

Effects of shoreline oiling on salt marsh epifaunal macroinvertebrates

Donald R Deis, John W Fleeger, Stefan M Bourgoin, Irving A Mendelsohn, Qianxin Lin, Aixin Hou

The *Deepwater Horizon* oil spill resulted in varying degrees of oiling in the salt marshes of northern Barataria Bay, Louisiana, USA. This study examines the effects of oiling intensity and recovery on two conspicuous marsh-platform macroinvertebrates, *Uca* spp., fiddler crabs, and *Littoraria irrorata*, the salt marsh periwinkle, from 2.5 to 4.5 years after the spill. The dominant fiddler crab within these marshes, *Uca longisignalis*, was the only species observed in field collections, and no significant difference in burrow density or burrow size was found among oiling levels over the study period indicating recovery from any negative effects of oiling already occurred for this species. The highest density of *L. irrorata* was found at moderately oiled sites compared to both reference (without visible oiling) and heavily oiled stations. *Spartina alterniflora* density recovered within two years after the spill at the moderately oiled stations facilitating recovery of *L. irrorata* approximately one year later. *L. irrorata* average shell length and length-frequency distributions were equivalent at moderately oiled and reference stations but snails were shorter at heavily oiled stations because of a greater proportion of subadults. Shell length data from the heavily oiled sites indicate that direct mortality due to oiling or oil-induced reductions in recruitment occurred in 2010 and that recovery was starting to occur at 48 months after the spill. The extent and duration of oil in the water during the spill and the biological responses we measured indicates that *L. irrorata* and *Uca longisignalis* were both affected in their ability to carry out their life cycle on the marsh and/or in the water column at all stations including the reference stations for some period following the entry of oil into the region.

15

16 Abstract

17 The *Deepwater Horizon* oil spill resulted in varying degrees of oiling in the salt marshes of
18 northern Barataria Bay, Louisiana, USA. This study examines the effects of oiling intensity and recovery
19 on two conspicuous marsh-platform macroinvertebrates, *Uca* spp., fiddler crabs, and *Littoraria irrorata*,
20 the salt marsh periwinkle, from 2.5 to 4.5 years after the spill. The dominant fiddler crab within these
21 marshes, *Uca longisignalis*, was the only species observed in field collections, and no significant
22 difference in burrow density or burrow size was found among oiling levels over the study period
23 indicating recovery from any negative effects of oiling already occurred for this species. The highest
24 density of *L. irrorata* was found at moderately oiled sites compared to both reference (without visible
25 oiling) and heavily oiled stations. *Spartina alterniflora* density recovered within two years after the spill
26 at the moderately oiled stations facilitating recovery of *L. irrorata* approximately one year later. *L.*
27 *irrorata* average shell length and length-frequency distributions were equivalent at moderately oiled
28 and reference stations but snails were shorter at heavily oiled stations because of a greater proportion
29 of subadults. Shell length data from the heavily oiled sites indicate that direct mortality due to oiling or
30 oil-induced reductions in recruitment occurred in 2010 and that recovery was starting to occur at 48
31 months after the spill. The extent and duration of oil in the water during the spill and the biological
32 responses we measured indicates that *L. irrorata* and *Uca* spp. were both affected in their ability to
33 carry out their life cycle on the marsh and/or in the water column at all stations including the reference
34 stations for some period following the entry of oil into the region.

35

36 Introduction

37 The release of a judge-ruled 3.19 million barrels of oil from the *Deepwater Horizon* (DWH) oil spill
38 (Malakoff, 2015) exposed the nation's largest and most productive wetland-estuarine environment to an

39 unprecedented potential for environmental damage. Oil spills can cause widespread impacts to the
40 structure, function, resilience, and sustainability of coastal wetlands depending upon the oil type, extent
41 of contamination of the vegetation and marsh soils, exposure to waves and currents, time of year of the
42 spill, and species sensitivity to oiling (Michel & Rutherford, 2014). Although the oil that made landfall in
43 the *DWH* oil spill was relatively “weathered” and consisted of emulsions of crude oil depleted of its more
44 volatile and toxic components, the spill resulted in the oiling of 796 km of coastal marsh shoreline, as
45 documented by Shoreline Cleanup Assessment Technique (SCAT) teams (Michel *et al.*, 2013). Of that total,
46 approximately 135 km were described as heavy and 165 km as moderate marsh oiling (Michel *et al.*, 2013).
47 Approximately 95% of the total marsh oiling occurred in coastal Louisiana, and the heaviest marsh oiling
48 was most widespread in northern Barataria Bay marshes dominated by *Spartina alterniflora* and to a lesser
49 extent *Juncus roemerianus* (Zengel *et al.* 2014, Michel *et al.* 2013). The plant communities in northern
50 Barataria Bay experienced strong responses to oiling, including heavy plant mortality that denuded
51 shorelines (Lin and Mendelssohn 2012; Silliman *et al.* 2012; Zengel and Michel 2013; Zengel *et al.* 2014;
52 Zengel *et al.*, 2015).

53 The marshes of the Mississippi River delta system provide a suite of environmentally and
54 economically important services including marsh platform elevation, the prevention of soil erosion, soil
55 nutrient cycling, food web support both grazing and detrital, and many others (McCall & Pennings, 2012;
56 Silliman *et al.*, 2012). Most, if not all, of these ecosystem services depend upon a healthy, functioning
57 plant-microbial-benthic system. Oil spills can exacerbate wetland loss by destabilizing these interrelated
58 processes that control the capacity of coastal wetlands to function properly. Initial impacts of the *DWH*
59 oil spill on coastal wetlands have been and are being reported (e.g., Whitehead, 2011, Lin and
60 Mendelssohn, 2012, McCall & Penning, 2012, Silliman *et al.*, 2012). This study is a part of a program
61 documenting the longer term (currently 4 years) impacts and recovery of the oiled marsh systems and
62 their potential for sustainability.

63 Other members of the study team are analyzing and providing data on plant parameters, soil
64 parameters, soil bacteria, benthic microalgae, and benthic meiofauna (Lin *et al.*, unpublished data; Fleeger
65 *et al.*, 2015). This and other studies have shown that different marsh plant species respond differently to
66 oiling (Alexander & Webb, 1987; Baca *et al.*, 1987; Mendelssohn *et al.*, 1990, 2012; Hoff *et al.*, 1993; Lin
67 & Mendelssohn, 1996, 1998, 2008, 2009; Hester & Mendelssohn, 2000; Pezeshki *et al.*, 2000; Lin *et al.*,
68 2002; DeLaune *et al.*, 2003; Culbertson *et al.*, 2008; Michel & Rutherford, 2014), demonstrating impacts
69 to coastal wetland vegetation, e.g. reduced plant photosynthesis, transpiration, shoot height, stem
70 density, and above and below ground biomass. These impacts on vegetation and the marsh surface can
71 result in cascading effects on soil bacteria and macro-, meio-, and micro-faunal communities that inhabit
72 wetlands and depend on the plant organic matter as carbon sources or as foundation species. For
73 example, benthic microalgae and meiofauna are, both individually and when monitored together,
74 important indicators of ecosystem function regarding food-web support and a broad range of effects and
75 recovery from oil spills (Fleeger *et al.*, 2015).

76 Our sampling focused on two conspicuous and foundational marsh macroinvertebrates, *Uca* spp.,
77 marsh fiddler crabs (Montague, 1980), and *Littoraria irrorata*, the salt marsh periwinkle (Silliman &
78 Zieman, 2001). Fiddler crabs are one of the most thoroughly-studied shore crab in North America, with
79 robust literature available that examines individual species population dynamics, life history and ecology
80 (Grimes *et al.*, 1989). Fiddler crabs greatly influence the marsh through burrowing and feeding activities,
81 in effect enhancing effects on vegetation productivity and biomass, altering sediment and nutrient
82 characteristics, altering biogeochemical cycles, altering microbial processes by aerating the marsh
83 sediment, increasing soil drainage, and facilitating nutrient transport. Generally, the presence of fiddler
84 crabs has been noted as indicating greater diversity of other marsh organisms, and crab population
85 densities can reflect the productivity of a wetland (Montague, 1980; Mouton & Felder, 1996). Fiddler

86 crabs have been shown to be sensitive to oil spills, making them a valuable environmental indicator
87 species (Burger *et al.* 1991, 1992; Burger & Gochfeld, 1992).

88 Various fiddler crab species inhabit the northern Gulf of Mexico coast. Two species in particular
89 are found in the Louisiana marshes, *Uca spinicarpa* and *U. longisignalis*. *Uca spinicarpa* prefers clay-
90 dominated substrates in brackish marshes ranging from nearly fresh to hypersaline. *Uca longisignalis* is
91 restricted to sediments of terrigenous origin ((i.e. mucky soils) and found primarily in lower salinity
92 environments (upper estuaries). The two species can be found in close proximity but have preferred
93 habitats based on elevation, vegetation and sediment character (Mouton & Felder, 1996; Zengel *et al.*,
94 2014). Although there may be more than one species of fiddler crab, we will refer to them collectively as
95 *Uca* except when we refer to a specific species.

96 *L. irrorata* also is an indicator species of the health of the salt marsh habitat (Silliman & Zieman,
97 2001). In areas dominated by short-to-intermediate form *Spartina alterniflora*, the species has been
98 noted to occur in densities of at least 100 individuals/m² (Silliman & Zieman 2001; Stagg & Mendelssohn
99 2012). *L. irrorata* is a rasping detritivore/herbivore specialist, feeding on organic matter on the marsh
100 surface during low tide and ascending the *Spartina* stems to feed upon standing-dead *Spartina* and its
101 associated microbial assemblages as the tide rises (Silliman & Zieman 2001). As a detritivore, *L. irrorata*
102 influences nutrient dynamics by expediting the decomposition of *Spartina alterniflora* and serves as an
103 important link between primary and secondary production (Stagg & Mendelssohn 2012). The presence of
104 *S. alterniflora* has been directly linked to increased abundance, growth and survival of *L. irrorata* in
105 marshes (Kiehn & Morris 2009; Stagg & Mendelssohn 2012).

106 Fiddler crabs (Krebs & Burns, 1977; Burns & Teal 1979; Burger *et al.*, 1991; Teal *et al.*, 1992;
107 Culbertson *et al.*, 2007; Morris *et al.* 2015) and the marsh periwinkle (Hershner & Moore 1977; Hershner
108 & Lake, 1980; Lee *et al.*, 1981; Bennett *et al.*, 1999; Garner *et al.* 2015) both can be severely impacted by
109 oil spills, with direct effects including direct mortality, reduced population densities, and sublethal effects,

110 e.g. behavior alterations and reproduction effects. Pennings *et al.* (in review), using only sites without
111 substantial oiling from this and other studies, evaluated the potential impact of the *DWH* oil spill on
112 recruitment of *L. irrorata* in Louisiana comparing the proportion of subadults that would have recruited
113 before the oil spill (pre-2011) to the proportion in 2011 and the proportion occurring in subsequent years
114 to evaluate recovery. They found that the proportion of subadults in *L. irrorata* populations in Louisiana
115 was reduced by 90% in 2011 suggesting recruitment failure in 2010. Effects of oiling can occur during the
116 portion of these species life spent on the marsh platform or, as indicated by the Pennings *et al.* (in review)
117 study, when they release fertilized eggs into the water and expect return of larvae to the marsh shoreline.
118 Recovery time following oil-induced impacts for these organisms can vary substantially based on a variety
119 of oiling and habitat conditions, from a year to several decades (Culbertson *et al.*, 2007).

120 In this study, we present the results of an investigation of the effects of the *DWH* oil spill on fiddler
121 crab and marsh periwinkle at different oiling levels between 30 and 54 months after the spill. As has been
122 indicated, Lin *et al.* (unpublished data) studied the response of the plant community including the
123 dominant salt marsh plants *S. alterniflora* and *J. roemerianus* in the same sampling stations as used for
124 this investigation.

125

126 **Methods**

127 The 21 shoreline sampling stations were established in 2011 within an approximate 8 km by 5 km
128 area in Wilkinson Bay and Bay Jimmy in northern Barataria Bay, Louisiana, USA (between coordinates N
129 29.44060° - 29.47459°, W 89.88492° - 89.94647°) that had been impacted to varying degrees by the *DWH*
130 oil spill (Fig. 1). Sampling stations were randomly selected using SCAT data and our own field observations,
131 and included seven locations each that received either no oiling (i.e., reference) (RF), moderate oiling
132 (MD), or heavy oiling (HV). Sampling occurred at various occasions (generally bi-annually) from 30 months

133 (November 2012) after the spill to 54 months (October 2014) after the spill. Sampling was generally in
134 the spring (April - June) and fall months (September – November). Total petroleum hydrocarbon and plant
135 community data were collected at the time of sampling (Lin *et al.*, unpublished data).

136

137 **Total Petroleum Hydrocarbon (TPH) analysis**

138

139 The 0–2 cm surface soils were collected from each station on each collection date, transported to
140 the Louisiana State University laboratory on ice, extracted with dichloromethane (DCM), and analyzed
141 gravimetrically (Lin & Mendelsohn, 2012). DCM extracts were transferred to pre-weighed dishes, where
142 the DCM was evaporated, and the unevaporated oil remaining in the dishes was weighed to the nearest
143 0.0001 g. TPH concentration was calculated and expressed as mg g⁻¹ dry soil. The results of the analysis
144 for 30 to 54 months after the spill are provided in Figure 8.

145

146 **Aboveground Biomass and Stem Density**

147

148 Plant aboveground biomass and stem density were taken at each station during each sampling
149 within a haphazardly located 0.25 m² quadrat. All plants rooted within the quadrat were then clipped to
150 the ground surface and separated into live and dead components by species. Stem density was
151 determined by counting the number of intact living stems for each dominant plant species. All
152 aboveground biomass was then dried to a constant mass at 60°C and weighed. Parameters reported
153 included total live and dead above ground biomass and above ground biomass and stem density for each
154 of the dominant species (*Spartina alterniflora* and *Juncus roemerianus*).

155

156 **Macroinvertebrate sampling**

157

158 Sampling included fiddler crab (*Uca*) burrow density and size and marsh periwinkle (*Littoraria*
159 *irrorata*) density and size for both components of the study. Sampling was conducted using three 0.25 m²
160 quadrats placed at random approximately 1 m inward from the marsh edge. Data was converted to m⁻²
161 basis for analysis. Each quadrat was sampled for both *L. irrorata* abundance and *Uca* burrow abundance.
162 *L. irrorata* were found on the marsh surface or attached to the vegetation within the plot; juvenile *L.*
163 *irrorata* were often found hiding in the leaf bracts of *Spartina alterniflora*. *L. irrorata* shell length and *Uca*
164 burrow size (diameter) were measured to the nearest millimeter using calipers and a transparent ruler,
165 respectively. Shell lengths were taken as a total height, a measurement from the base of the aperture to
166 the top point of the shell. Once measured, *L. irrorata* were returned to the marsh within their specific
167 sampled quadrat. As fiddler crabs are mobile and difficult to quantify within a certain area, their burrows
168 were used as a proxy for their abundance on the marsh. We were not able to measure crab burrows at
169 two sampling occasions (36 and 42 months after the spill) because water was present on the marsh
170 platform, covering the marsh sediment in the sampling area. Photos were taken of the general site setting
171 and each quadrat, and general notes were made concerning site flora and fauna composition and
172 characteristics. *Uca* adults were identified to species level and released if found in the sampling site
173 vicinity.

174 Measured *L. irrorata* were grouped into putative age classes based on their size: 0-6 mm were
175 classified as juveniles, 7-13 mm were classified as sub-adults, and 14+ mm were classified as adults
176 (Hamilton, 1978; Stagg & Mendelsohn, 2012). Sizes were examined as a percentage of the total
177 abundance for each site type (RF, MD, and HV; Figs. 5-7). Size frequency distributions of *L. irrorata* are
178 often bi- or tri-modal with the modes representing age class (Hamilton, 1978; Zengel *et al.*, 2014). The

179 largest snails in most populations range from 20 – 26 mm in shell length (Emerson and Jacobson, 1976;
180 Morris, 1975), though the largest reported size is 32 mm (Kaplan, 1988). Based on growth estimates
181 (Stiven and Hunter, 1976), juveniles would be <1 year of age, subadults would average about 1 year of
182 age, and adults would be 2 years and older in age. These designations were used in analyses to examine
183 life stage-specific parameters of *L. irrorata* abundance and distribution throughout the study. Evaluating
184 size distribution by comparing size frequency histograms over time is helpful in determining how
185 populations were impacted and tracing recovery trajectories (Zengel *et al.*, 2014; Zengel *et al.*, 2015;
186 Pennings *et al.*, in review).

187

188 **Statistical Analysis**

189

190 All statistical analyses were conducted using SAS (Statistical Analysis Systems, version 9.2, SAS
191 Institute, Cary, NC). *L. irrorata* abundance data were tested for normality and found to be skewed
192 [Shapiro-Wilk Test ($\alpha = 0.05$)]. Several transformations were tested and the natural log transformation
193 was the best fit; therefore, all *L. irrorata* abundance data were transformed as the natural log prior to
194 analysis. We used repeated measures, two-way mixed-model Analysis of Variance (ANOVA) with oiling
195 level, sampling period, and their interactions to test for variation in *L. irrorata* abundance. We used
196 Mauchly's Test of Sphericity to examine the form of the common covariance on the assumptions of the
197 repeated measures ANOVA and found that the data do not meet sphericity assumptions ($\text{Pr} > \text{ChiSq} =$
198 0.0057). An adjusted Tukey's test was used to determine differences between *L. irrorata* abundances and
199 oiling level at each sampling period.

200 We tested the *L. irrorata* shell size data for normality and found these data to be skewed [Shapiro-
201 Wilk Test ($\alpha = 0.05$)]. All attempted transformations (log, natural log, square root) were unsuccessful.

202 Kruskal-Wallis test was therefore used to examine shell size by oiling level and sampling period, e.g.
203 comparing shell size for the RF sites by sampling period.

204 The nonparametric Kolmogorov-Smirnov two-sample test was used to compare the total
205 abundance (total, adult, and subadult) and average shell length data between oiling levels across all
206 sampling periods with the null hypothesis that the two oiling levels have the same distribution.

207 *Uca* burrow abundance data were tested for normality and found to be skewed [Shapiro-Wilk Test
208 ($\alpha = 0.05$)]. Transformations and removal of the 36 and 40 month data sets which were mainly zeros
209 (periods of high water) were unable to normalize data. Oiling levels and abundance of burrows were
210 therefore tested using Kruskal-Wallis/Mann-Whitney (non-parametric) tests, both leaving in the 36 and
211 40 month datasets and removing those datasets from the analysis; however, no significant results were
212 found.

213 Correlations were performed, using Kendall's Tau non-parametric rank correlations with
214 dependence on variables, with oiling level and sampling period to 48 months after the spill because of the
215 lack of availability of plant and TPH data at the time of the analysis; *L. irrorata* abundance; *Uca* burrow
216 density; *S. alterniflora* stem density and biomass; *J. roemerianus* stem density and biomass; total live
217 biomass; total dead biomass; and TPH.

218 Significant difference was defined as $p \leq 0.05$. P-values are reported to 2 decimal places and, in
219 cases where $p = 0.00$, the p-value is reported as $p < 0.01$. All error terms are expressed in standard error
220 (SE). Raw data can be found at the following link: [doi:10.7266/N7FF3Q9S](https://doi.org/10.7266/N7FF3Q9S).

221

222 Results

223

224 *Littoraria irrorata* abundance

225 *L. irrorata* abundance varied among oiling levels when data were combined across all sampling
226 periods and size classes. *L. irrorata* were found to have the highest average density at MD (mean = 92.5
227 ind m⁻², n=3,888) compared to RF (mean = 38.1 ind m⁻², n =1604, Kolmogorov-Smirnov test, p < 0.01) and
228 HV sites (mean = 33.5 ind m⁻², n = 1404, Kolmogorov-Smirnov test, p < 0.01). RF sites were also found to
229 be statistically different than HV sites (Kolmogorov-Smirnov test, p = 0.02). This same trend was found
230 within adults as both RF and MD differed from HV sites (Kolmogorov-Smirnov test, p = 0.02 and <0.01,
231 respectively, Fig. 2). No difference was found among oiling levels for subadults. Juveniles were cryptic
232 and inconsistent in their distribution, and there was no significant difference between oiling levels and
233 abundance of juveniles. *L. irrorata* abundance also exhibited differences between size classes at all of the
234 oiling levels. Adults are significantly more abundant than both sub-adults (Kolmogorov-Smirnov test, p <
235 0.01) and juveniles (Kolmogorov-Smirnov test, p < 0.01), while sub-adults are significantly more abundant
236 than juveniles (Kolmogorov-Smirnov test, p < 0.01).

237 When sampling period and oiling level were analyzed together with ANOVA, oiling level had a
238 significant effect on *L. irrorata* total abundance (n = 7 and p < 0.01), but the sampling period and
239 interaction effect were not significant (Fig. 3). We examined within-subjects main effects tests to examine
240 changes in snail abundance over time with the null hypothesis that mean abundance did not change over
241 time. We rejected the null hypothesis using Wilk' test (Pr>F = 0.0139) and concluded that abundance
242 varied over time. We used the same method to test the interaction between time and oiling level. We
243 again rejected the null hypothesis and concluded that change in mean abundance across time depended
244 on oiling level (Pr>F = 0.0037). Significant differences in *L. irrorata* total density were noted between oiling
245 levels at different sampling periods. Significant differences existed between both MD (Tukey's test, p =
246 0.02) and RF (Tukey's test, p < 0.01) and HV sites at 36 months after the spill; between the MD and RF
247 sites (Tukey's test, p = 0.05) at 40 months after the spill; and MD and RF (Tukey's test, p = 0.05) and HV
248 sites at 36 months after the spill.

249

250 *Littoraria irrorata* shell size

251 *L. irrorata* body size also varied among oiling levels when data were combined across all sampling
252 periods. *L. irrorata* average shell length was significantly less at HV sites (mean = 15.44 mm) when
253 compared to both MD sites (mean = 17.37, Kolmogorov-Smirnov test, $p < 0.01$; Fig. 4) and RF sites (mean
254 = 16.62 mm, Kolmogorov-Smirnov test, $p < 0.01$). RF and MD sites showed no statistical difference in shell
255 length (Kolmogorov-Smirnov test, $p = 0.43$).

256 *L. irrorata* shell length was also used to examine size-frequency distributions at all oiling levels. RF
257 and MD sites exhibited similar proportions of juveniles, subadults, and adults, while the HV sites contained
258 a lower percentage of adults, in particular, large adults. This low proportion of adults at the HV sites likely
259 corresponded to the direct mortality of all size categories of *L. irrorata* at the HV sites due to the oiling in
260 2010. As indicated in methods, adults are two years or older; therefore, even at 30 months, smaller adults
261 would just be entering the populations and replacing these losses at the HV sites.

262 The null hypothesis of no difference in shell length across sampling periods was rejected (Kruskal-
263 Wallis test, $p < 0.01$) indicating that there was a difference in shell size among oiling levels (figure 8).
264 Periwinkles in all oiling categories averaged less than 15 mm in shell size 30 months after the spill. The
265 HV sites continued to average less than 15 mm in shell size up to 48 months after the spill; whereas, the
266 RF and MD sites achieve an average shell size greater than 17 mm at 48 months after the spill.

267

268 *Uca* burrow density and size

269 All of the fiddler crabs collected during all sampling periods were identified as *Uca longisignalis*.
270 No significant difference was found between oiling level and *Uca* burrow density. Because no significant
271 difference was found with density, burrow size was not tested.

272

273 **Correlations**

274 With all oiling levels and all stations, *L. irrorata* abundance was positively correlated with most of
275 the plant parameters including *S. alterniflora* above ground biomass ($p = 0.05$); *J. roemerianus* above
276 ground biomass ($p < 0.01$) and stem density ($p < 0.01$); and total live ($p < 0.01$) and dead above ground
277 biomass ($p = 0.06$). *Uca* burrow density was negatively correlated with *S. alterniflora* stem density ($p =$
278 0.03).

279 For the RF sites, the only significant correlation occurred at 30 months after the spill between *L.*
280 *irrorata* abundance and *Uca* burrow density ($p = 0.04$). The MD sites showed a significant positive
281 correlation between *L. irrorata* abundance and *J. roemerianus* above ground biomass ($p = 0.02$) and stem
282 density ($p = 0.03$) at 40 months after the spill; a significant negative correlation between *L. irrorata* and
283 *Uca* burrow density ($p = 0.01$) 42 months after the spill; and a significant negative correlation with *S.*
284 *alterniflora* stem density ($p = 0.03$) and positive correlation with *J. roemerianus* stem density ($p = 0.02$) at
285 48 months after the spill. The HV sites showed no significant correlations.

286 TPH did not correlate with either *L. irrorata* or *Uca* abundance; however, there was a positive
287 significant correlation between TPH and *S. alterniflora* stem density ($p = 0.04$, all data; $p < 0.01$, HV sites).
288 There were significant negative correlations between *J. roemerianus* above ground biomass ($p < 0.01$) and
289 stem density ($p < 0.01$) and total live and dead biomass (both, $p < 0.01$).

290

291 **Discussion**

292 ***Littoraria irrorata***

293 As stated in the Results, *L. irrorata* were found to have the highest average density at MD
294 compared to RF and HV sites. RF sites were also found to be statistically different than HV sites. This same

295 trend was found within adults as both RF and MD differed from HV sites. The reduced abundance at HV
296 compared to MD was due to the oiling, either by direct mortality or effects on recruitment by the loss of
297 vegetation at the HV sites. Many studies (Kiehn & Morris, 2009; Silliman & Zieman 2001; Silliman &
298 Bertness 2002; Silliman & Newell, 2003; Silliman *et al.*, 2005. Kiehn & Morris (2009) have noted that marsh
299 periwinkle density is positively correlated with *S. alterniflora* stem density. Stagg & Mendelsohn (2012),
300 in a study of marshes restored using sediment from dredging operations, found that *L. irrorata* growth,
301 survival, and productivity were positively correlated to increasing *S. alterniflora* canopy cover. High levels
302 of *J. roemerianus*, however, may be detrimental to *L. irrorata* density. Alber *et al.* (2008) noted that
303 densities of *L. irrorata* are generally low on *J. roemerianus* in their analysis of the possible reasons of
304 saltmarsh dieback. There may be a limit to the amount of *J. roemerianus* (biomass or stem density) within
305 the marsh that is beneficial compared to the amount that suppresses the *L. irrorata* population density.
306 Above ground biomass and stem density of *J. roemerianus* was equal to or greater at times than *S.*
307 *alterniflora* density at the RF stations (Lin *et al.*, unpublished data), potentially limiting the abundance of
308 *L. irrorata*. *J. roemerianus* has been shown to be more sensitive to oiling than *S. alterniflora* (Lin *et al.*,
309 unpublished data, Lin & Mendelsohn, 2012), and its density and biomass was expectedly suppressed at
310 the moderately and HV stations (Lin *et al.*, unpublished data).

311 Location may have also contributed to lower *L. irrorata* density at the RF sites. All of the RF sites
312 are located northwest of the moderately and HV stations in a cove that is connected to larger marsh
313 islands. This location could have a larger predator population than the smaller marsh islands where the
314 other stations are located. The location is also further north into the estuary and may be influenced by
315 freshwater, potentially altering the recruitment of *L. irrorata* and/or the population dynamics of *J.*
316 *roemerianus* and *S. alterniflora* (Pennings *et al.*, 2005). Alternatively, abundances in the MD sites may
317 have been higher than the RF sites because of an elevated stem density of *S. alterniflora* (Fleeger *et al.*,

318 2015). Increased stem density at the MD sites may have been a response by *S. alterniflora* to reduced
319 competition from *J. roemerianus* or a compensatory response associated with oiling.

320 Although the density of *L. irrorata* was low at RF sites, length-frequency data are similar to those
321 found in other gulf coast areas not impacted by oiling (Pennings *et al.*, in review), suggesting that these
322 data adequately represent a true reference population for comparison with oiled sites. Average *L. irrorata*
323 shell lengths (Fig. 4) of *L. irrorata* population at the MD and RF stations were equivalent indicating that
324 recovery at MD sites was achieved within the time period of this study. As an example of recovery of
325 lightly oiled areas, McCall and Pennings (2012) estimated *L. irrorata* density, not shell length frequency,
326 at oiled and control sites in Louisiana and Mississippi four and 16 months (August 2010 and 2011) after
327 the *DWH* spill. The sampling sites were located 1-2 m behind the HV zone in areas dominated by *Spartina*
328 *alterniflora*, and often partially coated with oil, with a very light (sheen) on the soil surface. McCall and
329 Pennings (2012) reported no difference in the population density at 4 or 16 months after the spill.

330 A similar comparison of the average shell length (Fig. 4) between the RF and MD stations and the
331 HV stations indicates that body size was much lower at the HV stations and that they did not fully recover
332 within the time period of the study. Shell length also indicates that all of the oiling levels may have initially
333 been affected by oiling within Barataria Bay because the average shell length was initially smaller than
334 that which was eventually achieved at the RF sites (17.71 mm). These data indicate that recovery may
335 have been occurring at the RF and MD sites approximately 36 months after the spill and, at the HV sites,
336 48 months after the spill. Other studies have investigated more heavily-oiled sites associated with the
337 *DWH* spill using population density. Silliman *et al.* (2012) sampled *L. irrorata* density at three reference
338 and three impacted sites, approximately 3 m from the shoreline, in Barataria Bay approximately 6 months
339 (October 2012) after the *DWH* spill. Their group found no live individuals at impacted stations and
340 approximately 50 m⁻² at the reference stations. Note that their reference stations had relatively low

341 densities (slightly greater than the density at our RF stations) and less than the average density of our MD
342 stations.

343 In a study of shoreline treatment options on a marsh island in northern Barataria Bay,
344 approximately 1 km south of our study sites, Zengel *et al.* (2015) monitored *L. irrorata* population densities
345 and shell size frequencies in relation to shoreline treatment options (manual, mechanical, and no
346 treatment; see Zengel and Michel (2013) 17 and 29 months (September 2011 and 2012) after the *DWH*
347 spill. This study provides data at reference and heavily-oiled stations between the time period of the
348 Silliman *et al.* (2012) and our study. They found minimal recovery of *L. irrorata* at treatment sites. An
349 interesting result was that the reference station had less than 50 m⁻² *L. irrorata* in 2011 (17 months after
350 the spill) and greater than 150 m⁻² in 2012 (29 months after the spill). Zengel *et al.* (2015) mentions two
351 potential reasons for the differences in densities between the sampling periods; one, under-sampling the
352 juvenile *L. irrorata* in the first sampling period due to not searching leaf bracts for juveniles and, two, the
353 possible effect of widespread oiling in the water surface within Barataria Bay during the summer of 2010
354 and the effect that may have had on the larvae of *L. irrorata*. We find the juvenile *L. irrorata* very patchy
355 in their distribution on the marsh platform because of the juveniles' preference, described in Zengel *et al.*
356 (2015) to aggregate and hide in areas on *S. alterniflora*, such as within leaf bracts. We also find the
357 juveniles sporadic between years potentially because of their broadcast life cycle and we do mention
358 below that both *L. irrorata* and *Uca* were affected in their ability to carry out their broadcast life cycle in
359 2010 throughout northern Barataria Bay because of oil on the water. This caused a potential recovery
360 effect at all of our stations including the RF stations.

361 The correlation of *L. irrorata* abundance with vegetation parameters is not unexpected. Kiehn &
362 Morris (2009) and Stagg & Mendelssohn (2012) found similar positive correlations between *S. alterniflora*
363 health (stem density, canopy cover) and *L. irrorata* health (density, growth, survival, productivity).

364 Additionally, Fleeger et al. (2015) found that the infauna at our study sites followed the recovery of *S.*
365 *alterniflora*. Of particular interest is the correlation of *L. irrorata* with *J. roemerianus* parameters (above
366 ground biomass, stem density, and total live and dead above ground biomass). This may indicate the
367 importance of *J. roemerianus* to the recovery of *L. irrorata* within the marsh. Hughes (2012) describes the
368 potential importance of *J. roemerianus* as alternative refuge for *L. irrorata*; as described above, however,
369 Alber et al. (2008) note that the densities of *L. irrorata* on *J. roemerianus* is generally low. We, therefore,
370 may be underestimating the importance of *J. roemerianus* within a diverse marsh system. The correlation
371 of *L. irrorata* and *J. roemerianus* at 40 months (above ground biomass and stem density) and 48 months
372 (stem density) at the MD stations, however, may indicate the coincidental recovery of the two species
373 with the reduction of oil at those stations (Figure 9).

374

375 ***Uca***

376 This study started 30 months after the *DWH* oil spill, and our data clearly show that that any effect
377 of the spill on fiddler crab, *Uca*, density passed prior to the beginning of this effort. We found that average
378 density of crab burrows within the area of our sampling (approximately 1 m from the shoreline edge) was
379 low, between 5 and 10 burrows m⁻². This is not surprising, as Mouton & Felder (1996) noted the variation
380 in burrow density of *U. longisignalis* along a 15-m transect from the edge into the marsh. The burrow
381 density was lowest near the marsh edge and highest in the middle and upper reaches of the transect with
382 no marked change in elevation noted beyond 3 m from the water's edge. Several studies have found
383 similar results. Silliman et al. (2012) sampled *Uca* sp. crab burrow density at the three reference and three
384 impacted sites described above and found no difference between the density of crab burrows
385 (approximately 10 m⁻²) at the two site types. McCall & Pennings (2012) sampled *Uca* burrows at the
386 sampling sites described above. Because they were sampling further back in the marsh, McCall &

387 Pennings (2012) reported greater numbers of burrows (approximately 20 m⁻², see Mouton & Felder 1996
388 above) and found a significantly lower density of burrows at the oiled sites 4 months after the spill and no
389 difference at 16 months after the spill.

390 Zengel *et al.* (2015) monitored *Uca* burrow densities in relation to shoreline treatment options
391 after the *DWH* spill (see above). *Uca* burrow densities in heavily-oiled and treated plots were similar to
392 reference at both 17 and 29 months; however, the heavily-oiled sites that were not treated were
393 significantly different at 17 months, but similar at 29 months. Zengel *et al.* (2014) revisited the treatment
394 sites at 41 months after the spill (September 2013) and found significant differences between the oiled
395 control sites (no treatment) relative to the references sites. Maximum average burrow density was
396 approximately 10-15 burrows m⁻² similar to densities in our study. We also identified only *Uca longisignalis*
397 within our study sites. The study at the treatment sites (Zengel *et al.*, 2014; Zengel *et al.*, 2015) identified
398 *U. spinicarpa* occurring at the heavily-oiled plots where there was reduced vegetation coupled with areas
399 of surface oil residue overlaid with thin algal mats and clay-like sediments.

400 Morris *et al.* (2015) conducted studies on adult male and female *Uca longisignalis* placing the
401 individuals in Total Polycyclic Aromatic Hydrocarbon (TPAH)₅₀ concentrations from 0.07 (reference
402 sediment) to 26 mg/kg in the upper 2 cm of sediment. During the 10 day exposure period several females
403 became gravid. The gravid females were removed after 10 days and placed in clean water until the
404 embryos hatched. The zoea were collected, held in clean water, and exposed to varying levels of ambient
405 sunlight. They found substantial toxicity (calculated LC₂₀ value of 0.62 mg/kg TPAH₅₀ in the upper 2 cm
406 of sediment) to *Uca* zoea at relatively low concentrations of oil in the sediments. Fig. 9 provides the total
407 petroleum hydrocarbon concentrations from 30 to 54 months after the spill at the 21 stations from this
408 study. It is difficult to compare the two hydrocarbon parameters and much of the aromatic portions of
409 the oil have weathered reducing the toxicity; however, the levels were found to be significant higher at
410 the HV sites compared to the RF and MD sites (Lin *et al.* unpublished data).

411 The negative correlations between *Uca* sp. burrow density and *S. alterniflora* stem density (all
412 oiling levels /all stations) and *L. irrorata* (MD stations 42 months after the spill) may be indicative of the
413 conflict between the burrowing and feeding activity of the fiddler crab in and on the marsh and the density
414 of *S. alterniflora*. Mouton & Felder (1996) indicate that *U. longisignalis* burrow density increased
415 landward of the 4-m into the marsh where the vegetation became more open and scattered. They report
416 the maximum density of burrows near the 8-m to 12-m marks into the marsh suggesting a potential
417 relationship between tidal flooding and the deposition of wrack contributing to food resources.

418 The extent of shoreline oiling within northern Barataria Bay (Zengel & Michel 2013) and the extent
419 and duration of oil in and on the water indicated in the Environmental Response Management Application
420 (ERMA) (<http://gomex.erma.noaa.gov/erma>) would indicate that the populations of *L. irrorata* and *Uca*
421 were affected in their ability to carry out their life cycle on the marsh (Morris *et al.* 2015) and in the water
422 column at all stations including the reference stations for some period following the entry of oil into the
423 region (Fodrie *et al.*, 2014; Pennings *et al.*, unpublished data). This study found that the dominant fiddler
424 crab within these marshes, *U. longisignalis*, recovered at all oil levels prior to sampling at 30 months after
425 the *DWH* spill. There are indications that *L. irrorata* started recovery at the MD stations at 40 months
426 after the spill and population density is beginning to demonstrate seasonal cycling. Recovery, however,
427 has not occurred at the HV stations.

577

578 Fig. 1. Stations locations within Barataria Bay, LA.

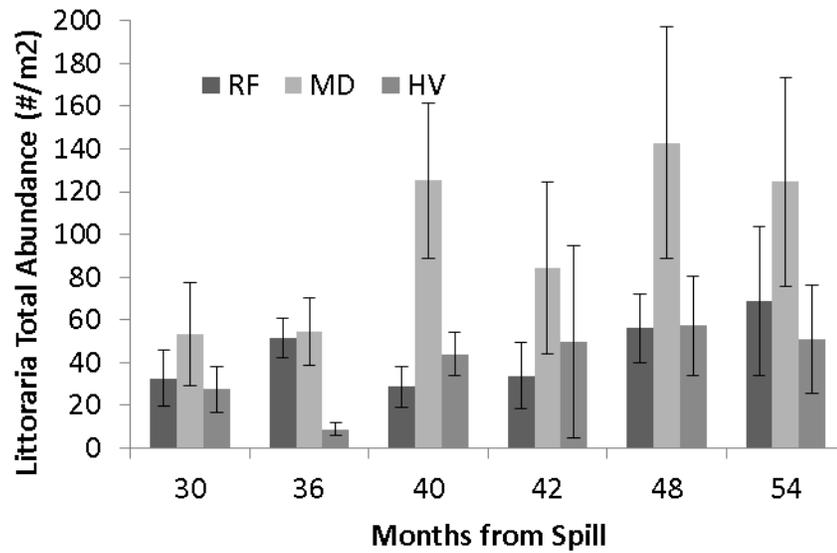

580

581 Fig. 2. Mean *Littoraria* abundance between oiling levels across all sampling times and within various size
582 classes. X-axis = site type, Y-axis = average density/m². Black = adults, grey = sub-adults, and light grey =
583 juveniles.

584

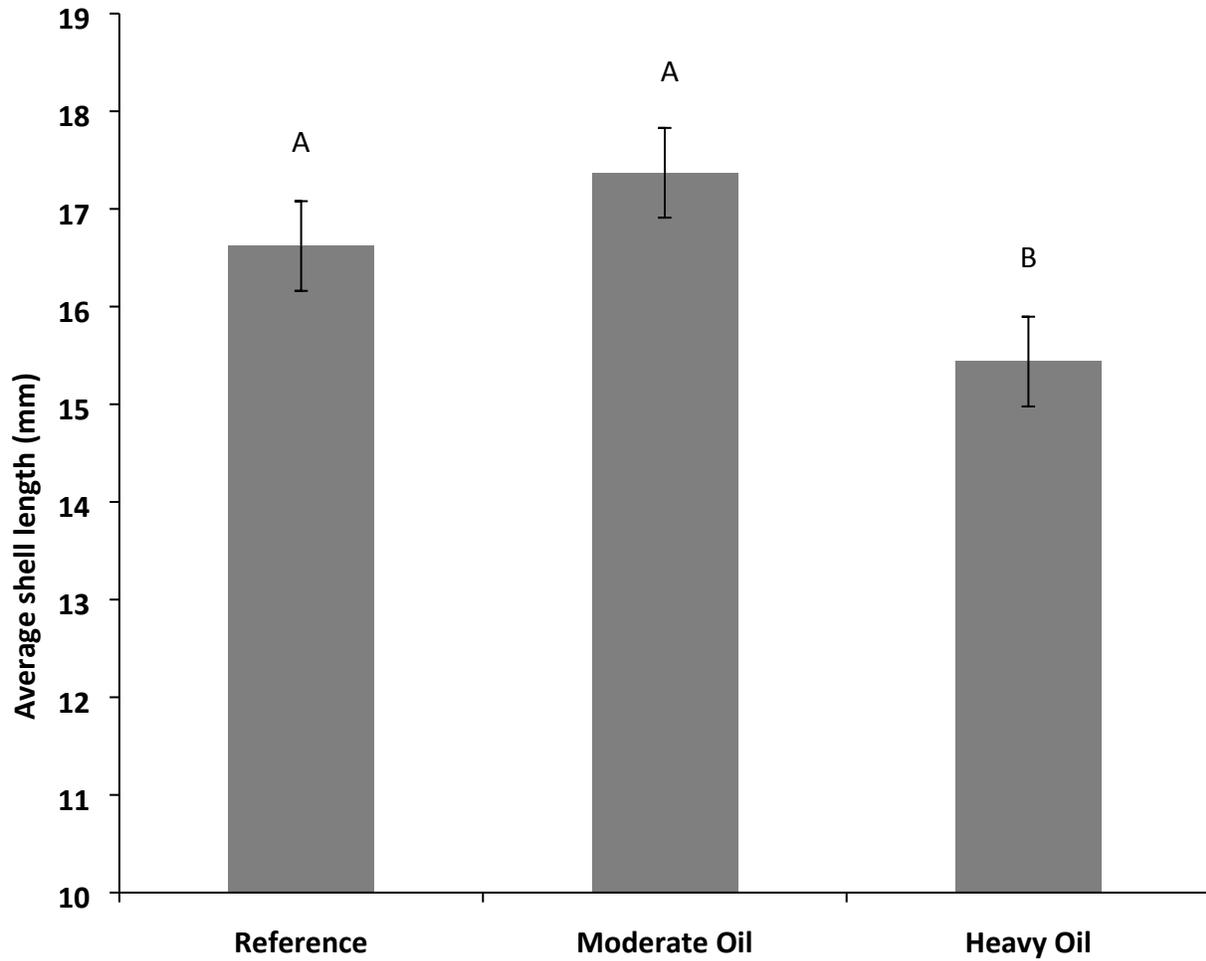

585

586

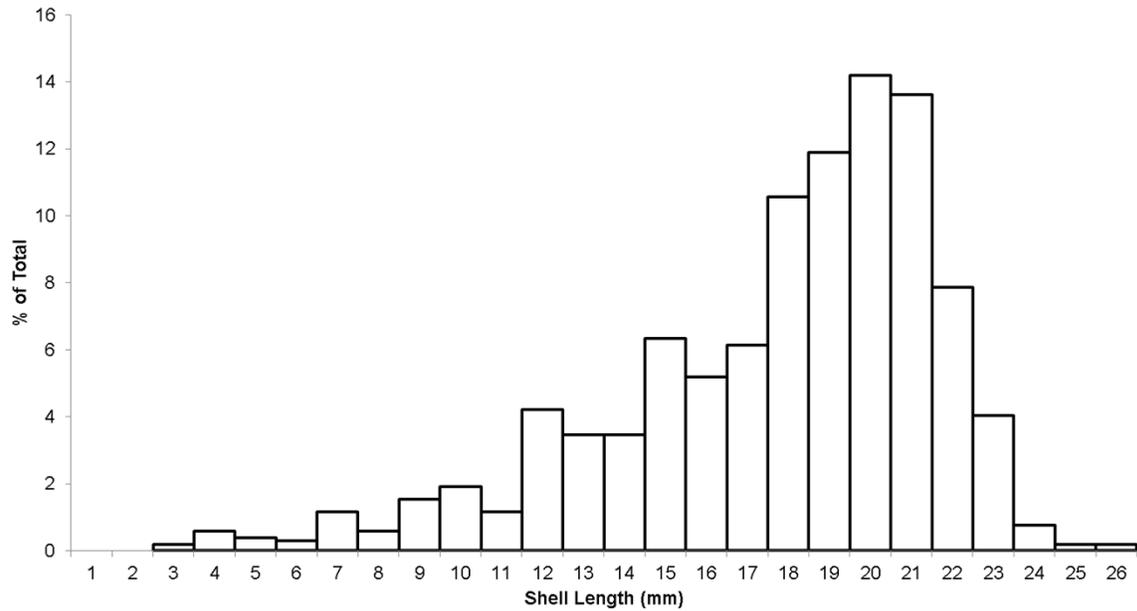

587 Fig. 3. *Littoraria irrorata* total density m⁻² 30 to 54 months after the *DWH* oil spill. Values are means (\pm SE;
588 n=7) for reference (RF), moderately-oiled (MD), and heavily-oiled (HV) shoreline marshes of northern
589 Barataria Bay, LA, USA.

590

591

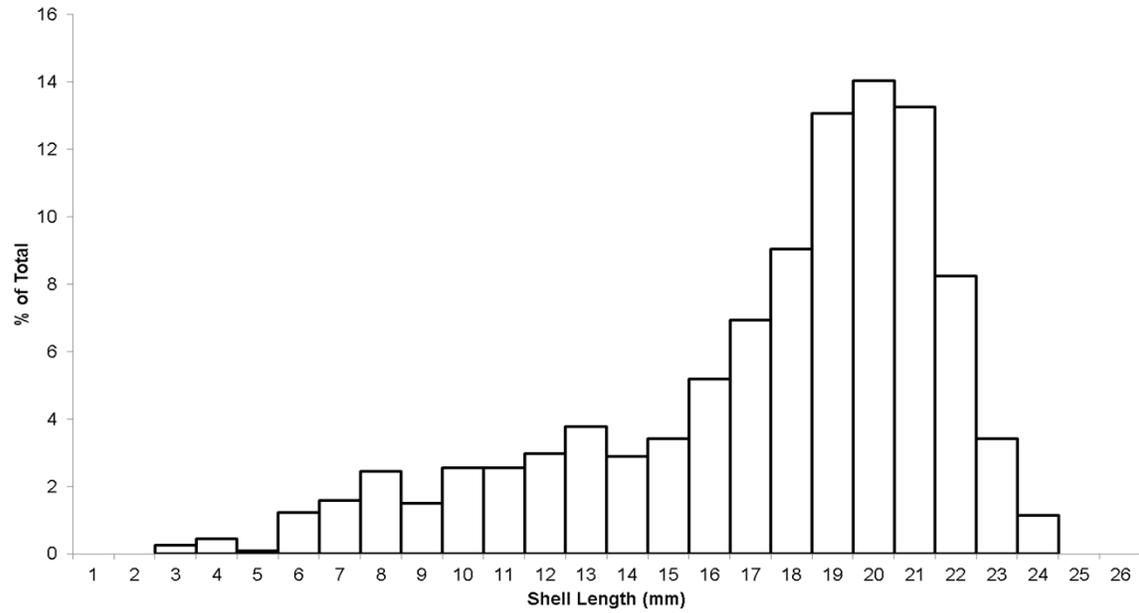

592 Fig. 4. Average *Littoraria* shell length by sampling site type across all sampling times. X-axis = site type, Y-
593 axis = average shell length (mm). Heavily-oiled (HV) sites had significantly smaller *Littoraria* than
594 reference (RF) or moderately-oiled (MD) sites.

595

596 Fig. 5. Reference (RF) sites *Littoraria* size distribution by percentage of total abundance. X-axis = shell
597 length in mm, Y-axis = percentage of total abundance represented by each specific shell length across all
598 sampling times.

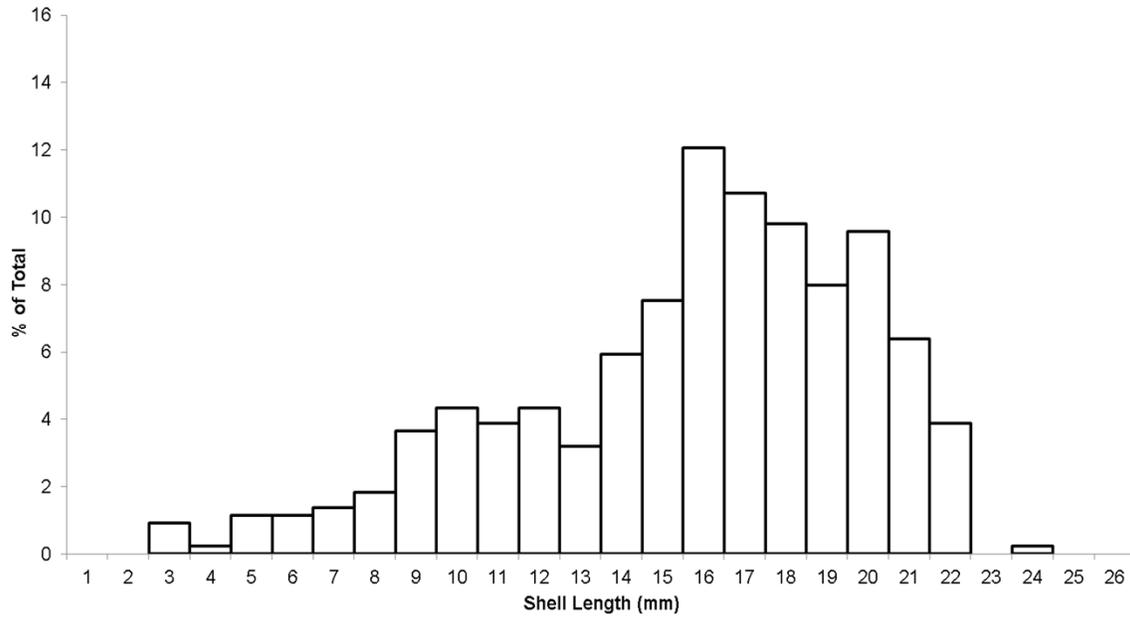

599

600

601 Fig. 6. Moderately-oiled (MD) sites *Littoraria* size distribution by percentage of total abundance. X-axis =
602 shell length in mm, Y-axis = percentage of total abundance represented by each specific shell length
603 across all sampling times.

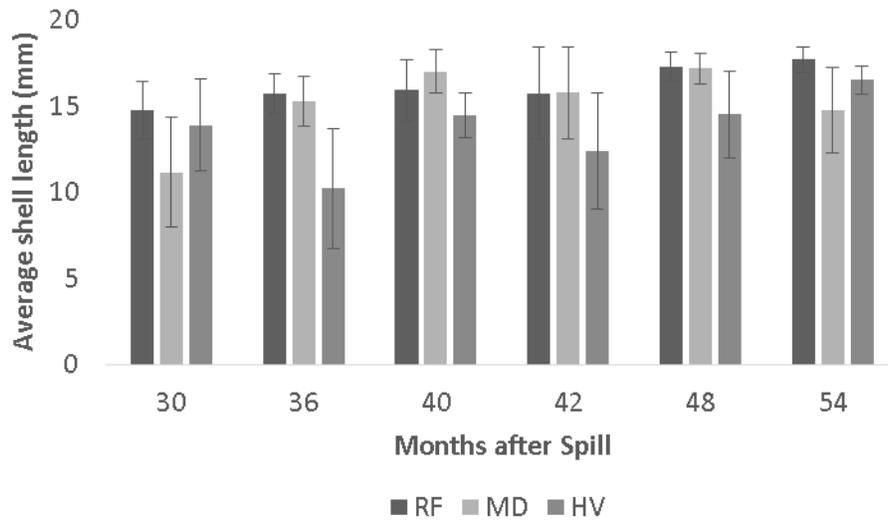

604

605

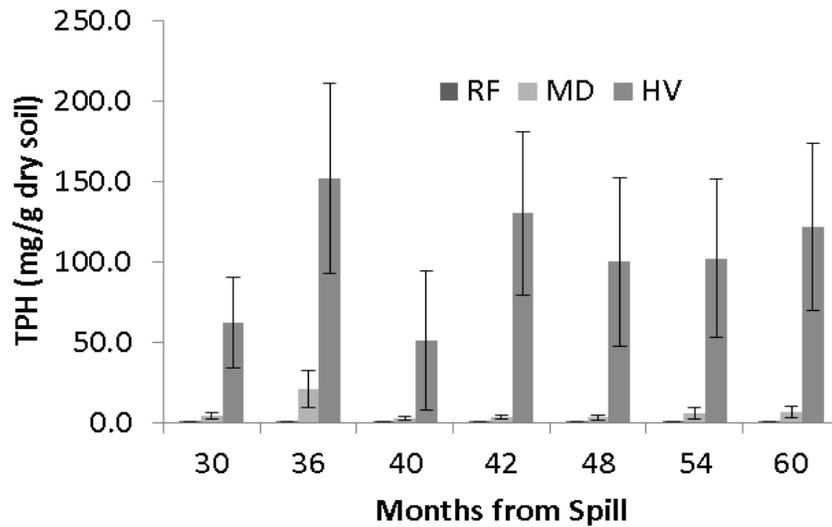

606 Fig. 7. Heavily-oiled (HV) sites *Littoraria* size distribution as percentage of total abundance. X-axis = shell
607 length in mm, Y-axis = percentage of total abundance represented by each specific shell length across all
608 sampling times.

609

610

611 Figure 8. Average shell length (mm) for each oiling level within each sampling period after the spill.

612

613 Fig. 9. Surface soil (0-2 cm) total petroleum hydrocarbon concentrations 30 to 54 months after the *DWH*
614 oil spill. Values are means (\pm SE; n=7) for reference (RF), moderately-oiled (MD), and heavily-oiled (HV)
615 shoreline marshes of northern Barataria Bay, LA, USA (from Lin *et al.* unpublished data).
