46 Abstract

47 Carbon nanotubes (CNTs) have a broad range of applications and are generally considered
48 human-engineered nanomaterials. However, carbon nanostructures have been found in ice cores
49 and oil wells, suggesting that nature may provide appropriate conditions for CNT synthesis.
50 During forest wildfires, materials such as turpentine and conifer tissues containing iron under
51 high temperatures may create chemical conditions favorable for CNT generation, similar to those
52 in synthetic methods. Here, we show evidence of naturally occurring multiwalled carbon
53 nanotubes (MWCNTs) produced from *Pinus oocarpa* and *Pinus pseudostrobus*, following a
54 forest wildfire. The MWCNTs showed an average of 10 walls, with internal diameters of ~2.5
55 nm and outer diameters of ~14.5 nm. To verify whether MWCNT generation during forest
56 wildfires has a biological effect on some characteristic plant species of these ecosystems,
57 germination and development of seedlings were conducted. Results show that the utilization of
58 comparable synthetic MWCNTs increased seed germination rates and the development
59 of *Lupinus elegans* and *Eysenhardtia polystachya*, two plants species found in the burned forest
60 ecosystem. The finding provides evidence that supports the generation and possible ecological
61 functions of MWCNTs in nature.

62

63 Introduction

64 Carbon nanotubes (CNTs) have been the subject of extensive research in recent years because of
65 their extraordinary properties and broad range of biotechnological applications. Although CNTs
66 are commonly considered human-engineered nanomaterials, it has been generally accepted that
67 nature may provide appropriate conditions for their synthesis. CNT occurrences have usually
68 been sought in extreme environments (e.g., at high temperatures and pressures), where evidence

69 has suggested their formation. For example, encapsulated CNTs have been found in the coal-
70 petroleum mix of oil wells (Velasco-Santos et al. 2003) and in Greenland ice-core samples dated
71 from the Neolithic Stone Age (10,000 years ago) (Esquivel & Murr 2004); however, the source
72 of these CNTs has not yet been identified. There have also been questions regarding the validity
73 of these reports because of the lack of clear high-resolution transmission electron microscopy
74 (HR-TEM) images, Raman analysis, or diffraction patterns (Mackenzie et al. 2008).

75 Previous studies have speculated that CNTs can form in volcanoes, based on the observation that
76 Mount Etna's lava can catalyze the synthesis of multiwalled CNTs (MWCNTs) (Su et al. 2008;
77 Su & Chen 2007). However, no direct evidence of the formation of CNTs within volcanoes has
78 been confirmed. Further, plant products such as turpentine, eucalyptus oil, neem oil, palm oil,
79 and olive oil have been used as raw materials for chemical vapor deposition (CVD) in CNT
80 synthesis (Afre et al. 2005; Ghosh et al. 2007; Kumar et al. 2011; Suriani et al. 2009). In
81 addition, plant and fungal tissues containing transition metals have been used as natural catalyst
82 precursors in the production of CNTs by CVD (Zhao et al. 2011).

83 Oleoresin extraction is commonly performed in the forestlands of Michoacán, México, where
84 oleoresin is collected from the trunks of living pines, and turpentine is obtained from steam
85 distillation. Alpha-pinene, which is used as a raw material for solvent production, is one of the
86 most important components of turpentine documented as an effective compound from which
87 high-quality and high-yield MWCNTs can be synthesized by CVD (Lara-Romero et al. 2011).

88 Pine species such as *Pinus leiophylla*, *Pinus oocarpa*, *Pinus montezumae*, *Pinus pseudostrobus*,
89 and *Pinus teocote* are considered the most important tree species for oleoresin extraction in the
90 Mexican industry. The ecosystems in Michoacán, México, associated with these species of
91 conifers are prone to wildfires. During the drought season, wildfires can cause temperatures

92 between 600 and 900 °C; this, coupled with the presence of turpentines (or alpha-pinene) and
93 conifer tissues containing iron, provides conditions similar to those required for CNT formation
94 in a process like CVD.

95 Moreover, MWCNTs have also been described as plant growth promoters, favoring seed
96 germination and an increase in the fresh weight of tomato plants (Khodakovskaya et al. 2012;
97 Yang et al. 2017). Recently, nanotechnology tools have developed CNTs for potential
98 applications in agriculture, including crop protection, pollution control, waste management,
99 pesticide detection, nanosensing, and as nanofertilizers (De La Torre-Roche et al. 2012; Gogos et
100 al. 2012; Hong et al. 2013; Khodakovskaya et al. 2012; Yang et al. 2017). Contrary to the
101 beneficial applications of CNTs, negative effects of nanoparticles on edible plants have also been
102 discussed (Miralles et al. 2012); thus, the known effects of MWCNTs on plants are still limited,
103 as are the responses of the natural and agricultural ecosystems to human-engineered
104 nanomaterials (Yang et al. 2017).

105 This report, as a first attempt to understand the roles of crystalline nanomaterials in plant
106 ecosystems and to scarce evidence of naturally-formed MWCNTs in the biosphere. The main
107 objective of this study was to provide evidence of spontaneously and naturally occurring
108 MWCNTs from *Pinus* species following a forest wildfire event, and their possible effects on
109 germination and development of species found in the burned forest ecosystem.

110

111 **Materials & Methods**

112 ***Sample collection from a pine forest***

113 During the dry season (June 2012), samples of burned wood were randomly collected from
114 mature trees of two different pine forest sites in Michoacán, west-central México, which had

115 been recently affected by forest wildfires. The sites were 'Cerro Huashan, Nahuatzen' ($19^{\circ}38'35''$
116 N, $101^{\circ}56'46''$ W; sampling *P. oocarpa* 2 weeks after fire extinguishment) and 'Cerro de la Cruz,
117 Uruapan' ($19^{\circ}26'40''$ N, $102^{\circ}2'56''$ W; sampling *P. pseudostrobus* and *P. montezumae* 8 weeks
118 after fire extinguishment). At least 20 samples of each pinus species were collected from each
119 forest wildfire site. Sampling was collected under the supervision of the Ministry of Environment
120 and Natural Resources specifications (Nom-059-SEMARNAT-2010) and the conservation
121 program for flora and fauna of the Pico de Tancítaro (APFFPT) from Michoacán, México;
122 established by the Mexican decree law of august 19, 2009; and the Program for the Sustainable
123 Management of Mountain Ecosystems Pico de Tancítaro, Michoacán, México (APFFPT-2009).
124 Wood samples were ground and thoroughly mixed for further analyses.

125

126 **CNT analysis**

127 Samples of burned wood from various types of pine trees were characterized by Raman
128 spectroscopy, thermogravimetry (TGA), and high-resolution transmission electron microscopy
129 (HR-TEM), at least 20 samples of each pinus species were analyzed. Raman spectroscopy was
130 performed using a micro-Raman spectrometer (Labram System model Dilor) equipped with a 20
131 mW He-Ne laser emitting at 514 nm, a holographic notch filter (supertNotch-Plus, Kaiser
132 Optical Systems, Inc.), and a 256×1024 pixel charge-coupled device (CCD) image recorder. All
133 measurements were carried out at room temperature with no special sample preparation.
134 TGA was carried out using a microbalance (Chan D-200) (Doudrick et al. 2012), where 40–50
135 mg samples of burned wood from the different pine species collected after a natural fire and
136 MWCNTs synthesized by spray pyrolysis of α -pinene/ferrocene were air-heated between 25 to
137 700 °C at a rate of 5 °C/min, to obtain TGA combustion curves of the samples.

138 HR-TEM micrographs were obtained from a Philips CM-200 analytical TEM operating at 200
139 kV. Specimens for HR-TEM analysis were prepared by dispersing the samples in acetone
140 through sonication for 2 min and air-drying a drop of the suspension on a perforated, carbon-
141 coated Cu° grid.

142

143 ***Seed germination and plant pot-growing using synthetic MWCNTs***

144 Seeds of *Lupinus elegans* and *Eysenhardtia polystachya*, collected from the pine forest of
145 Michoacán, México, were sterilized with 95% sulfuric acid for 20 min and by soaking in 1%
146 sodium hypochlorite (NaOCl) for 3 min, respectively; both were then rinsed with sterile distilled
147 water. The seeds of each species were divided into six separate sets of 100 seeds and incubated
148 in a suspension of 0 (Control), 10, 20, 30, 40, or 50 µg/mL MWCNTs (Sigma-Aldrich, St. Louis,
149 MO, USA; Cat. No. 698849; CVD-produced synthetic multiwalled CNTs, OD = 6.0–13.0 nm,
150 ID = 2.0–6.0 nm length = 2.5–20 µm, average wall thickness 7–13 graphene layers, > 98%
151 purity) for 10 min. The MWCNTs were dispersed in water by a three-step acid treatment. First
152 step consists on ultrasonic mixing the MWCNTs with concentrated HCl for 4 h, after refluxing
153 MWCNTs in nitric acid for 8 h at 80°C, and finally refluxing sample in a 1:1 mixture of sulfuric
154 and nitric acids for 4 h at 80°C. Each seed set was then placed on moistened filter papers in five
155 Petri plates (20–30 seeds per plate) and randomly distributed in a germination chamber.
156 Germination was evaluated after 10 days of incubation at 26 °C with a 12:12 light/dark cycles.
157 Pot-growing tests examined samples from all six treatments, each with 12 replicates (72 plants in
158 total for each seed type). Previously sterilized seeds (as described above) were directly planted in
159 5-cm-diameter polyethylene containers filled with 375 mL of the growth medium (Creci-root)
160 provided by a local nursery. These containers were then divided into six separate sets and seeds

161 were treated directly with 1.0 mL of a suspension of either 0 (Control), 10, 20, 30, 40, or 50
162 µg/mL MWCNTs, then covered with ~1.0 cm of plant growth substrate. The containers were
163 arranged at random in trays and watered on alternate days for 5 weeks. At the end of the 5-week
164 period, the plants were harvested, and biometric variables (leaf area and, fresh and dry weights of
165 shoots and roots) were recorded. Data were statistically analyzed using Graph Pad software with
166 an analysis of variance (one-way ANOVA), and mean were compared using Tukey's post hoc
167 tests at a significance level of $p < 0.05$.

168

169 Results

170 ***Identification and characterization of CNTs in the burned wood of resinous forests, after*** 171 ***wildfire***

172 Burned wood samples were collected after an intense wildfire in a resinous pine forest in the
173 Michoacán state of Mexico (June 2012). This forest mainly comprised *P. oocarpa*, *P.*
174 *pseudostrobus*, and *P. montezumae*. Samples of the carbonized trees of these species were first
175 analyzed by Raman spectroscopy. The Raman spectra of three different burned wood samples
176 indicate that *P. oocarpa* and *P. pseudostrobus* samples show characteristic bands for CNTs, *i.e.*,
177 the *D* and *G* bands (Fig. 1A). The *D* band was observed at approximately 1370 cm⁻¹, and the *G*
178 band, also known as the tangential band, was observed at approximately 1600 cm⁻¹, which arises
179 from the *E_{2g}* mode of the graphite plane and confirms the presence of sp² electronic hybridization
180 in the carbon bond network. Unexpectedly, the 2*D* (*G'*) band, which is associated with the source
181 or metal load and temperature during synthesis, was not found in the Raman spectra. Moreover,
182 no CNT signals were detected in the samples of burned tree bark obtained from *P. montezumae*
183 (Fig. 1A).

184 Thermogravimetric analysis (TGA) was used to determinate the amount of MWCNTs in the
185 burned wood of *P. oocarpa*, *P. pseudostrobus*, and *P. montezumae* (Fig. 1B). Weight losses up to
186 ~150 °C correspond to the release of water contained in the samples, whereas weight losses in
187 the range of 200–300 °C and 300–400 °C are attributed to the degradation of hemicellulose and
188 cellulose, respectively. Weight losses in the range of 370–550 °C are attributed to the ligneous
189 components such as biochar (Esquivel & Murr 2004; Mackenzie et al. 2008; Velasco-Santos et
190 al. 2003). Relevantly, the weight loss detected at 610 °C in the *P. oocarpa* samples, which
191 coincides with that in a synthetic-origin MWCNTs sample, corresponds to CNT combustion.
192 Thus, according to the TGA analysis, *P. montezumae* contains approximately 10% (w/w)
193 moisture, 38% (w/w) hemicellulose, 46% (w/w) cellulose, and 4% (w/w) ligneous species; *P.*
194 *pseudostrobus* is composed of approximately 5% (w/w) moisture, 7% (w/w) hemicellulose, 22%
195 (w/w) cellulose, and 66% (w/w) of ligneous components; and *P. oocarpa* is composed of
196 approximately 14% (w/w) moisture, 18% (w/w) hemicellulose and cellulose, and 60% (w/w)
197 ligneous components. Relevantly, the TGA plot indicates that the burned wood samples of *P.*
198 *oocarpa* contained ~2.8% (w/w) of CNTs and *P. pseudostrobus* less than 0.1% (w/w), and the
199 remaining weight of ~5–10% (w/w) is attributed to metals and elements.
200 HR-TEM images and fast Fourier transforms (FFTs) of the *P. oocarpa* samples clearly indicated
201 the presence of CNTs. HR-TEM images and their corresponding FFTs show diffraction patterns
202 characteristic of graphitic crystalline carbon (Fig. 2A–C). HR-TEM data obtained from *P.*
203 *oocarpa* samples revealed the presence of highly crystalline MWCNTs, consisting of 10 walls
204 with inner and outer diameters of ~2.52 nm and ~12–15 nm, respectively (Fig. 2C). The FFT
205 image displayed one pair of sharp spots, and a line scan along those spots confirmed the presence
206 of sharp spots corresponding to highly ordered carbon (narrow spots). The estimated plane-to-

207 plane distance between the walls is 0.335 nm, which is in agreement with the nominal distance
208 between the planes in crystalline CNTs (Fig. 2D–E). The bright spots in the dark-field HR-TEM
209 images indicate the presence of metals on the carbon tubes, and the corresponding energy-
210 dispersive X-ray spectroscopy (EDS) analysis confirmed the presence of iron (Fig. 2F),
211 suggesting that this iron could have acted as a catalyst during CNT formation.

212 For the burned wood samples of *P. pseudostrobus*, HR-TEM images and the corresponding FFT
213 data show preferential formation of coil-shaped nanoparticles consisting of curved crystalline
214 multiwalled carbon layers (Fig. 3A). The FFT images of these MWCNTs reveal one pair of
215 sharp spots and a line scan along those spots confirmed the presence of highly ordered carbon.
216 The estimated distance between the lattice fringes of the carbon walls is 0.335 nm, which is in
217 agreement with the nominal distance between the planes of graphite (Fig. 3B–C). The
218 corresponding EDS analysis reveals the presence of several elements such as calcium, potassium,
219 and phosphorous, but no evidence of the presence of iron or other transition metals is found (Fig.
220 3D). Unexpectedly, no evidence of CNT structures was found in *P. montezumae* samples;
221 however, amorphous carbon structures were abundant (Fig. 4A–B). The FFT spectrum displayed
222 diffuse spots, characteristic of amorphous carbon, and EDS analysis confirmed the presence of
223 iron, calcium, and phosphorous (Fig. 4C–E). These findings provided evidence of naturally
224 occurring MWCNTs from *Pinus* species after forest wildfire events.

225

226 ***Synthetic multiwalled CNTs increase seed germination in plants growing in resinous Pinus***
227 ***forests***

228 The MWCNTs found in burned *P. oocarpa* and *P. pseudostrobus* wood samples had ~10 layers,
229 with an inner diameter of ~2.52 nm and an outer diameter of ~14.59 nm. To investigate if

230 MWCNTs with structural features similar to those found in the natural samples could have a
231 biological effect over some plants species characteristic of these ecosystems (*L. elegans* and *E.*
232 *polystachya*), we conducted a germination and development of seedlings test. This assay was
233 based on previous studies on the positive or negative effects on plant germination and the
234 development of seedlings grown by MWCNT treatment (Hong et al. 2013; Khodakovskaya et al.
235 2012; Miralles et al. 2012). We supplemented the seed germination and early seedling growth
236 with 10–50 µg/mL of the synthetic MWCNTs with structural features similar to those found in
237 the *P. oocarpa* and *P. pseudostrobus* wood samples of burned forest (average wall thickness ~7–
238 13 layers; inner diameter of ~2–6 nm; outer diameter of ~12–20 nm; length of 2.5–20 µm).
239 Seed germination results showed that the addition of MWCNTs increased the number of
240 germinated seeds and significantly shortened the germination period (Fig. 5A). Seeds of *L.*
241 *elegans* and *E. polystachya* treated with MWCNTs exhibited increased germination rates
242 compared to untreated seeds. For *L. elegans*, a prolific plant in this forest, seed germination rates
243 were 62.5% higher after the addition of 30 µg/mL of the synthetic MWCNTs compared to those
244 of untreated plants. Moreover, *E. polystachya* seeds treated with MWCNTs reached germination
245 rates 40% higher than those of the untreated seeds (Fig. 5A–C).
246 We further investigated the effects of MWCNTs on the growth and development of *L. elegans*
247 and *E. polystachya* seedlings by growing them in a medium supplemented with different
248 concentrations of the synthetic nanoparticles and measuring the yield of variables such as fresh
249 and dry plant biomass, number of lateral roots, and foliar area (Fig. 6A–B). *L. elegans* plants
250 germinated and grown in the MWCNT dose range of 10 to 50 µg/L exhibited a significant
251 amount of vegetative biomass at 30 µg/L and a decrease at 50 µg/L of MWCNTs (Fig. 6A).
252 Significant increases in the fresh weight of the shoot and root, dry weight of the shoot, number of

253 lateral roots, and foliar area (90.23%, 132.59%, 84.51%, 91.05%, and 93.72%, respectively)
254 were observed in treated plants, compared to the untreated plants (Fig. 6C–H). Results also
255 suggest that the plant growth stimulation correlates with the increment in the shoot and root dry
256 weights; when plants were treated with 30 µg/L of MWCNTs these variables reached a
257 maximum of 45.2% and 120.46%, respectively, compared to those of the untreated plants (Fig.
258 6E–F). *E. polystachya* plants grown in media supplemented with increasing doses of MWCNTs
259 (10–50 µg/L) showed a large vegetative biomass at 50 µg/L and no negative effects of these
260 nanotubes were recorded at any dosage level tested (Fig. 6B). The maximum increases in the
261 shoot and root fresh and dry weight, number of lateral roots, and foliar area (87.8%, 302.78%,
262 148%, 114.54%, 313.66%, and 150.39%, respectively) were observed in treated plants,
263 compared to the untreated ones (Fig. 6C–H). These results show that synthetic MWCNTs
264 increase seed germination and plant growth in two plant species growing in the studied resinous
265 *Pinus* forests ecosystem.

266

267 **Discussion**

268 Our observations clearly support the hypothesis that MWCNTs can be formed spontaneously in
269 nature and are capable of self-assemble without human interference. Although the process was
270 not directly studied, the formation of MWCNTs during a resinous forest wildfire could be the
271 consequence of a synthetic CVD-like mechanism. Production of MWCNTs by CVD requires the
272 presence of volatile carbon compounds, which may act as precursors, in the gaseous state. *P.*
273 *oocarpa* is a species rich in turpentine, and its oleoresin is a mixture of highly volatile
274 monoterpenes, including α - and β -pinenes, which have been identified as highly effective
275 MWCNT precursors capable of providing a high yield (Lara-Romero et al. 2011). According to

276 previous studies, coil-shaped crystalline nanoparticles cannot be synthesized by processes other
277 than CVD (Fejes & Hernádi 2010; Mhlanga et al. 2011). Therefore, the above hypothesis is also
278 supported by the detection of coil-shaped crystalline carbon nanoparticles in the HR-TEM
279 images of the burned *P. oocarpa* and *P. pseudostrobus* wood. In addition, as mentioned above,
280 the impossibility to find MWCNTs into the *P. montezumae* samples and the sole presence of
281 amorphous carbon structures in this species, indicates that *P. montezumae* trees lacks either the
282 concentration of catalytics or the type of metal required for an effective synthesis of these
283 structures by a CVD like method (Lara-Romero et al. 2011; Zhao et al. 2011).

284 The presence of iron in the samples of *P. oocarpa* containing MWCNTs suggests that this metal
285 provided catalytically active sites for the CNT synthesis. Previous studies that used plant tissue
286 precursors to catalyze CNT growth have suggested that iron catalytic sites are uniformly
287 distributed in plant cells (Zhao et al. 2011). Consequently, CNTs formed in plant tissues could be
288 expected to have uniform diameters. This is consistent with our HR-TEM observations (average
289 wall thickness ~7–13 layers; inner diameter of ~2–6 nm; outer diameter of ~12–20 nm; length of
290 2.5–20 µm), which revealed that the MWCNTs had homogeneous number of layers and external
291 diameters. In addition, the TGA results indicated that the burned wood samples of *P. oocarpa*
292 after pyrolysis degradation contain ~2.8% wt of CNTs. Although it has been generally accepted
293 that nature could provide the conditions for their synthesis, there is scarce evidence of naturally
294 formed MWCNTs in the biosphere. Therefore, we provide evidence of spontaneously and
295 naturally produced MWCNTs from *Pinus* species, following forest wildfires.

296 In another context, the effects of nanomaterials such as CNTs on plant growth and development
297 has been documented, and it has been suggested that their effects are because of factors such as
298 the type of nanoparticles, concentration, plant species, and experimental conditions, including

299 the method of nanoparticle uptake (Tiwari et al. 2014); in contrast, studies indicate that some
300 CNTs nanomaterials show toxic effects on several plant models (Miralles et al. 2012). With
301 respect to human engineered MWCNTs, several molecular mechanisms involved in their
302 biological effects have been described. Genomic analyses of *Lycopersicon esculentum* have
303 indicated that exposure to MWCNTs altered the total gene expression, with up-regulation of
304 stress-related genes (Lahiani et al. 2015; Mohamed et al. 2016), while that in *Nicotiana tabacum*
305 has been found to cause alterations in total gene expression, with up-regulation of genes related
306 to cell-wall assembly/cell growth, regulation of cell cycle progression, and aquaporin production
307 (Lahiani et al. 2015; Miralles et al. 2012; Mukherjee et al. 2016; Yang et al. 2017). Thus, the
308 authors have suggested that size, composition, and specific surface characteristics of the
309 engineered nanomaterials may play important roles in their phytotoxicity (Hong et al. 2013;
310 Mukherjee et al. 2016).

311 In our work, the effect of MWCNTs was evaluated using two plant species found in the burned
312 forest ecosystem, although the MWCNTs utilized are of synthetic origin; these were acquired
313 with structural characteristics similar to those of CNTs found in burned wood samples from the
314 resinous forest. Interestingly, seed germination and growth promotion were observed in both the
315 *L. elegans* and *E. polystachya* plant species tested, with the influence of all the quantified
316 biometrical plant variables; it was unlikely that seed germination and growth promotion occurred
317 exclusively owing to water retention in the plant tissues (Fig. 6). In addition, the results did not
318 indicate that CNTs had toxic effects on seed germination or plant development in the
319 concentration range used, suggesting that at low dosages, MWCNTs function as plant-growth
320 promoters. The plant growth dose-dependence also suggests that the concentrations at which
321 CNTs exert their maximum plant growth-promoting effect depend on the plant species. Although

322 the mechanisms of the observed biological effects were not investigated, the findings indicate
323 that the seed germination and plant-growth promotion was due to the activation of the cell
324 division and nutrient uptake and also increased water influx as previously suggested , rather than
325 an increase in the cell volume.

326 Forest fires are known to enhance the recruitment of a number of important native species
327 associated with forest ecosystems (Keeley & Fotheringham 1998; Keeley et al. ; Turner et al.
328 1997), including *E. polystachya* (Orozco 2008) and *L. elegans* (Díaz-Rodríguez B 2013). In
329 addition, products resulting from the combustion of wood, such as ash (Keeley & Fotheringham
330 1998) and charred wood (Roy & Sonie 1992), have also been shown to trigger germination and
331 plant growth after forest fire events. The influence of MWCNTs formed in burned wood after
332 forest wildfires on plant growth or other post-fire characteristic events in terrestrial ecosystems
333 requires extensive studies.

334 CNT formation has usually been associated with extreme environments; however, we have
335 provided evidence that MWCNTs can be found in biotic environments after atmospheric events.
336 MWCNTs, formed in forest wildfires could be introduced into the soil by burned plant material
337 such as smoke or solid particles. If this is true, then MWCNTs have been interacting with soil
338 organisms and plant species since a long time. This may explain our findings, which strongly
339 suggest that MWCNTs produced in resinous forest wildfires promote seed germination and
340 growth of native plants in forest ecosystems.

341

342 Conclusion

343 This study shows direct evidence of MWCNT generation during forest wildfires as a natural
344 phenomenon, strongly suggesting a possible impact on natural plants of the resinous forest

345 ecosystems through their effects on seed germination and plant growth promotion.

Figure 1

Analysis of the burned wood samples of *Pinus* species collected after a forest wildfire event.

(A) Raman scattering spectra (He-Ne laser emitting at 514 nm) of the *Pinus* burned wood samples of: (black) MWCNTs produced by chemical vapor deposition method using alpha-pinene/ferrocene as raw material, (red) *P. oocarpa*, (blue) *P. pseudostrobus*, and (green) *P. montezumae*. The characteristic bands of CNTs, i.e., the D band (1370 cm^{-1}), G band (1600 cm^{-1}), and G' band (2640 cm^{-1}) are shown. (B) Thermogravimetric analysis (TGA) of the burned wood samples from *P. oocarpa*, *P. pseudostrobus*, *P. montezumae*, and synthetic MWCNTs (pyrolyzed at $610\text{ }^{\circ}\text{C}$).

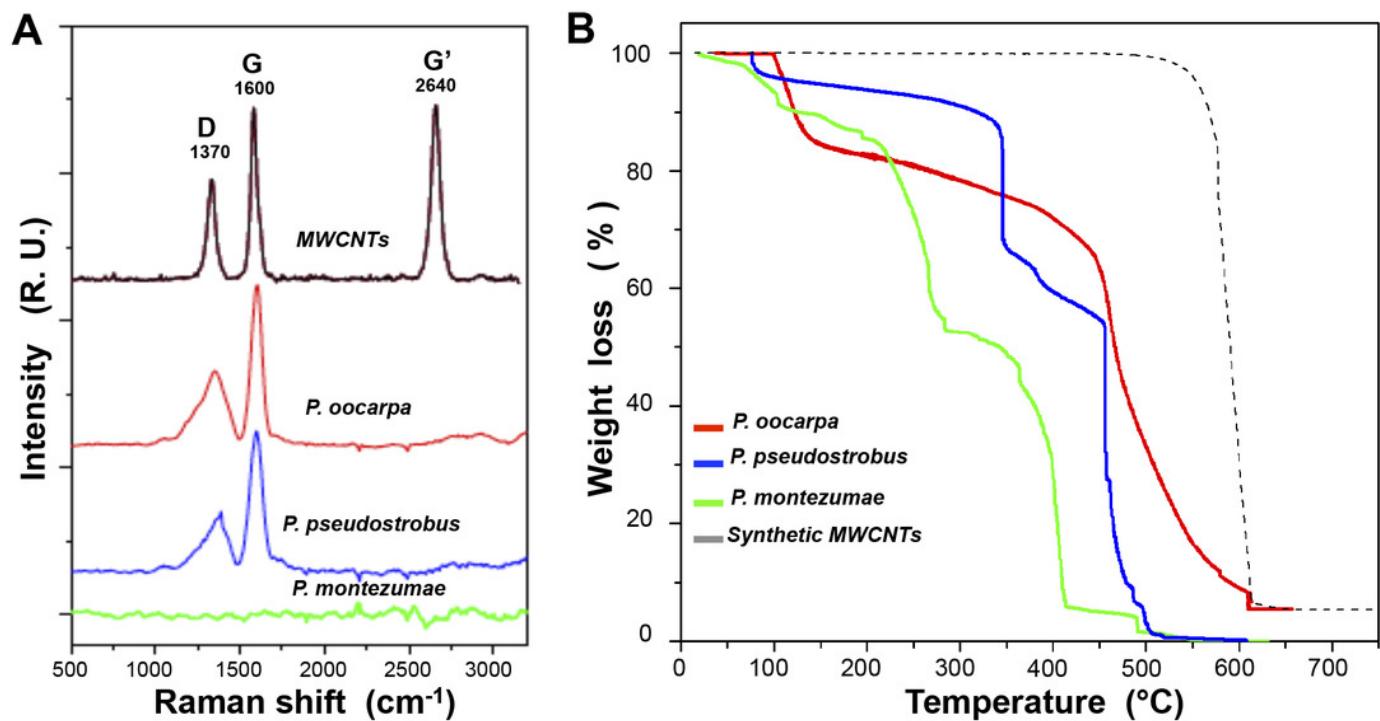

Figure 2

Identification of MWCNTs in the burned wood samples of *Pinus oocarpa* collected after a forest wildfire event.

(**A-C**) HR-TEM images of the burned wood samples at different magnifications, (**D**) FFT image, (**E**) analysis of the FFT image, and (**F**) EDS analysis. Representative images are shown.

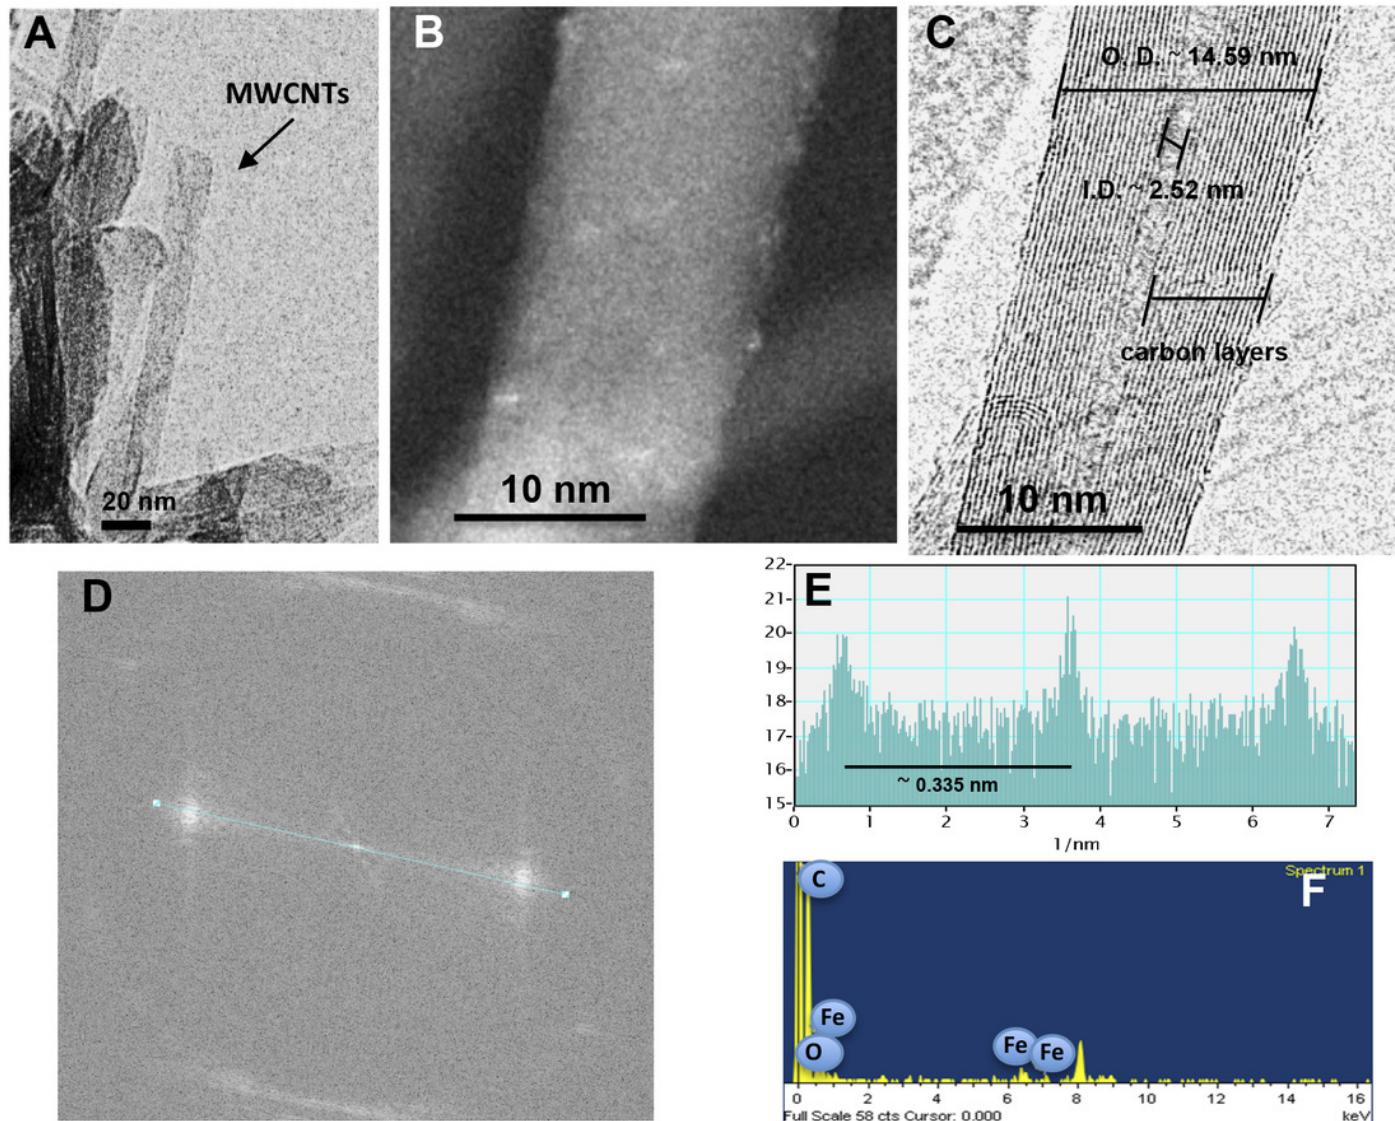

Figure 3

Identification of MWCNTs in the burned wood samples of *Pinus pseudostrobus* collected after a forest wildfire event.

(A) HR-TEM images of the burned wood samples at several magnifications, (B) FFT image, (C) FFT analysis, and (D) EDS analysis. Representative images are shown.

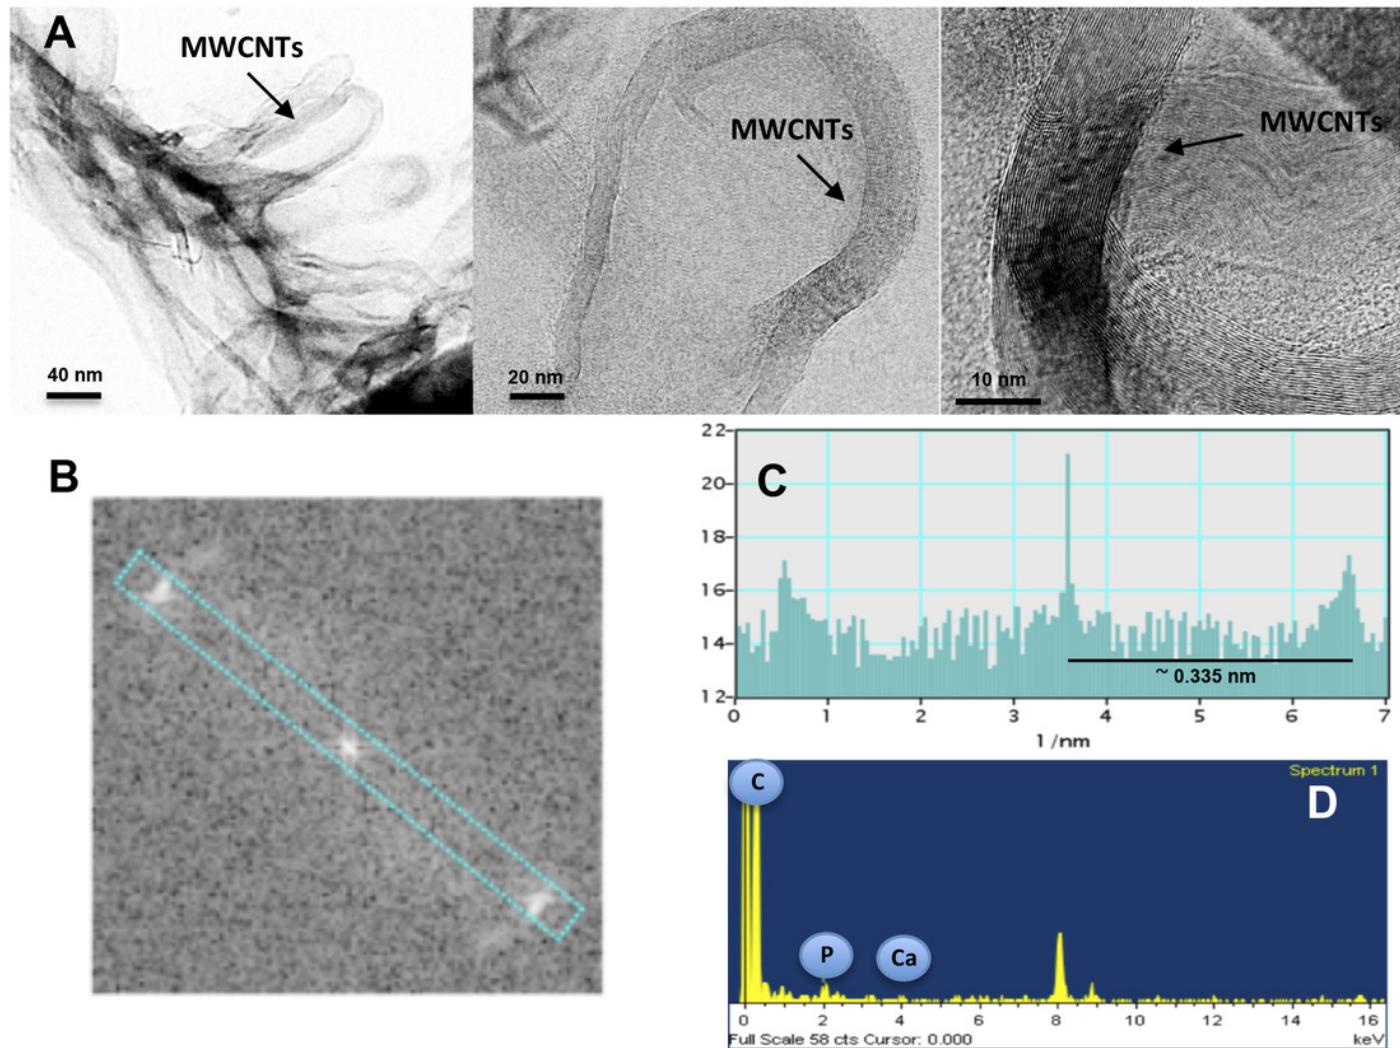

Figure 4

Identification of the carbon structures in the burned wood samples of *Pinus montezumae* collected after a forest wildfire event.

(A) HR-TEM images of the burned wood samples at several magnifications, (B) FFT image, (C) FFT analysis, and (D) EDS analysis. Representative images are shown.

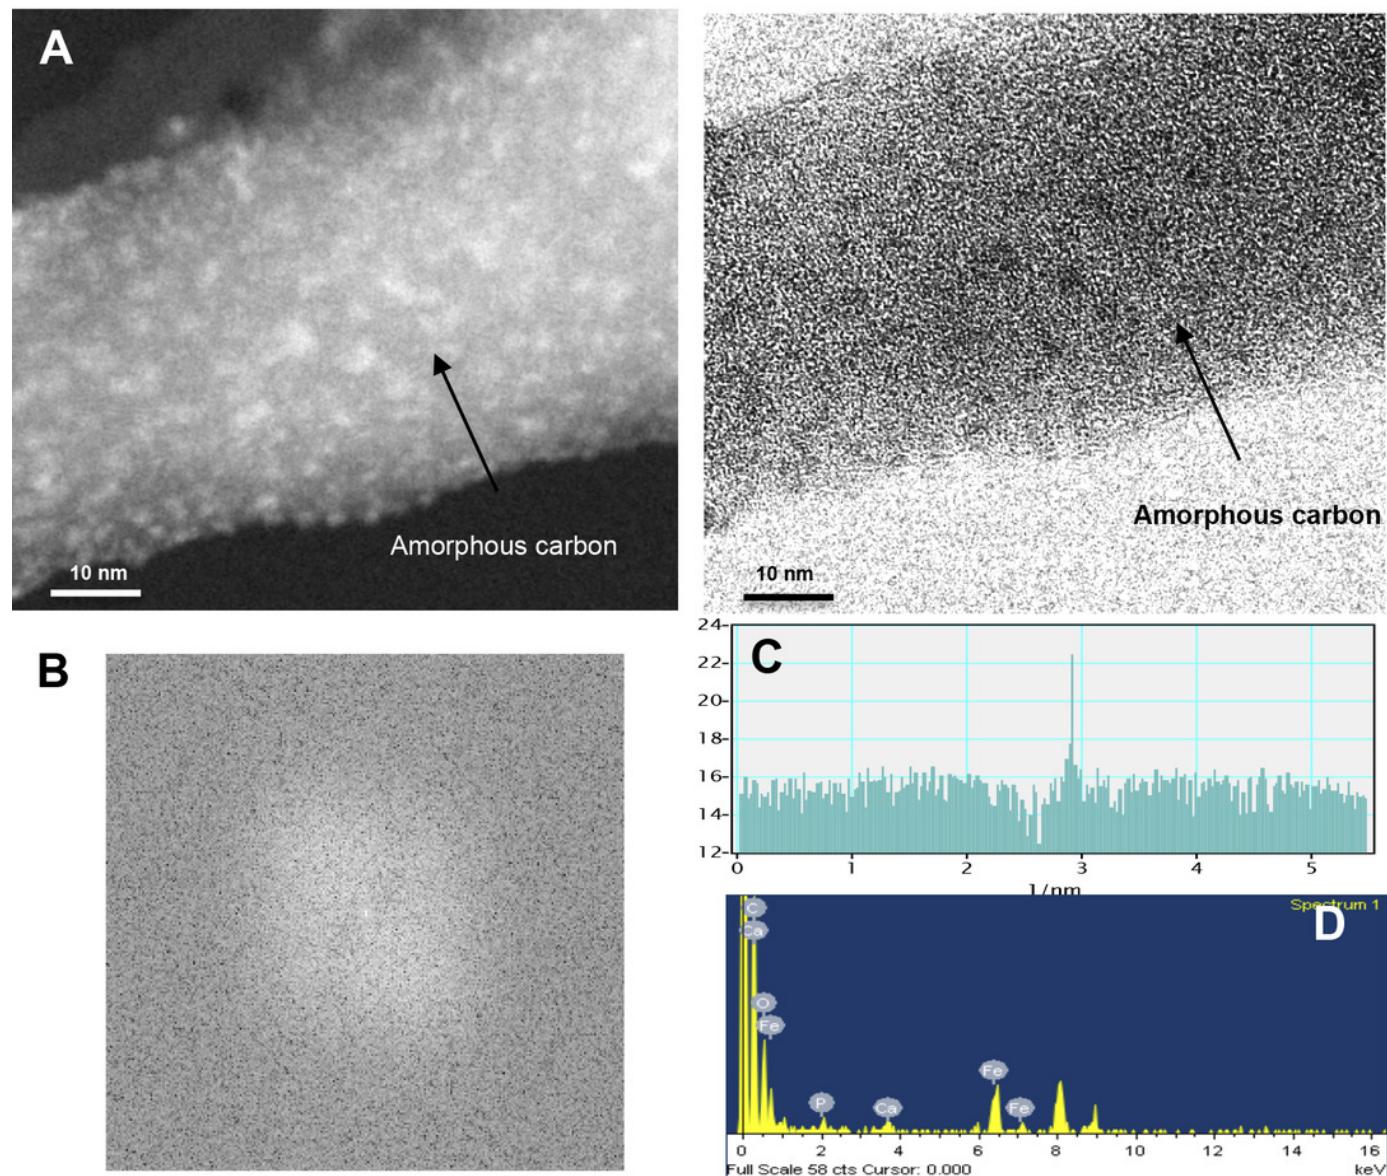

Figure 5

Effect of synthetic MWCNTs on the seed germination rate of *Lupinus elegans* and *Eysenhardtia polystachya*.

Seed germination of the native plants from the *Pinus* forest was evaluated after 10 days with MWCNTs treatment and recorded after 5-week of cultivation. **(A)** *L. elegans* seed germination, **(B)** *E. polystachya* seed germination, **(C)** quantitative data **(A)** and **(B)** assays. Bars represent mean \pm standard error of three independent experiments, $n = 30$ each. One-way analysis of variance (ANOVA) was carried out with Tukey's *post hoc* test; statistical significance ($P < 0.05$) between treatments with respect to control is indicated with different lowercase letters.

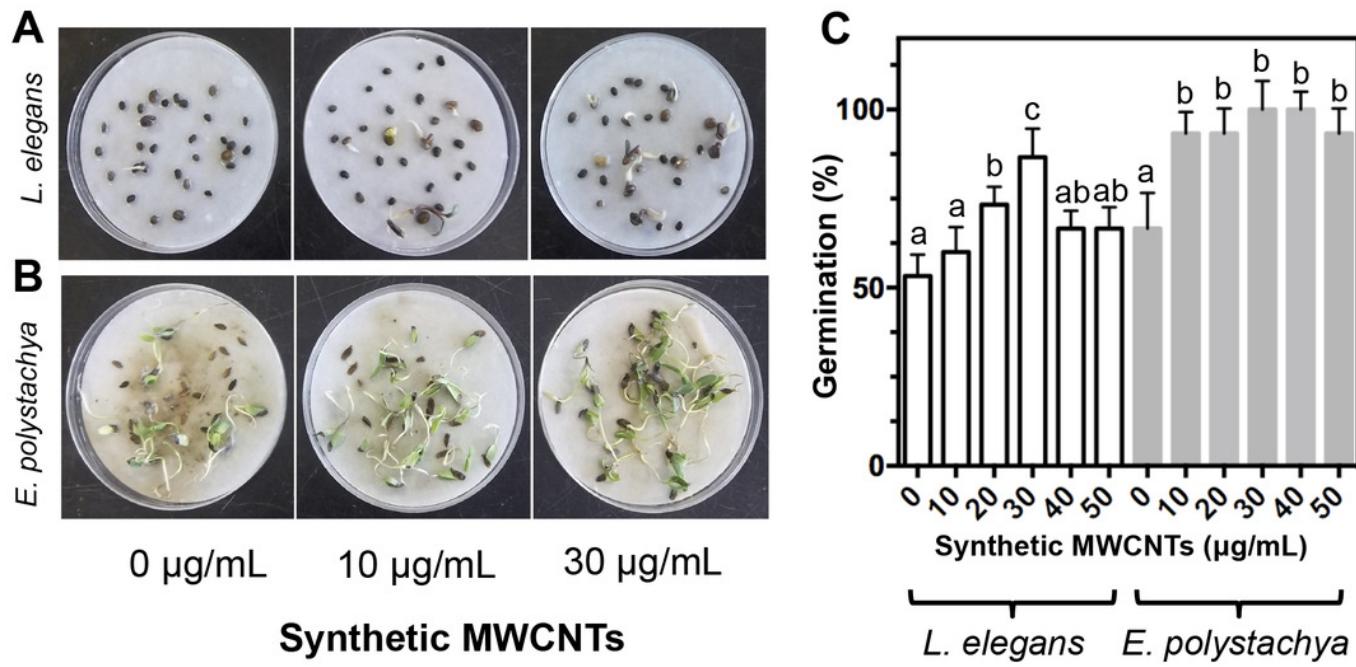

Figure 6

Effect of synthetic MWCNTs on the plant growth rate of *Lupinus elegans* and *Eysenhardtia polystachya*.

After seed germination of the native plants from the *Pinus* forest (as described above), they were planted in 5-cm-diameter polyethylene containers filled with growth medium (Creci-root). These containers were then divided into six separate sets and the seedlings were treated directly with 1.0 mL of the suspension consisting of either 0 (control), 10, 20, 30, 40, or 50 µg/mL of synthetic MWCNTs. At the end of the 5-week period, the plants were harvested, and biometric variables were recorded. (A) *L. elegans* plant growth, (B) *E. polystachya* plant growth, (C) determination of the growth variables (A) and (B) assays: (C) shoot in fresh weight, (D) root in fresh weight, (E) shoot in dry weight, (F) root in dry weight, (G), lateral roots number, and (H) foliar area. Bars represent mean ± standard error of three independent assays, $n = 72$. One-way analysis of variance (ANOVA) was carried out with Tukey's *post hoc* test; statistical significance ($P < 0.05$) between treatments with respect to control is indicated with different lowercase letters.
