

## Population structure of *Bathymodiolus manusensis*, a deep-sea hydrothermal vent-dependent mussel from Manus Basin

Andrew D Thaler, William Saleu, Jens Carlsson, Thomas F. Schultz, Cindy L. Van Dover

Deep-sea hydrothermal vents in the western Pacific are increasingly being assessed for their potential mineral wealth. In order to anticipate the potential impacts on biodiversity and connectivity among populations at these vents, environmental baselines need to be established. *Bathymodiolus manusensis* is a deep-sea mussel found in close association with hydrothermal vents in Manus Basin, Papua New Guinea. Using multiple genetic markers (*cytochrome C-oxidase subunit-1* and 8 microsatellites), we examined population structure at two sites in Manus Basin separated by 40 km and near a potential mining prospect, where the species has not been observed. No population structure was detected in mussels sampled from these two sites. The genetic diversity observed can be used as a baseline against which changes in genetic diversity within the population may be assessed following the proposed mining event.

#### 14 **Abstract**

15 Deep-sea hydrothermal vents in the western Pacific are increasingly being assessed for their  
16 potential mineral wealth. In order to anticipate the potential impacts on biodiversity and  
17 connectivity among populations at these vents, environmental baselines need to be established.  
18 *Bathymodiolus manusensis* is a deep-sea mussel found in close association with hydrothermal  
19 vents in Manus Basin, Papua New Guinea. Using multiple genetic markers (cytochrome C-  
20 oxidase subunit-1 and 8 microsatellites), we examined population structure at two sites in Manus  
21 Basin separated by 40 km and near a potential mining prospect, where the species has not been  
22 observed. No population structure was detected in mussels sampled from these two sites. The  
23 genetic diversity observed can be used as a baseline against which changes in genetic diversity  
24 within the population may be assessed following the proposed mining event.

## 25 Introduction

26 Hydrothermal vents support large, endemic communities fueled by chemoautotrophic  
27 primary production (Gage & Tyler 1991; Van Dover 2000), in contrast to the relatively low-  
28 biomass deep seafloor. In southwest Pacific back-arc basins, active vents are patchily distributed  
29 and subject to local disturbances, including the waxing and waning of hydrothermal flow on  
30 short time scales and cessation of flow on millennial timescales (Van Dover 2000; Vrijenhoek  
31 2010). Species demographics may be driven as much by stochastic processes related to  
32 disturbance as by response to changing environmental conditions or other ecological phenomena  
33 (Vrijenhoek 2010; Thaler et al. 2014). In general, hydrothermal vent communities are thought to  
34 be more resilient to disturbance compared to other deep-sea ecosystems (Van Dover 2014).

35 Deep-sea hydrothermal vents are increasingly being explored for potential mineral  
36 extraction (Van Dover 2010). Almost 20% of all known global vent fields currently fall within  
37 mining exploration leases (Beaulieu et al. 2013). Establishing baselines for the diversity and  
38 connectivity of vent systems is a necessary first step in effective environmental management  
39 regimes (Collins et al. 2013). As vents become targets for mineral extraction, managers will need  
40 to assess regional biodiversity and connectivity and potential cumulative impacts of multiple  
41 mining events in a region (Boschen *et al.* 2013, Van Dover 2014) and design refugia to mitigate  
42 the impacts of mining on the vent ecosystem (Collins et al. 2012).

43 *Bathymodiolus manusensis* is a deep-sea mussel found at hydrothermal vents in the  
44 Manus Basin, Papua New Guinea. It commonly occurs around low-temperature diffuse-flow  
45 vent sites on the periphery of active hydrothermal chimneys (Hashimoto & Furuta 2007).  
46 Though *B. manusensis* shares close affinity with other bathymodiolin mussels in Lau and North  
47 Fiji Basins (*B. brevior*), *B. manusensis* is known only from a few sites within Manus Basin

48 (Hashimoto & Furuta 2007; Kyuno & Shintaku 2009). *B. manusensis* is one of several habitat-  
49 forming mollusks that host chemoautotrophic endosymbionts and derive chemical energy from  
50 hydrothermal vent effluent in Manus Basin (Galkin 1997). While other endosymbiont-hosting  
51 species at Manus Basin vents, such as *Ifremeria nautiliei* and *Alviniconcha* spp. (Urakawa et al.  
52 2005; Bouchet & Waren 1991; Kojima et al. 2001), tend to cluster around orifices where vent  
53 effluent is most concentrated, *B. manusensis* occupies the periphery of hydrothermal ecosystems,  
54 taking advantage of the less space-restrictive regions around diffuse flow sites (Kyuno &  
55 Shintaku 2009).

56         The Solwara 1 vent site in Manus Basin is licensed for extraction of metals associated  
57 with seafloor massive sulfides (Coffey Natural Systems 2008). While *B. manusensis* does not  
58 occur at Solwara 1, it is abundant at the neighboring Solwara 8 site (40 km distant) and at the  
59 proposed set-aside, South Su (2.5 km distant; (Coffey Natural Systems 2008)). Previous studies  
60 of connectivity in invertebrate taxa at these sites reveal species-specific patterns of connectivity  
61 among sites. *Ifremeria nautiliei* and *Chorocaris* sp. 2, two endosymbiont-hosting vent species  
62 show no signs of genetic differentiation among Solwara 1, Solwara 8, and South Su (Thaler et al.  
63 2011; Thaler et al. 2014) while significant local differentiation was detected in the vent-  
64 associated *Munidopsis lauensis* (Thaler et al. 2014). *B. manusensis* has a limited geographic  
65 range and is not ubiquitous at active vents in Manus Basin, leading us to anticipate that it might  
66 exhibit local-scale genetic differentiation. Because *B. manusensis* is absent from Solwara 1 and  
67 because Solwara 1 is situated between Solwara 8 and South Su, we tested the hypothesis that  
68 populations from South Su and Solwara 8 are isolated from each other, forming two genetically  
69 distinct populations.

70

71

## 72 **Materials and Methods**

73

74

### 75 **Sample collection and DNA extraction**

76 *Bathymodiolus manusensis* were collected from two hydrothermal vent sites in Manus  
77 Basin (Solwara 8 and South Su; Figure 1) during the *M/V Nor Sky* research campaign (June-July  
78 2008; Chief Scientist: S. Smith) using an ST200 ROV modified for biological sampling. For *COI*  
79 analyses, *B. manusensis* were analyzed from two discrete sulfide mounds at each site (Table 1),  
80 with 10 to 43 individuals per mound (Table 2). For microsatellite analyses, up to 142 individuals  
81 per locus were analyzed. All sampling was undertaken with the permission of the government of  
82 Papua New Guinea and did not involve endangered or protected species.

83 Mantle tissue was dissected from each individual and preserved in 95% ethanol prior to  
84 DNA extraction. Genomic DNA was isolated using a standard Chelex-Proteinase-K extraction  
85 (10–30 mg digested with 120 µg Proteinase K (Bioline: Taunton, MA) in 600 µl 10% Chelex-  
86 100 resin (Bio-Rad: Hercules, CA) overnight at 60°C, heated to 100°C for 15 min, and  
87 centrifuged at 10,000 rpm for 5 minutes; (Walsh et al. 1991). Extracted DNA was stored at 4°C  
88 until amplification and archived at -20°C.

89

### 90 ***COI* sequencing and analysis**

91 *Bathymodiolus manusensis* mitochondrial *COI* fragments were amplified using the  
92 following reaction conditions: 10 to 100 ng of DNA template was combined with 2 µL 10x PCR  
93 buffer (200 mM Tris, pH 8.8; 500 mM KCl; 0.1% Triton X-100; 0.2 mg/ml BSA), 2 mM MgCl<sub>2</sub>,  
94 0.2 mM dNTPs, 0.5 µM *LCOI1490* and 0.5 µM *HCOI2198* primers (Folmer et al. 1994), and 1  
95 unit of Taq polymerase in a 20 µL reaction with the following PCR protocol: initial melting  
96 temperature of 94°C for 240 seconds; 35 cycles of 94°C for 15 seconds, 48°C for 15 seconds,

97 72°C for 30 seconds; and a final extension of 72°C for 300 seconds. Reactions were stored at  
98 4°C until purification.

99 Fourteen  $\mu$ l of PCR product was incubated with 0.2 $\mu$ l 10X ExoAP buffer (500 mM Bis-  
100 Tris, 10 mM MgCl<sub>2</sub>, 1 mM ZnSO<sub>4</sub>), 0.05 $\mu$ l Antarctic Phosphatase (New England Biolabs:  
101 Ipswich, MA), 0.05 $\mu$ l Exonuclease I (New England Biolabs: Ipswich, MA) at 37°C for 60 min  
102 followed by 85°C for 15 min to remove unincorporated nucleotides. Sequencing reactions were  
103 executed with Big Dye Terminator v3 reactions (Applied Biosystems: Foster City, CA). AMPure  
104 magnetic beads (Agencourt: Morrisville, NC) were used to remove excess dye, products were  
105 analyzed on an ABI 3730xl DNA Analyzer (Applied Biosystems International), and  
106 chromatograms were edited using CodonCode Aligner (version 3.7.1; CodonCode Corporation:  
107 Dedham, MA). Consensus sequences were compared against the NCBI GenBank database to  
108 confirm identity when available (Benson 1997) and sequence alignments were constructed using  
109 the MUSCLE alignment algorithm (Edgar 2004) implemented in CodonCode Aligner.  
110 Representative sequences of dominant haplotypes were deposited in GenBank (Accession #  
111 KF498731 - KF498847). Full *COI* sequences for each individual are provided as FASTA files  
112 (Supplemental File 1).

113 Standard summary statistics, including number of haplotypes ( $H$ ), haplotype diversity  
114 ( $Hd$ ), nucleotide diversity ( $\pi$ ), and Fu's  $F_S$  were calculated using DnaSP version 5.10.01  
115 (Librado & Rozas 2009). To detect potential cryptic species, maximum-parsimony phylograms  
116 of aligned mitochondrial sequences were assembled in MEGA version 5 (10,000 replicates;  
117 Tamura 3-parameter substitution model determined by Mega 5: Find Best-Fit Substitution  
118 Model; Tamura et al. 2011). To visualize potential population structure, statistical-parsimony  
119 networks were assembled in TCS version 1.21 (default settings; Clement et al. 2000). To detect

120 population structure, Arlequin version 3.5.1.2 (Excoffier et al. 2005) was used to estimate  
121 pairwise  $\phi_{ST}$ . Sequential Bonferroni was used in all appropriate comparisons to correct for  
122 multiple tests (Rice 1989).

123

#### 124 **Microsatellite genotyping and statistical analyses**

125       Eight microsatellite markers (*Bm17*, *Bm22*, *Bm23*, *Bm53*, *Bm63*, *Bm76*, *Bm81*, *Bm83*)  
126 were amplified from *Bathymodiolus manusensis* in Manus Basin following methods reported in  
127 (Schultz et al. 2010). To test whether these markers provided sufficient power to evaluate the  
128 null hypothesis of genetic homogeneity, models of the dataset were implemented in POWSIM  
129 (Settings based on observed allele distributions, Supplement 1; Ryman and Palm, 2006). Full  
130 microsatellite genotypes for each individual are provided as GENPOP files (Supplemental File  
131 2).

132       Standard summary statistics, including divergence from expected Hardy-Weinberg  
133 Equilibrium (HWE) and allelic richness were assessed using GENEPOP (default settings;  
134 version 4.0; Rousset 2008) and Microsatellite Analyzer (version 4.05; Dieringer & Schlötterer  
135 2003), respectively. Permutation tests were used to determine significant variation in allelic  
136 richness (F-stat; default settings; version 2.9.3.2; Goudet 1995). MicroChecker (version 2.2.3;  
137 1000 randomizations; van Oosterhout et al. 2004) was used to detect the potential presence of  
138 null alleles, stutter, and large allele dropout. To test for the potential influence of selection, loci  
139 were screened using LOSITAN (25,000 simulations; IA and SMM; Antao et al. 2008; Beaumont  
140 & Nichols 1996).

141       Pairwise genetic differentiation ( $F_{ST}$ ) between aggregations, sites, and basins was  
142 analyzed using Microsatellite Analyzer. Alpha levels were adjusted via Sequential Bonferroni to

143 correct for multiple tests (Rice 1989). Structure version 2.3.3 (admixture model, sampling  
144 locations as prior distributions; Pritchard et al. 2000) was used to visualize potential population  
145 structure. Analyses were conducted with a 1,000,000 step burn-in, 10,000,000 repetitions, and 3  
146 replicates per level from  $K = 1$  to 7. Effective population size was estimated based on  
147 microsatellite linkage-disequilibrium using LDNe (default parameters; Waples & Do 2008).

148

149

**150 Results**

151 Of 21 *COI* haplotypes (409 bp) identified, 5 were shared at both sites, 3 were only found  
152 in Solwara 8 samples, and 13 were only found at South Su. *Bathymodiolus manusensis* from  
153 Solwara 8 (47 individuals) and South Su (53 individuals) in Manus Basin (Table 2) comprised a  
154 single haplogroup, based on *COI* analysis. A maximum of 5 base-pair mutations separated the  
155 most divergent haplotypes (Table 2, Figure 2). The statistical parsimony network for  
156 *Bathymodiolus manusensis* has a wheel-and-spoke topology, with a single central dominant  
157 haplotype and numerous low-abundance secondary haplotypes (Figure 2). The dominant  
158 haplotype is roughly evenly distributed among both sites and all relatively abundant haplotypes  
159 ( $n \geq 3$ ) occur at both Solwara 8 and South Su (Figure 2). Fu's  $F_S$  values for CO1 sequence data  
160 were significantly negative for samples pooled from both sites, as well as within sites and at  
161 Mound 1 (Solwara 8) and Mound 4 (South Su; Table 2).

162 Eight microsatellite loci were amplified from *Bathymodiolus manusensis* (35 to 142  
163 individuals per site; Table 3). Alleles per locus ranged from 3 to 20 (mean = 10). Allelic richness  
164 ( $R_s$ ) did not vary significantly among mounds or sites (10,000 permutations,  $P > 0.05$ ; Table 3)  
165 and neither balancing nor directional selection was detected at any spatial scale (LOSITAN,  $P >$   
166 0.05). Only one marker deviated from Hardy-Weinberg expectations and showed evidence for  
167 heterozygote deficiency at Solwara (*Bm53*; Table 3). POWSIM indicated that the sample set has  
168 sufficient statistical power to accept or reject the null hypothesis of genetic homogeneity.  
169 MicroChecker indicated that null alleles were present at that loci and were responsible for  
170 heterozygote deficiencies. As the presence of null alleles has been shown not to severely bias  
171 assignment tests (Carlsson 2008), this marker was included in subsequent analyses.

172 Analysis of Molecular Variance (AMOVA) and pairwise tests for population  
173 differentiation ( $F_{ST}$  and  $\phi_{ST}$ ) based on *COI* sequences and microsatellite markers indicated no

174 significant genetic differentiation among *Bathymodiolus manusensis* from Solwara 8 and South  
175 Su (Table 4). Assignment tests for combined *COI* and microsatellite data placed all *B.*  
176 *manusensis* into a single population (Structure,  $K = 1$ , data not shown). Effective population size  
177 estimated from microsatellite linkage disequilibrium was functionally infinite.

178

179

180 **Discussion**

181 **Population structure of *Bathymodiolus manusensis* in Manus Basin**

182 *Bathymodiolus manusensis* forms a single, coherent population between Solwara 8 and  
183 South Su in Manus Basin, Papua New Guinea. No genetic differentiation was detected at any  
184 spatial scale using either mitochondrial *COI* or nuclear microsatellite markers. Despite this  
185 apparent lack of population structure, *B. manusensis* is absent from Solwara 1, a site that occurs  
186 between Solwara 8 and South Su and that is within 2.5 kilometers of South Su. Further, Solwara  
187 1 shares many vent-dependent and vent-associated species with Solwara 8 and South Su (Coffey  
188 Natural Systems 2008; Erickson et al. 2009; Thaler et al. 2011; Thaler et al. 2014; Plouviez et al.  
189 2013).

190 The relatively homogeneous distribution of both *COI* haplotype and microsatellite  
191 markers for *Bathymodiolus manusensis* within Manus Basin is consistent with high gene flow  
192 between Solwara 8 and South Su. Similar levels of gene flow were observed in *Ifremeria nautilei*  
193 (Thaler et al. 2011) and *Chorocaris* sp. 2 (Thaler et al. 2014), although in both cases, the species  
194 were also found at Solwara 1. A significant, negative  $F_u$ 's  $F_S$  indicates that the population may  
195 have undergone a recent, rapid expansion, an observation consistent with other species examined  
196 from these sites (Thaler et al. 2011, Plouviez et al. 2013, Thaler et al. 2014). *COI* haplotype  
197 diversity is higher at South Su (0.59 compared to Solwara 8's 0.45; Table 2), however, there is  
198 no consistent pattern of microsatellite richness between the two sites, nor are unique alleles  
199 consistently identified at one site over the other.

200 In more than ten years of exploration and environmental observations, consisting of at  
201 least 4 research campaigns, neither *Bathymodiolus manusensis* nor any other mussel in the genus  
202 *Bathymodiolus* has been observed at Solwara 1 (Saleu, personal observation). Visual surveys of

203 the seafloor suggest that adequate habitat exists within the Solwara 1 site for *B. manusensis* to  
204 settle (Thaler, personal observation), although the fluid chemistry that might influence mussel  
205 recruitment has not been characterized for Manus vents. In a previous study, we identified a  
206 similar pattern of presence/absence among populations of *Munidopsis lauensis* at Solwara 8 and  
207 South Su (Thaler et al. 2014). One population of *M. lauensis* was found at Solwara 8 and South  
208 Su, but absent at Solwara 1, while a second population was restricted to samples from Solwara 1  
209 (Thaler et al. 2014). We hypothesized that sweepstakes effects related to the survival and  
210 settlement of recruits at vent sites in Manus Basin was responsible for the observed population  
211 structure of *M. lauensis* and that time series sampling would reveal a stochastic, dynamic  
212 distribution of these populations throughout the basin (Thaler et al. 2014).

213         That *Bathymodiolus manusensis* shares the same pattern of presence/absence with one  
214 population of *Munidopsis lauensis* suggests that the apparent exclusion of certain species or  
215 populations from Solwara 1 may be the result of a consistent, species- and population-dependent,  
216 dispersal barrier, rather than stochastic recruitment events. Other “leaky” dispersal barriers have  
217 been observed for hydrothermal vent populations across the equatorial East Pacific Rise  
218 (Plouviez et al. 2010; Plouviez et al. 2009; Vrijenhoek 2010), but those sites were separated by  
219 thousands of kilometers, whereas the Manus Basin sites are 2.5 to 40 km apart. In order to  
220 determine if there is a barrier restricting some, but not all, species (or populations) from  
221 recruiting to Solwara 1, we would need to sample additional species to identify consistent  
222 patterns across multiple taxa and sample the same species at additional time points to establish if  
223 observed patterns are temporally stable. The alternative hypothesis that species and populations  
224 are adapted to particular environmental conditions that are not always present at a site remains  
225 plausible (and not mutually exclusive), especially given well-documented evidence for such

226 circumstances in *Alviniconcha* species in Lau Basin (Beinart et al. 2012) and the lack of fluid  
227 chemistry data from evident and putative mussel habitats at Manus Basin vents.

228

### 229 **Implications for management strategies**

230         The limited distribution of *Bathymodiolus manusensis* and of a *Munidopsis lauensis*  
231 population within Manus Basin underscores the potential complexity of connectivity and habitat  
232 availability within vent ecosystems and the value of comprehensive environmental baselines  
233 prior to the initiation of an extractive regime (Collins et al. 2012; Collins et al. 2013; Thaler et al.  
234 2014; Boschen et al. 2016). It is possible that multiple mining events in Manus Basin could  
235 affect source-sink dynamics of *Bathymodiolus manusensis* and other taxa, resulting in regime  
236 shifts in vent communities of Manus Basin as has been noted in other marine ecosystems  
237 (Scheffer & Carpenter 2003). A similar phenomenon was observed in Moorea coral reef  
238 communities, where persistent disturbance, caused, in this case, by invasive crown-of-thorn  
239 starfish resulted in permanent changes in community structure as opportunistic recruits occupied  
240 newly exposed ecologic niches (Berumen & Pratchett 2006).

241         The potential for regime shifts, where species not present at the disturbance site but  
242 occurring at neighboring sites establish a foothold following anthropogenic impacts, creates a  
243 challenge for environmental management and mitigation programs. At the very least, there is a  
244 need to understand if such a regime shift constitutes a significant adverse impact that should  
245 trigger a management response. Managers need to understand the extent of local variation in  
246 population and community structure to anticipate cumulative impacts and ecological  
247 consequences of regime changes following disturbance.
