Aim: To prospectively evaluate the effects of vitamin D₃ on disease activity and quality of life in ulcerative colitis (UC) patients with hypovitaminosis D. **Methods:** The study was a prospective double-blinded, randomized trial conducted at Community Regional Medical Center, Fresno, CA from 2012 - 2013. Patients with UC and a serum 25(OH)D level <30ng/ml were eligible for the study. Enrolled subjects were randomized to receive either 2,000 IU or 4,000 IU of oral vitamin D₃ daily for a total of 90 days. The Short IBD Questionnaire (SIBDQ) for quality of life, the Partial Mayo Score for UC disease activity and serum lab tests were compared between the two treatment groups. Matched pair t-tests were computed to assess differences between the vitamin D levels, CRP, UC disease activity and SIBDQ scores before and after vitamin D₃ therapy using SPSS version 21. **Results:** Eight UC patients received 2,000 IU/daily and ten UC patients received 4,000 IU/daily of vitamin D₃ for 90 days. Vitamin D levels increased after 90 days of oral vitamin D₃ in both dose groups. However, the increase in vitamin D levels after 90 days of oral vitamin D₃, in the 4,000 IU group was significantly higher 16.80 ± 9.15 ($p < 0.001$) compared to the 2,000 IU group of vitamin D 5.00 ± 3.12 ($p = 0.008$). Normal vitamin D levels (> 30 ng/dl) were achieved in four out of the ten UC patients (40%) in the 4,000 IU group and in one out of the eight UC patients (12%) in the 2,000 IU group. In the group receiving 4,000 IU/day of vitamin D₃ the increase in quality life scores (SIBDQ) was significant 1.0 ± 1.0 ($p = 0.017$) but not in the 2,000 IU vitamin D₃ group 0.1 ± 1.0 ($p = 0.87$). In the 2,000 IU of vitamin D₃ group the mean decrease in the Partial Mayo UC Score was -0.5 ± 1.5 ($p = 0.38$) compared to -1.3 ± 2.9 ($p = 0.19$) in the 4,000 IU vitamin D₃ group but this was not statistically significant. CRP levels decreased after 90 days of daily vitamin D₃ in both the 2,000 IU group and 4,000 IU group by -3.0 ± 9.4 ($p = 0.4$) and -10.8 ± 35.0 ($p = 0.36$) respectively. **Conclusion:** Vitamin D₃ may improve the quality of life and decrease disease activity in UC patients with hypovitaminosis D.

Funding:

This study was supported by a grant received from Central California Faculty Medical Group in Fresno, California.

IRB statement:

The Community Medical Centers Institutional Review Board granted approval to carry out this study within its facilities. (IRB Number 2012043)

Clinical trial registration statement:

The study is registered at www.clinicaltrial.gov. The registration identification number is NCT01877577.

Informed consent:

Before enrollment in the study, all study participants signed a written voluntary informed consent document approved by the IRB.

Conflict of Interest:

All the authors of the study have no conflicts of interest to declare.

Introduction:

Ulcerative colitis (UC) is an idiopathic, chronic, immune mediated disease that affects the gastrointestinal tract. It results from an exaggerated host immune response to luminal antigens or intestinal microflora in the gastrointestinal tract causing inflammation and has a relapsing and remitting course.^{1, 2} What triggers this exaggerated immune response is not clearly understood and is thought to be due to a complex interplay of genetic, environmental, immune and microbial factors.³ The concordance estimates of UC between twins is 20% or less, suggesting non-genetic factors also play a significant role in the pathogenesis of UC.⁴ There is an increasing emphasis in identifying both the intestinal microbiome and external environment factors which may play a major role in the pathogenesis of inflammatory bowel disease (IBD). Some environmental factors that have been associated with IBD include cigarette smoking, oral contraceptive use, vitamin D levels, dietary factors, stress, non-steroidal anti-inflammatory drugs, physical activity and duration of sleep.² Vitamin D is increasingly being identified as an important environmental factor influencing many chronic disease including cancers, cardiovascular disease, and autoimmune diseases such as multiple sclerosis and IBD.⁵

Vitamin D is a fat soluble vitamin and its role in maintaining and promoting bone health by increasing intestinal absorption of calcium is well known. However, the role of vitamin D as an immunomodulator is now being increasingly recognized. The first evidence of vitamin D as an immune regulator came in 1983^{6,7} with the discovery of vitamin D receptors (VDR) on immune cells- peripheral monocytes, leukocytes and antigen presenting cells- macrophages, dendritic cells and CD₄ and CD₈ T cells.⁸ Vitamin D can down regulate the inflammatory cascade by decreasing the proliferation of T cells (Th1), inhibiting cytokine production of IL-2 and INF- γ and inducing proliferation of regulatory T cells.⁹ 1,25 (OH)₂D₃ also inhibits differentiation of peripheral blood monocytes into dendritic cells.¹ The prevalence of vitamin D deficiency in UC patients ranges from 45-60%.¹⁰ Animal experiments, epidemiologic and genetic studies have suggested that vitamin D levels may influence IBD. Murine experiments with IL-10 knockout mice that are genetically predisposed to IBD, who are either deficient in vitamin D receptors (VDR) or were fed diets low in vitamin D, developed a fulminant and lethal enterocolitis within 6-8 weeks.⁸ VDR plays an important role in maintaining the integrity of the epithelial barrier which has been shown in animal experiments.¹¹ An arrest in IBD progression and symptom resolution in IL-10 knockout mice when supplemented with oral vitamin D suggest

that vitamin D may affect disease progression in IBD.¹² Furthermore, epidemiology studies also suggest a link between vitamin D and IBD with observations of greater prevalence of IBD at higher latitudes,¹³ low vitamin D levels seen in newly diagnosed UC patients in winter,¹⁴ and peak UC flares occurring in December. These observations suggest that vitamin D may account for the “north - south gradient” seen in the incidence of IBD.^{1, 15, 16} Further genetic studies also have also shown an association between single nucleotide polymorphisms in VDRs and the development of IBD.¹⁷⁻²⁰

Large population studies including the prospective Nurses Health Study have shown that increased vitamin D intake was associated with a reduced incidence of IBD.²¹ In a cross-sectional study of UC patients, vitamin D deficiency was independently associated with higher disease activity scores and increased steroid use than patients with sufficient vitamin D levels.²² Despite the evidence suggesting an association between vitamin D and IBD, there have been no prospective human studies looking at the effects of vitamin D₃ in patients with ulcerative colitis. The appropriate dose of vitamin D₃ in the management of IBD and hypovitaminosis D (vitamin D levels <30 ng/ml) is also not well understood. The purpose of this pilot study was to examine prospectively the effects of two different doses of vitamin D₃ on vitamin D levels, disease activity, and quality of life in UC patients with hypovitaminosis D.

Methods:

The Community Medical Centers Institutional Review Board granted approval to carry out this study within its facilities. (IRB number 2012043) The study was a prospective double-blinded, randomized pilot trial conducted at Community Regional Medical Center (CRMC) in Fresno, California from June 2012- July 2013. Patients with ulcerative colitis and serum 25(OH) vitamin D levels less than 30 ng/ml within a year of enrollment, were eligible for participation in the study. Exclusion criteria included age less than eighteen years, pregnant females and patients on vitamin D supplementation > 2,000 IU/day. All study participants signed a written voluntary informed consent document approved by the IRB prior to their enrollment in the study.

Ulcerative colitis patients at CRMC are routinely screened for vitamin D deficiency by checking serum 25(OH) vitamin D levels. Interested and eligible patients were referred by their providers to the research coordinator and co-investigators of the study for possible enrollment and were confirmed to meet eligibility criteria. Participants were required to come for two study

visits - first at the time of enrollment and next at the end of the ninety-day study period. During the initial visit each participant completed a data collection form including information regarding: age, sex, medical history, duration and location of UC, smoking history, current medications, sun exposure, and last corticosteroid use. At both study visits, participants completed two questionnaires together with the investigators and had serum blood drawn for laboratory studies. The two questionnaires included the Partial Mayo Score (PMS) to determine UC disease activity and the short IBD quality of life questionnaire score (SIBDQ) to measure quality of life in UC patients. The validated Partial Mayo Score for UC disease activity includes sub-scores ranging from 0-3 in the following categories: stool frequency, rectal bleeding, and physician's global assessment of well-being.²³ The Partial Mayo Score is the sum of these three sub-scores and ranges from zero which is normal and up to nine for severe disease. The validated ten item SIBDQ includes questions based on bowel, systemic, emotional and social domains with each question score ranging from 1-7. The total SIBDQ score is calculated by adding the total points of the ten items and then dividing it by ten with one being the lowest quality of life and seven being the highest quality of life.²⁴ Serum blood draws for laboratory studies were completed at both study visits and included: a complete blood count (CBC) with differential, liver function tests, renal function test, serum phosphorous, serum calcium, serum parathyroid hormone (PTH), erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) and 25(OH) vitamin D.

Each study participant was randomized to receive 2,000 IU/daily or 4,000 IU/daily of vitamin D₃ for ninety days. (Figure 1) The ninety day supply of vitamin D₃ for each subject was relabeled and packaged so that both the subjects and the investigators were blinded throughout the study. The packages were distributed by block-randomization among the study participants as they enrolled into the study and a record was kept by a randomization list. The sealed envelope with the randomization list was never opened by the investigators to unmask blinding until study completion. Medication compliance was evaluated through patient interview and by counting the number of pills left at the final visit. Adverse events of vitamin D were monitored for and participants were asked about any possible side effects associated with vitamin D toxicity during the study visits and with a follow up phone call at day forty-five.

Statistical Methods:

Funding limited the sample size and enrollment of this pilot study to twenty subjects. Partial Mayo Score for UC disease activity, SIBDQ score and serum lab values for 25(OH) vitamin D and CRP before and after ninety days of vitamin D₃ treatment were compared and analyzed between the 2,000 IU and 4,000 IU groups at the end of the study. The correlation between change in 25(OH) vitamin D levels and change in disease activity and quality of life scores were also compared across all study subjects using Pearson correlation coefficient. All tests were two-sided with a p value of $p < 0.05$ considered as statistically significant. Continuous variables were compared using student T-test and categorical variables were compared using Fisher's exact test. The data was analyzed using SPSS.

Results:

Twenty patients with ulcerative colitis and hypovitaminosis D were enrolled during the study period. Two patients were excluded from the study: one patient had normal vitamin D levels at the time of randomization, and one patient left the study without taking their vitamin D₃ treatment. Thus, a total of eighteen patients completed the study and were included in the analysis of results. Eight patients received 2,000 IU of vitamin D₃ and ten patients received 4,000 IU of vitamin D₃ for ninety days and were followed prospectively.

At study enrollment and baseline there were no significant differences in sex, age, smoking status, BMI, UC duration history, daily sun exposure and use of anti-TNF and immunomodulator therapies between the two treatment groups. Baseline serum levels of 25(OH) vitamin D, ESR, CRP, PTH, calcium, albumin, and phosphorus and SIBDQ quality of life scores were also similar between the two groups. The baseline Partial Mayo Score for UC disease activity was significantly higher in the 4,000 IU vitamin D₃ group compared to the 2,000 IU vitamin D₃ group, with a mean score of 4.0 versus 1.4 respectively. (Table 1) None of the patients enrolled in the study had a colectomy.

Vitamin D levels increased after ninety days of oral vitamin D₃ in both treatment groups. However, the increase in vitamin D level in the 4,000 IU group of 16.80 ± 9.15 ($p < 0.001$) was significantly higher compared to the increase in the 2,000 IU group of 5.00 ± 3.82 ($p = 0.008$). (Figure 2) Normal vitamin D levels (> 30 ng/dl) were achieved in four of ten (40%) of UC patients in the 4,000 IU group and in one of eight (12%) of UC patients in the 2,000 IU group

after ninety days of vitamin D₃ treatment. Quality of life scores as measured by SIBDQ increased among all the UC patients after ninety days of vitamin D₃. This increase in SIBDQ scores was statistically significant in the 4,000 IU vitamin D₃ group 1.00 ± 1.00 ($p=0.017$) but not in the 2,000 IU vitamin D₃ group 0.10 ± 1.00 ($p=0.87$). (Figure 3)

Overall UC disease activity scores decreased in both treatment dose groups after ninety days of vitamin D₃ however this change was not statistically significant. In the group receiving 2,000 IU of vitamin D₃ daily, the mean decrease in the Partial Mayo Score was -0.5 ± 1.5 ($p=0.38$) compared to -1.3 ± 2.9 ($p=0.19$) in the 4,000 IU group. (Figure 4) Similarly CRP levels overall decreased in both treatment dose groups after ninety days of vitamin D₃ however this change was not statistically significant. CRP level decreased by 3.0 ± 9.4 ($p=0.40$) in the group receiving 2,000 IU of vitamin D₃ and decreased by 10.0 ± 35.0 ($p=0.36$) in the 4,000 IU group. (Figure 5)

Across all eighteen UC patients in the study, the increase in vitamin D levels after ninety days correlated with an increase in SIBDQ quality of life scores with a Pearson correlation coefficient of 0.52, $p = 0.028$, and this increase in vitamin D level also correlated with a decrease in Partial Mayo UC activity scores at -0.58 , $p = 0.012$.

Discussion:

This is the first prospective randomized pilot study to our knowledge evaluating the effects of vitamin D₃ on the disease activity and quality of life in patients with UC. The prevalence of vitamin D deficiency in adults with ulcerative colitis has been reported to be as high as about 45-50% and has been attributed to various factors including decreased sunlight exposure, low oral vitamin D intake, disturbed enterohepatic circulation and increased loss of vitamin D as the result of protein-losing enteropathy.²⁵ However, it is unclear if vitamin D deficiency is an environmental trigger for autoimmunity in IBD or if IBD directly causes vitamin D deficiency. Factors that have been associated with lower QOL in IBD patients include: early age of onset, increased number of hospitalizations for flares, female gender, and low vitamin D levels.²⁵ This study evaluated the effects of oral vitamin D₃ on QOL after ninety days in patients with UC and hypovitaminosis D. The results show that UC subjects receiving 4,000 IU/day of vitamin D₃ had significantly higher quality of life scores after ninety days as compared to the

2,000 IU/day group. This suggests that higher doses of oral vitamin D₃ may be needed to achieve beneficial vitamin D levels and higher QOL in UC patients.

Vitamin D deficiency in IBD patients has also been shown to be an independent risk factor for higher disease activity scores and increased frequency of corticosteroid use.^{22, 25} Vitamin D affects both the innate and adaptive immune systems and leads to immune-tolerance of self-structures.²⁶ Vitamin D has been used in other autoimmune diseases such as multiple sclerosis, rheumatoid arthritis, and systemic lupus erythematosus and found to have a beneficial effect in reducing disease severity. Vitamin D through its receptors influences the maturation and differentiation of antigen presenting cells, dendritic cells and macrophages, resulting in the decreased activation of T cells and suppression of inflammatory cytokines¹ and may thereby reduce disease activity in IBD.

In this study oral vitamin D₃ for ninety days in UC patients decreased UC disease activity scores, but this failed to reach statistical significance. An explanation for this could be because only 40% of UC patients (4 of 10) in the 4,000 IU/day group and 12% (1 of 8) in the 2,000 IU/day group achieved sufficient vitamin D levels of >30 ng/ml after ninety days. This suggests that a longer duration or higher doses of vitamin D are required to achieve sufficient vitamin D levels >30 ng/ml to affect UC disease activity. It has been suggested that there may be two levels of vitamin D that could be relevant to the management of IBD: vitamin D levels less than <20 ng/ml that are associated with higher risk for developing osteoporosis, osteomalacia, or rickets and vitamin D levels >30 ng/ml which may ensure normal immune system regulation.¹ Oral vitamin D₃ was well-tolerated by all the study participants with no adverse events reported throughout the study. Serum calcium and parathyroid hormone levels were checked during the study and were normal. There were no signs or symptoms of vitamin D toxicity observed in either dose groups.

In this study, increases in vitamin D levels correlated with higher QOL scores and decreased UC disease activity scores in UC patients after ninety days of oral vitamin D₃. Other studies have shown normal vitamin D levels can predict a decreased incidence risk of IBD.²¹ Similarly lower vitamin D levels have been reported in newly diagnosed children with IBD.²⁷ To date there is no consensus on the appropriate dosage of vitamin D needed in patients with UC with vitamin D deficiency. This pilot study compared the effects of two different doses of vitamin D₃ with 2,000 IU/daily versus 4,000 IU/day in UC patients. Patients with UC who

received 4,000 IU/day of vitamin D₃ for ninety days had significantly higher vitamin D levels and increased quality of life scores compared to the 2,000 IU/day group. The UC group with 4,000 IU/day of vitamin D₃ also tended to have decreased UC disease activity scores and lower CRP levels compared to the 2,000 IU/day group after ninety days but these differences did not reach statistical significance and was most likely limited by the small sample size as a pilot study. Another limitation of the study was the lack of a placebo control group which was not feasible with the study investigators and IRB both agreeing that appropriate care would be to treat all UC patients with hypovitaminosis D with vitamin D replacement therapy. This study also does not include endoscopic evaluation for mucosal healing, and potential dietary sources of vitamin D may be a confounding variable.

This is the first prospective human study evaluating the effects of vitamin D₃ in UC patients with hypovitaminosis D. We conclude from this study that oral vitamin D₃ is effective in improving quality of life in UC patients with hypovitaminosis D and may decrease UC disease activity. Vitamin D₃ at a higher dose of 4,000 IU/day is more effective than a lower dose of 2,000 IU/day in increasing vitamin D to sufficient levels in UC patients with hypovitaminosis D, however higher doses or treatment beyond ninety days is likely needed. Further larger and longer-term studies are needed to investigate the effects of vitamin D in ulcerative colitis.

Figure 1: Study overview

IBD patients seen for clinical encounter get screened for vitamin D deficiency

Patients with UC and vitamin D deficiency are identified and enrolled after providing informed consent (n = 20)

Enrollment Visit - Day 0: (n = 20)

- Baseline medical history questionnaire
- Partial Mayo Score for UC disease activity
- SIBDQ quality of life score
- Serum labs drawn

2 patients excluded

- 1 normal 25(OH) vitamin D level
- 1 left study without taking vitamin D₃

Randomization (n = 18)

Vitamin D₃ 2,000 IU/day x 90 days
(n = 8)

Vitamin D₃ 4,000 IU/day x 90 days
(n = 10)

Completion Visit – Day 90 (n = 18):

- Partial Mayo Score for UC disease activity
- SIBDQ quality of life score
- Serum labs drawn
- Pill count for compliance

Analysis (n = 18)

Figure 2: Change in vitamin D levels after ninety days

Figure 3: Change in quality of life after ninety days

Figure 4: Change in UC disease activity after ninety days

Figure 5: Change in CRP levels after ninety days

432 **Table 1: Baseline characteristics**
433

Characteristic	Vitamin D ₃ 2,000 IU group (n = 8)	Vitamin D ₃ 4,000 IU group (n = 10)	p value
Sex: n (%)			
a) Male	7(88)	6(60)	0.20
b) Female	1(13)	4(40)	
Age in years at enrollment (mean, SD)	41.1 (13.7)	40.2 (16.2)	0.90
Ethnicity: n (%)			0.64
a) White	4 (50)	5 (50)	
b) Hispanic	3 (38)	3 (30)	
c) African American	1 (13)	0 (0)	
d) Asian	0 (0)	2 (20)	
Current smoker: n (%)			0.44
a) Yes	1(13)	0 (0)	
b) No	7 (88)	10 (100)	
BMI mean (SD)	27.78 (4)	25.7(5.4)	0.32
UC duration in years mean (SD)	3.7 (2.9)	5.2 (4.7)	0.57
Daily hours of sun mean (SD)	3.6 (2.4)	2.4 (2.5)	0.22
Baseline vitamin D level (ng/ml) mean (SD)	17 (5.24)	14.3 (4.24)	0.243
Partial Mayo UC disease activity score mean (SD)	1.4 (1.2)	4.0 (2.3)	0.03
SIBDQ score mean (SD)	5.6 (0.6)	4.8 (1.4)	0.21
ESR (mm/hr) (normal: 0-10) mean (SD)	10.5 (8.4)	27.0 (26.7)	0.20

CRP (mg/dl) (normal: 0-3) mean (SD)	6.9(8.8)	20.8 (34.8)	0.21
PTH (pg/ml) (normal: 14-72) mean (SD)	42.7(12.7)	46.4 (15.8)	1.0
Calcium (mEq/L) (normal: 8.5-10.5) mean (SD)	9.5(0.5)	9.3 (0.5)	0.6
Albumin (g/dl) (normal: 3.4- 4.8) mean (SD)	4.5 (0.3)	4.2 (0.6)	0.66
Phosphorous (mg/dl) (normal: 2.7-4.5) mean (SD)	3.2 (0.7)	3.7 (0.9)	0.38
