peaked in May, after 303 the period of energetic stress. In fact, the number of conceptions leading to births was not equally 304 distributed, with fewer conceptions than expected during the period of energetic stress (10 305 conceptions between November and March) and more than expected during the rest of the year 306 (39 conceptions between April and October) ( $X^2 = 9.38$ , df = 1, p < 0.005,  $\varphi = 0.19$ ).

307

#### 308 Emigration

We recorded emigrations in all but one of our study groups, with 62 individuals emigrating from groups (Tables 1 & 2). Thirty-four of these were adults (13 adult males and 21 adult females), 7 were sub-adults (2 males, 2 females, and 3 of unknown sex), 13 were juveniles and 8 were infants.

We recorded 24 natal emigrations (52.8% of emigrations of known origin). One by an adult male, 6 by adult females, 3 by subadults, 11 by juveniles and 7 by infants. Of the 7 infants, 4 left the group soon after the birth of a sibling and 8 left the group soon after one or more individuals had immigrated into their group.

We recorded 22 secondary emigrations (47.8% of emigrations of known origin).
Nineteen of these were adults (11 males and 8 females), 1 was a male sub-adult, 1 was a juvenile
and 1 was an infant that transferred to the group together with her mother, and then left with her

after one month of permanence in the group. The mean time that the individuals spent in a group prior to secondary transfer was  $18.4 \pm 21.1$  months (range = 1 - 90 months).

On 16 occasions, we were not able to determine whether the emigrating individuals were born in the group they emigrated from or whether they had previously immigrated into the group. Accordingly these emigrations were of unknown origin and were not classified as natal or secondary.

326 Emigrations occurred throughout the year, but there were clear differences in emigration patterns among the age-sex classes (Fig. 3b, Tables 1 & 2). Male emigration peaked in August 327 328 (33.1% of cases) and January-February (43.9%), when more emigrations occurred than expected  $(X^2 = 8.57, df = 1, p < 0.005, \phi = 0.66; and X^2 = 8.14, df = 1, p < 0.005, \phi = 0.63, respectively),$ 329 330 female emigration showed a very clear peak in August-September (49.6% of cases), when more 331 emigrations occurred than expected ( $X^2 = 14.49$ , df = 1, p < 0.001,  $\varphi = 0.69$ ), and subadult and 332 juvenile emigration showed a peak in November-December (38.9% of cases), when more emigrations happened than expected ( $X^2 = 8.87$ , df = 1, p < 0.005,  $\varphi = 0.48$ ). However, the r 333 334 statistic for seasonality was non-significant in all cases, only trending towards significance in the 335 females (unimodal r = 0.34, p = 0.08).

336

#### 337 *Immigration*

We recorded immigrations in all the forest fragments that we studied and in all but one of our study groups (this group was only followed for one year). We recorded 57 individuals immigrating into new groups (Tables 1 & 2); 46 were adults (22 males and 24 females), 6 were sub-adults (3 males and 3 females), 3 were juveniles and 2 were infants. Of these, we were able to determine the date of immigration to within one month in 41 cases (Table 1).

343 Immigration occurred throughout the year, but there were clear differences in 344 immigration patterns among the age-sex classes (Fig. 3c, Tables 1 & 2). Adult male 345 immigrations peaked in April-May (40.5% of cases), when more immigrations occurred than 346 expected ( $X^2 = 5.88$ , df = 1, p < 0.05,  $\varphi = 0.39$ ) and again in September-December (52.2%), though this was not significantly more than expected by chance. Female immigration showed a 347 348 clear peak from September-December (79.3% of cases), when more immigrations occurred than expected ( $X^2 = 12.89$ , df = 1, p < 0.001,  $\varphi = 0.92$ ), and subadults and juveniles showed a peak in 349 350 immigration between August-September (65.3% of cases), when more immigrations occurred than expected ( $X^2 = 12.10$ , df = 1, p < 0.001,  $\varphi = 1.51$ ). Despite these peaks in immigration, the r 351 352 statistic for seasonality was non-significant in all cases

#### 353

#### 354 Deaths

We registered 18 deaths, and at least one death was registered in eight of the 10 groups (Table 2). 355 356 Thirteen of these individuals were infants: eight were younger than four months of age, three 357 between four and eight months, and two were 10 months of age. Of these, we only observed one 358 death directly, when, a one-month old infant died shortly after we found it lying by its dead 359 mother which was seemingly killed by another howler monkey (see below). On another occasion 360 we assumed that an infant had died shortly after its mother had died and it was observed falling 361 in a tree. We assumed one juvenile to have died having shown signs of physical weakness and 362 struggling to keep up with the group. The remaining four deaths were all adults. We recovered 363 the body of one female, which had several serious bite marks. Post-mortem examination by a 364 veterinarian found the cause of death to be lung perforation, consistent, in terms of bite shape, 365 breadth and depth, with an attack by another howler monkey (Escorcia-Quintana, personal

366	communication). One adult male probably died after we observed it with severe open wounds
367	resulting from an attack by two immigrating males. Another adult male showed signs of
368	paralysis and lethargy before his assumed death. A further adult male showed signs of old age,
369	lack of appetite and was unable to keep up with the group.
370	We registered deaths in most months of the year, but there was a clear peak between
371	November and March when 75.3% of deaths occurred (Fig. 3d, Table 1). There were more
372	deaths than expected during the period of energetic stress ( $N = 14$ ), and fewer than expected in
373	the rest of the year (N = 4) ( $X^2$ = 9.66, df = 1, p < 0.005, $\varphi$ = 0.54). However, the <i>r</i> statistic for
374	seasonality was not significant (unimodal $r = 0.08$ , p = 0.89; bimodal $r = 0.25$ , p = 0.30).
375	
376	Disappeared
377	We were unable to interpret the history of 27 individuals from the data, which we recorded as

We were unable to interpret the history of 27 individuals from the data, which we recorded asdisappeared (Table 2).

379

#### 380 **DISCUSSION**

381 We present data on 11 years of demographic events in 10 groups of mantled howler monkeys 382 living in an anthropogenic landscape in Mexico. Due to the discontinuous nature of our sampling 383 method, it is likely that we failed to record some events. For example, we might have missed short-term dispersal events, or births followed quickly by deaths. Also it is possible that some 384 385 events were recorded incorrectly: e.g., when we did not observe an individual in a group for 386 more than one month, we assumed that it had migrated, but it is also possible that it had died 387 suddenly, or been killed by a predator or conspecific. However, given that the number of 388 emigrations closely matched the number of immigrations, and that no natural predators of howler

monkeys remain in Los Tuxtlas (Cristóbal-Azkarate & Dunn, 2013), we consider our assumption
to be reasonable.

391 While acknowledging the limitations of our study, our data suggest a dynamic population 392 with frequent demographic change, including a large number of migrations, births and deaths. 393 While births were distributed throughout the year, they were highly seasonal, with a clear peak 394 between October and December and a secondary peak in February. Another study carried out in 395 a different area of Los Tuxtlas found similar results (Carrera- Sánchez, Medel-Palacios & 396 Rodríguez-Luna, 2003). This suggests that the majority of conceptions that lead to births occur 397 between April and June (Fig. 3a), coinciding with the annual peak in fruit availability and 398 increase in ambient temperature (Figs. 2a & 2b). Accordingly, our data suggest that the higher 399 energetic stress between November and March may be inhibiting the reproduction of females 400 and that the improved conditions from April to June results in an increase in fertility. Other 401 studies have also reported that the time of conception is associated with the availability of food 402 and temperature in howler monkeys (Kowalewski & Zunino, 2004). This supports the idea that 403 howler monkeys are income breeders (rather than capital breeders) and that they use energy 404 acquired during the reproductive period for reproduction instead of stored energy (Brockman & 405 van Schaik, 2005; Janson & Verdolin, 2005). Similarly, the weaning of offspring would also 406 occur in April and May, supporting the idea that the weaning of offspring in howler monkeys 407 occurs at times of year in which the availability of high quality food is higher and the climate is 408 more benign (Kowalewski & Zunino, 2004).

The mean birth rate of the study groups is within the range reported for other growing populations in the Neotropics (Table 3), which suggests that, in principle, our study population is not constrained by its reproductive output, and the IBI is also within the range previously

### Manuscript to be reviewed

reported for the species (Table 3). However, comparisons of birth rate and IBI across studies
should be made with caution, owing to differences in methods. The death of an infant
significantly reduced the IBI, a phenomenon also reported for other primate species (Fedigan &
Rose, 1995).

416 We recorded numerous migration events, with both emigration and immigration being 417 observed in almost all of the study groups. This included the groups that inhabited a forest 418 fragment with no other groups, as they all received immigrants, and all but one were a source of 419 emigrants. This suggests that, in our study landscape, howler monkeys are able to transfer 420 between forest fragments. This behaviour has also been reported elsewhere for howler monkeys, 421 and the probability of dispersal has been negatively related to the isolation distance of the 422 fragment and positively related to the connectivity of the fragment and heterogeneity of the 423 landscape (Glander, 1992; Mandujano, Escobedo-Morales & Palacios-silva, 2004; Estrada et al., 424 2006; Mandujano et al., 2006; Asensio et al., 2009). Accordingly, we believe that the high levels 425 of dispersal recorded in our study population are probably related to the high level of landscape 426 connectivity.

427 The high number of migratory events that we observed is a good sign for the long-term 428 viability of the population, as transfer among forest fragments may serve to mitigate the negative 429 effects of forest fragmentation on howler monkeys, by improving access to resources and promoting outbreeding. Unfortunately, we were unable to determine the exact origin and 430 431 destination of most migrations. Determining which groups and fragments are in migratory 432 contact with each other, in addition to identifying important dispersal routes, would allow for 433 better modeling of the dynamics of our study population and help identify priority areas for 434 conservation. This gap in our knowledge should be addressed in the future with research focused

435 on molecular genetic methods in addition to telemetry to follow the movement of individuals in436 the landscape.

437 Both natal and secondary emigration was common in our population. The fact that most 438 juveniles leave their natal group is well described in the literature (Glander, 1992), but it was not 439 until very recently that it was proposed that secondary dispersal may be a common and important 440 component of the reproductive strategy of mantled howler monkeys (Clarke & Glander, 2010). The fact that almost half of all emigrations in our study population were secondary dispersals 441 provides strong support for this hypothesis. While emigration was not found to be strongly 442 443 seasonal, males and females showed clear peaks (males in January-February and August; 444 females August-September) which preceded the peaks in immigration by less than two months 445 (Figs. 3b & 3c), while the emigration of subadults and juveniles peaked in November, coinciding 446 with the beginning of the period of fruit scarcity and higher levels of physiological stress (Dunn 447 et al., 2013). This could suggest that the timing of adult emigration might be associated with 448 factors determining the best time for transferring to a new group (e.g., resource availability and 449 reproduction), while the emigration of subadults and juveniles might be driven by competition 450 for food. However, we cannot rule out the possibility that the January-February peak in male 451 emigration might also be associated with competition for food. Without more information on the 452 life of solitary individuals in Los Tuxtlas, including data on the duration of this period for males 453 and females, it is not possible to draw any definitive conclusions from these data.

Like emigration, immigration was not found to be strongly seasonal in statistical terms. However, for both sexes these events were more common during the primary and secondary peaks in fruit availability and consumption by howler monkeys in Los Tuxtlas (Dunn, Cristóbalazkarate & Veà, 2010), which suggests that resident individuals may be more willing to accept

458 immigrants during periods of relative resource abundance. Moreover, the primary peak in male 459 immigration (April-May) coincides with the time when most conceptions leading to births 460 occurred. It is not clear whether in Los Tuxtlas immigrating males achieve alpha status 461 immediately upon immigration as described in Alouatta palliata palliata in Costa Rica (Glander, 462 1980a). However, several males were observed mating with females shortly after immigration 463 (pers. communication) and, nonetheless, mantled howler males are not reported to monopolize reproduction (Jones, 1995; Wang & Milton, 2003). Therefore, the availability of fertile females 464 may be driving, at least in part, the timing of immigration of males. On the other hand, by joining 465 466 the group several months before the onset of the period with the highest number of conceptions 467 leading to births (April-May), the females may have more time to achieve an adequate position in the group to maximise their chances for successful reproduction when the environmental 468 469 conditions are optimal.

470 The fact that we only recorded 3 immigrations by juveniles, but recorded 13 emigrations, suggests that the mortality of juveniles may be high during these periods, and/or that 471 472 immigration into groups is easier for fully grown adults and juveniles may need to spend several 473 years as solitary individuals before forming a new group or joining an established group 474 (Glander, 1992). Although intense fighting has previously been reported between resident males 475 and adult male immigrants (Clarke & Glander, 2004; Dias et al., 2010), and evidence from facial scarring and injuries suggests that fighting may be common in howler monkeys in Los Tuxtlas 476 477 (Cristóbal-Azkarate, Dias & Veà, 2004), we only observed one such fight during our study, and apart from this occasion, we did not observe any males with injuries following an immigration 478 479 event.

### Manuscript to be reviewed

480 We registered 18 assumed deaths, which were predominantly infants, although we were 481 unable to determine the cause of death for most of the cases. The fact that a group female was, 482 seemingly, killed by a conspecific while carrying a 1-month-old infant is noteworthy, and may 483 have been the result of an attempted infanticidal attack. However, this is speculative and, without 484 more information of the context and details of the event, it is difficult to interpret. One male 485 probably died after we observed it with severe open wounds resulting from an attack by two 486 immigrating males. Ignoring these cases, which were seemingly the result of intraspecific 487 aggression, deaths showed a clear pattern with 75% of total deaths, and 100% of adult deaths, 488 occurring in the period of energetic stress. Thus, it seems that energetic constraints may be an 489 important factor regulating the population dynamics of howler monkeys in the region.

490 Overall, our results suggest that the population of howler monkeys in Los Tuxtlas has 491 increased during the eleven-year study period (though this increase is largely due to two groups). 492 Moreover, we found migration events to be frequent between groups and fragments, despite the isolating effects of forest fragmentation. However, the study period was short relative to the long 493 494 life span and slow life-history of howler monkeys, and the fragmentation history is relatively 495 recent in the region, meaning that group size and composition may not yet be well suited to the 496 current environmental conditions. Only studies covering several generation-times, which 497 incorporate indices of health, reproduction and fitness (e.g., ecophysiology, molecular genetics) 498 in conjunction with intensive data on demographic evolution, would allow us to fully examine 499 the long-term conservation prospects of this population.

500

#### 501 ACKNOWLEDGEMENTS

- 502 This paper is dedicated to the wonderful memory of our colleague Dr Joaquim Vea-Baro,
- 503 founder of this long-term research project, who died in February 2016. Joaquim was a passionate
- 504 ethologist and primatologist, whose legacy in terms of both scientific output and the training of
- 505 students will continue for decades to come. We are grateful to all of the field assistants and
- 506 researchers that, during their time in the field, have collected demographic data for our analyses:
- 507 Lino Mendoza, Pedro Dias, Sira Vegas-Carillo, Blanca Hervier, Norberto Asensio, Iñaki
- 508 Aldekoa. We also thank Ernesto Rodríguez-Luna and Rosamond Coates for their valuable
- solution assistance with our research and Carmen Galán for help with Figure 1.
- 510
