The perceived duration of a sound is affected by its fundamental frequency and intensity: higher sounds are judged to be longer, as are sounds with greater intensity. Since increasing intensity lengthens the perceived duration of the auditory object, and increasing the fundamental frequency increases the sound's perceived loudness (up to ca. 3 kHz), frequency modulation of duration could be potentially explained by a confounding effect where the primary cause of the modulation would be variations in intensity. Here, a series of experiments are described that were designed to disentangle the contributions of fundamental frequency, intensity, and duration to perceived loudness and duration. In two forced-choice tasks, participants judged duration and intensity differences between two sounds varying simultaneously in intensity, fundamental frequency, fundamental frequency gliding range, and duration. The results suggest that fundamental frequency and intensity each have an impact on duration judgments, while frequency gliding range did not influence the present results. We also demonstrate that the modulation of perceived duration by sound fundamental frequency cannot be fully explained by the confounding relationship between frequency and intensity.

Running title: Duration modulation

# ABSTRACT

The perceived duration of a sound is affected by its fundamental frequency and intensity: higher sounds are judged to be longer, as are sounds with greater intensity. Since increasing intensity lengthens the perceived duration of the auditory object, and increasing the fundamental frequency increases the sound's perceived loudness (up to ca. 3 kHz), frequency modulation of duration could be potentially explained by a confounding effect where the primary cause of the modulation would be variations in intensity. Here, a series of experiments are described that were designed to disentangle the contributions of fundamental frequency, intensity, and duration to perceived loudness and duration. In two forced-choice tasks, participants judged duration and intensity differences between two sounds varying simultaneously in intensity, fundamental frequency, fundamental frequency gliding range, and duration.

The results suggest that fundamental frequency and intensity each have an impact on duration judgments, while frequency gliding range did not influence the present results. We also demonstrate that the modulation of perceived duration by sound fundamental frequency cannot be fully explained by the confounding relationship between frequency and intensity.

# I. INTRODUCTION

A simple sinusoid sound is characterized by three parameters: duration, frequency, and intensity. The subjective and objective duration of a sound (or other sensory stimulus) are not equal(1, 2) and depend on the state of the observer(3) and the organization of consecutive sounds in time(4), as well as the structure of the sound signal itself. In particular, sound signals with larger amplitudes are perceived as longer when compared with sounds of the same objective duration but smaller amplitude, indicating that sound intensity contributes to duration perception(5). The perceived duration of sounds is also prolonged by frequency, with higher tones being perceived as longer than lower ones; this has been documented for simple sinusoid sounds (6) as well as for more spectrally complex tones (7, 8, 9). Analogous modulation phenomena exist in visual and tactile sensory modalities (11, 12, 13, 14).

However, it is not clear whether intensity and fundamental frequency can influence the perceived duration of sounds independently, and to what extent. Since the frequency of sinusoidal sounds contributes to their intensity as well as to their perceived loudness (10), the modulation effect of frequency on perceived duration could potentially be explained as a byproduct of the modulation of perceived duration by intensity alone.

The duration coding mechanism that might be partly responsible for the observed frequency modulations in duration perception could be based on two different phenomena: first, the neural spikes corresponding to the onset or offset of the sound may be delayed as a function of intensity and phase-locked modulation frequency (i.e. fundamental frequency) (9) (see also (33) for neurophysiological evidence); second, the accumulation of input spikes may be affected by the intensity and frequency of the sound (as in the dual klepsydra model (34)).

In addition to low level mechanisms, several high level explanations for the duration modulation by frequency have been proposed. According to a Gestalt approach, a high frequency sound is perceived as intrinsically smaller – and consequently, shorter – than a low frequency

43 sound (36). Also, speech-like auditory objects may be subject to a compensatory strategy  
 44 as high pitched syllables in many languages (e.g., lexical tones in Mandarin Chinese) are  
 45 produced shorter than low-pitch tones (28). (This explanation can, of course, be reversed,  
 46 with pitch-dependency of the production patterns interpreted as a compensatory consequence  
 47 of perceptually driven pitch-modulation of perceived duration, e.g., (44)).

48 Disentangling influences of intensity and fundamental frequency on perceived duration of  
 49 a sound is demanding for several reasons. First and foremost is the fact that intensity and  
 50 frequency are themselves not independent from each other. Physically, intensity of a (simple)  
 51 sound is a function of its frequency. As equal loudness contours show, the sound frequency  
 52 also positively contributes to its perceived loudness up to about 3.2 kHz.

53 Apart from purely psychoacoustic considerations, the interactions between fundamental  
 54 frequency, intensity and duration perception are also of linguistic and phonetic interest.  
 55 Relative prominence of speech constituents, encoding lexical stress, emphasis, etc., is signalled  
 56 through a complex, context-sensitive and language-dependent interplay between these three  
 57 sound characteristics (as well as spectral properties), which underline the necessity of stimulus  
 58 choice in experimental settings. While sinusoidal sounds are an important research tool, they  
 59 are scarce in biologically plausible sound environment of human communication where sounds  
 60 are complex and the fundamental frequency is constantly moving. In tone languages, syllable  
 61 duration cannot be separated from the underlying tone (23, 24, 28). In quantity languages, the  
 62 fundamental frequency ( $f_o$ ) contours contribute to distinguishing between quantity categories  
 63 (25, 26, 27). In addition to  $f_o$  level, its movement also interacts with perception of syllable  
 64 duration, albeit in somewhat language-dependent way (7, 8, 22, 28, 29, 30); this interaction  
 65 may depend on the linguistic or non-linguistic goals of the experimental paradigm.

66 In the present work, we revisit this issue with a special focus on disentangling the contributions  
 67 of fundamental frequency and intensity to the perceived duration of a sound. We report the  
 68 results of two forced choice experiments in which the listeners were asked to compare the

durations and intensity levels, respectively, of two sounds varying simultaneously in multiple  
 dimensions of duration, fundamental frequency and intensity. The possible confounds between  
 fundamental frequency and intensity are addressed in two ways. First, the sounds presented  
 to the participants have rich spectral content that is band pass filtered to a narrow spectral  
 frequency range well separated from the fundamental frequency. This results in a pitch  
 sensation that corresponds to the fundamental frequency although almost no energy is left  
 at that frequency. This percept is sometimes named the missing fundamental phenomenon  
 since the auditory nerve fibres corresponding to the fundamental are not encoding the signal.  
 Instead, the amplitude modulated movement of the basilar membrane at the band pass  
 frequencies conveys the information with slow oscillations corresponding to the fundamental.  
 Second, using logistic linear regression analysis, the effects of fundamental frequency on  
 both duration and intensity judgments are quantified. Comparing these influences allows us  
 to evaluate whether the contribution of fundamental frequency to loudness is sufficient to  
 explain its effect on duration perception.

## II. METHODS

### A. Participants

In a pilot phase and in an earlier work where similar stimuli were used, the fundamental  
 frequency had an impact on duration judgments of each participant (30). Since every  
 individual recruited for the study was expected to show fundamental frequency modulation  
 of the duration judgment on an individual level, there was no constraint to the minimum  
 sample size. If a participant was not affected by fundamental frequency in their duration  
 judgments, they would be excluded from the analyses since the experimental question for  
 these individuals would not make sense.

Eleven native monolingual Finnish speakers aged 18-40 participated in the experiment. They

93 were screened for normal hearing ( $<20$  dB). The stimuli were presented through headphones  
 94 that were calibrated for each participant so that the standard sound always had a fixed  
 95 intensity level of 66 dB SPL (A-weighted) measured by a PeakTech 5055 sound level meter.  
 96 Every participant took part in both discrimination tasks reported here<sup>1</sup>. The experiments  
 97 were performed according to the guidelines of the Declaration of Helsinki at the University of  
 98 Helsinki, Finland; the Committee for ethical review granted ethical approval to carry out the  
 99 study within its facilities and the participants gave their written consent to take part in the  
 100 experiments.

## 101 B. Procedure

102 Two 2-alternative forced choice discrimination tests were performed to evaluate multifeature  
 103 intensity and duration discrimination, respectively. The sounds presented to the participants  
 104 were varied in four parameters: duration,  $f_o$  level, dynamic  $f_o$  range, and intensity level,  
 105 and were drawn at random so that the probability distribution of each parameter formed a  
 106 truncated normal distribution.

107 The tasks were performed in two blocks (intensity discrimination block and duration discrim-  
 108 ination block) and the order of the blocks was randomized between the subjects. In each  
 109 block, the participants were presented with 300 pairs of stimuli. After presentation of each  
 110 pair they were asked to identify which of the two sounds was louder or longer, respectively,  
 111 by typing *a* (for the first) or *x* (for the second) on a standard (Finnish) QWERTY keyboard.

---

<sup>1</sup>In addition, the participants also performed two additional experiments preceding the discrimination tasks reported here.

# C. Signal generation

Every sound stimulus was fully characterized by four parameters—duration,  $f_o$  level, dynamic  $f_o$  interval and intensity level—drawn for each sound from a truncated normal probability distribution (if a randomly generated parameter was more than two standard deviations away from the mean, it was discarded and a new value was generated). The duration of each sound was drawn independently from the normal distribution with mean 300 ms and standard deviation 75 ms.  $f_o$  level followed a truncated normal distribution with mean 150 Hz (corresponding to 0 semitones) and a standard deviation of 4 semitones (hence, there were more sounds over 200 Hz than under 100 Hz). Here the semitone is defined as the twelfth root of two, i.e., the fixed ratio between frequencies of adjacent keys of an equally tempered keyboard. The dynamic  $f_o$  range followed a truncated normal distribution with mean 0 (static sound) and standard deviation of 4 semitones, and the intensity level followed a truncated normal distribution with mean 66 dB and standard deviation 3 dB. Altogether, the durations varied from 150 ms to 450 ms and the instantaneous pitch of the sound varied between 75 Hz and 300 Hz (this is 8+4 semitones below and above 150 Hz). Since the gammatone filter used for signal generation (see below) had a center frequency over 3 kHz, even the highest instantaneous  $f_o$  had only unresolved harmonics within the band. At the biomechanical level of the cochlea, the basilar membrane vibrations are amplitude modulated to the fundamental frequency, creating the same pattern in the auditory nerve signal. With sufficient separation (as here) between the active spectral band and the fundamental frequency, the individual harmonics of the sound should not be discernible. The intensity levels varied between 60 dB and 72 dB. Because the distributions are truncated, the true standard deviations of the generated distributions are slightly smaller.

For each randomly generated set of parameters, a positive sawtooth wave of the given duration was frequency modulated so that the instantaneous fundamental frequency was exponentially increasing/decreasing depending on the sign of the interval, and the frequency at the middle

138 of the signal duration corresponded to the given  $f_o$  level (see Fig. 1, A). To avoid a jump in  
 139 the waveform at the end of the signal, the predetermined duration was prolonged to the next  
 140 zero crossing. The sawtooth waveform was selected to ensure a rich spectral content on the  
 141 targeted frequency band.

142 The sawtooth wave was subsequently band-pass filtered using a 4th order approximation  
 143 of the gammatone filter with center frequency  $f_c = 3141.6$  Hz (39) (Fig. 1, B). The center  
 144 frequency was chosen so that the fundamental frequency was always well separated from the  
 145 frequency band containing the signal energy. Further, a normalization of the energy of the  
 146 signal was performed to even out residual loudness differences; the normalization was based  
 147 on the energy average over the first 100 ms of the waveform. Finally, the signal amplitude  
 148 was changed to reach the desired intensity level, completing the single sound generation.

149 Having generated the pair of stimuli for each trial in this way, the sounds were joined using  
 150 randomly generated inter-stimulus interval: a duration was drawn from a truncated normal  
 151 distribution with mean 800 ms and standard deviation 10 ms, and used as an interval from  
 152 the onsets of the first to the onset of the second sound. Then, 600 ms of silence was added  
 153 before the onset of the first sound and after the offset of the second sound and a white  
 154 noise was added (to the entire signal, including these pre- and post-stimulus intervals) with  
 155 10 dB signal to noise ratio in order to mask nonlinear distortion tones and guarantee a  
 156 narrow spectral band. In the pilot phase, the stimuli presented without noise did not have a  
 157 perceivable distortion product but for very similar sounds presence or absence of noise has  
 158 reportedly changed their pitch percept (45). Finally, linear onset and offset ramps covering  
 159 the first and the last 200 ms of the entire stimulus containing the two sounds were created.  
 160 Fig. 2 shows an example of one trial.

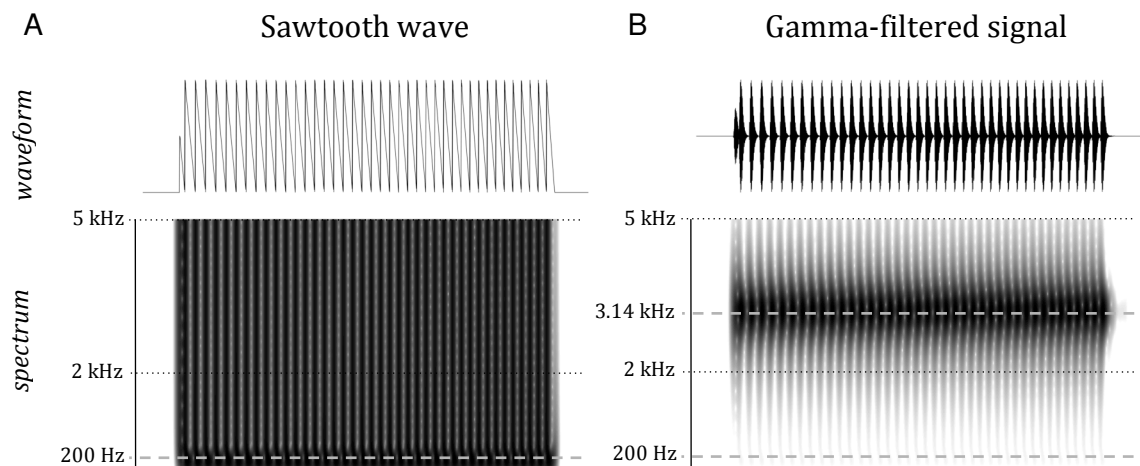

Figure 1: The waveform and spectrum of the original (A) and gamma-filtered (B) sawtooth wave. The wave mid-point fundamental frequency is 200 Hz, duration 200 ms. The frequency movement interval is 4 semitones. Note that the energy in the filtered signal is centered around the gammatone filter's center frequency of 3.14 kHz, and is negligible around the signal's fundamental frequency of 200 Hz.

Figure 2: An example of a trial with two stimuli with waveform (top) and spectrum (bottom). The fundamental frequency and duration parameters of the first stimulus are identical with that in Fig. 1, the second stimulus is 150 ms long, with central frequency of 150 Hz and  $f_o$  movement interval -3 semitones. The gain for the first signal is 0 dB, for the second 0.5 dB. Inter-stimulus interval of this example trial (between the onsets of the sounds) is 805 ms. The central frequency of the gammatone filter is superimposed over the spectrogram.

# D. Predictability and correlations between the design factors

Because the final periods of the sounds were completed, duration and fundamental frequency were somewhat correlated. In order to evaluate the amount of resulting interaction between the variables and its impact on the actual durations of the stimuli, linear regression models were fitted to the actual acoustic characteristics of the stimuli that were played to the participants.

A third order non-linear regression model with the sound duration as a dependent variable and  $f_o$  level and dynamic  $f_o$  interval as predictors explained 0.02% of the durational variation with a significant effect of the  $f_o$  level; the dynamic  $f_o$  interval effect was not significant. The small artificial lengthening of the sounds thus does not provide strong cues to the stimulus duration. In fact, the amount of durational manipulation was typically small, on average 1.5 ms.

The  $f_o$  gliding speed, on the other hand, gives much more information. A linear model with gliding speed as an independent and duration as a dependent variable fitted to the generated stimuli explained 9.5% of the variation and a 15th order nonlinear model explained 11.6% of the variation (increasing the order of the model beyond 15 did not increase the  $r^2$  value any more). The effect size as estimated from the (first order) linear model is quite large: the statistical model predicts a 23 ms shorter duration for a sound with a change rate of 10 semitones per second as opposed to a static sound of the same duration. This is the largest single source of bias in the data; however, it should not affect the results since participants would not know that the gliding speed is related to duration and they should not be able to detect it during the experiment.

In fact, the design of the current work was such that these biases work, in general, against the hypotheses that higher and more dynamic  $f_o$  are perceived as longer. As the last period of each generated sound was prolonged up to the end of the last period, the low  $f_o$  stimuli and falling sounds were effectively lengthened more than the high/rising ones. Additionally,

187 in the current design, the probability of a long sound was reduced by observing a very fast  
188 moving stimulus—if a subject inferred this relationship, she or he would consequently judge  
189 the more dynamical stimuli as shorter rather than longer.

## 190 E. Statistical analysis of the response data

191 Separate mixed effect logistic regression (logit) models were fitted for each discrimination  
192 task, with participants' response as a dependent variable (with values 1: the first sound  
193 louder/longer, and 0: the second sound louder/longer). The fixed effects were the differences  
194 between the actual signal parameters of the two stimuli in each trial (a value for the first  
195 sound minus the corresponding value for the second sound): the difference between durations  
196 (in s), the difference between intensity levels (in dB), the difference between  $f_o$  levels (in  
197 semitones), and the difference between the dynamic  $f_o$  ranges.

198 For the last difference variable we tested two alternative versions, the first representing the  
199 difference in absolute dynamicity (the difference between *absolute* values of the  $f_o$  ranges), and  
200 the second representing the difference in dynamicity including direction of the fundamental  
201 frequency slope (the difference between the *raw* values of the  $f_o$  ranges). All the manipulated  
202 variables (differences) were used as random slopes for the subjects.

203 Full models with interactions among these fixed effects as well as models without interactions  
204 were fitted. Statistical significance was estimated using Monte Carlo simulations as imple-  
205 mented in the R package lme4 (41). Deviance reduction was calculated for the individual  
206 models in order to assess the quality of fits (42).

207 In addition, in order to compare the performance of individual participants with the group  
208 effects (captured by the mixed effect models), we fitted simple logistic models for the same  
209 dependent and fixed effect variables as above (without interactions) for each participant  
210 separately.

# III. RESULTS

## A. Intensity discrimination

Logistic regression analysis of the data shows that duration difference,  $f_o$  difference, and intensity difference all had a significant impact on intensity judgments. The dynamic  $f_o$  range difference did not reach significance, whether conceived as a difference in absolute (Table 1) or raw (Table 2) values of the range. The interactions were not significant, therefore only the coefficients from the models containing just the main effects are reported.

Table 1: Mixed effects model fitted to the responses of *intensity discrimination* with frequency range difference calculated as the difference between the **absolute values** of the dynamic  $f_o$  ranges.

Effect	size	error	z value	p (MCMC)
Intercept	0.14	0.076	1.8	0.07
Duration difference	6.5	0.71	9.2	$2 \cdot 10^{-16}$
Intensity difference	0.34	0.055	6.2	$4 \cdot 10^{-10}$
Frequency difference	0.14	0.036	3.9	$1 \cdot 10^{-4}$
Frequency range difference	0.028	0.020	1.4	0.2

Table 2: Mixed effects model fitted to the responses of *intensity discrimination* with frequency range difference calculated as the difference between the **raw values** of the dynamic  $f_o$  ranges.

Effect	size	error	z value	p (MCMC)
Intercept	0.14	0.0768	1.8	0.07
Duration difference	6.6	0.68	9.6	$2 \cdot 10^{-16}$
Intensity difference	0.34	0.054	6.3	$2 \cdot 10^{-10}$
Frequency difference	0.14	0.036	3.9	$1 \cdot 10^{-4}$
Raw frequency range difference	-0.006	0.011	-0.57	0.56

The effects of duration, intensity, and fundamental frequency differences are all positive and highly significant, indicating that increases in any of these parameters are associated with a perceived increase in loudness (the greater the difference, the relatively greater the parameter value for the first sound, and, according to the model, the greater likelihood of a ‘first sound

222 louder' response). Also relevant are the almost identical values of the estimates of these fixed  
223 effects between the two models with different dynamic range comparison variables.

224 By comparing deviance of the experimental models to the deviance of the null model which  
225 includes only random intercepts for the subjects, the current models both reduce approximately  
226 26 % of the deviance for intensity judgments, showing that the addition of the modulating  
227 variables produces a better fit to the data for both models.

228 Comparing the model parameters allows us to compare the relative effects of sound manipu-  
229 lation between different acoustic parameters. Increasing the intensity level of the first sound  
230 by 1 dB adds 0.34 to the linear combination of the dependent variables in the inverse logit  
231 function fitted by the model. The same quantitative effect can be achieved by 52 ms (0.052 s)  
232 durational lengthening of the sound ( $6.5 \times 0.052 \simeq 6.6 \times 0.052 \simeq 0.34$ ) or 2.4 semitones  
233 increase in fundamental frequency ( $0.14 \times 2.4 \simeq 0.34$ ).

234 The standard deviations of the random slopes were 1.8 and 1.6 for duration, 0.18 and 0.17  
235 for intensity, 0.11 and 0.11 for fundamental frequency, and 0.05 and 0.02 for frequency range  
236 (respectively, for the two models). Comparing these estimates to the effect sizes indicate more  
237 inter-subject variability in frequency range response compared to the other signal parameters  
238 (for this variable only, the standard deviation is actually greater than the estimate).

239 This assessment is explicitly confirmed by the separate logistic models with the same dependent  
240 and independent variables fitted for each participant individually (the estimates and their  
241 significances are reported in full in the Appendix Tables 1 and 2). The duration difference and  
242 intensity difference variables are significant and positive for both versions of the model and  
243 for *all* eleven participants. Also, the effect of  $f_o$  difference is significantly positive for all but  
244 two subjects (subject number 1 and 8) in both models. On the other hand, the dynamicity  
245 difference is only significant (and positive) for one participant in the case of difference in  
246 absolute range and two participants (one negative, the other positive) for the directional  
247 difference in raw dynamic ranges.

# B. Duration discrimination

Duration difference, intensity difference, and  $f_o$  difference had a significant effect on duration discrimination, but dynamic  $f_o$  range difference did not reach significance (Table 3). The interactions were not significant; therefore only the coefficients from the models containing just the main effects are reported.

Table 3: Mixed effects model fitted to the responses of *duration discrimination* with frequency range difference calculated as the difference between the **absolute values** of the dynamic  $f_o$  ranges.

Effect	size	error	z value	p (MCMC)
Intercept	0.47	0.19	2.4	0.016
Duration difference	29	2.8	10	$2 \cdot 10^{-16}$
Intensity difference	0.073	0.018	4.1	$4 \cdot 10^{-5}$
Frequency difference	0.19	0.029	6.8	$1 \cdot 10^{-11}$
Frequency range difference	0.021	0.020	1.0	0.3

Table 4: Mixed effects model fitted to the responses of *duration discrimination* with frequency range difference calculated as the difference between the **raw values** of the dynamic  $f_o$  ranges.

Effect	size	error	z value	p (MCMC)
Intercept	0.45	0.19	2.4	0.018
Duration difference	29	2.9	10	$2 \cdot 10^{-16}$
Intensity difference	0.072	0.018	4.0	$8 \cdot 10^{-5}$
Frequency difference	0.19	0.029	6.9	$5 \cdot 10^{-12}$
Raw frequency range difference	0.035	0.014	2.5	0.014

Comparing deviance of the experimental models to the deviance of the null model which includes only random intercepts for the subjects, both current model reduce approximately 45% of the deviance for duration judgments, showing once again that the addition of the modulating variables produces a better fit to the data.

Using the same technique as in the previous section shows that the duration judgments were equally impacted by 10 ms duration increase, an intensity increase by 4.0 dB, and a 1.5 semitone fundamental frequency raise. An intensity increase by 1 dB corresponds to

260 fundamental frequency increase of 0.38 semitone.

261 These findings hold for both models with the alternative definitions of the effect of dynamic  
 262  $f_o$  range effects. However, for duration discrimination task, the directional effect of the  $f_o$   
 263 dynamicity reached significance (Table 4) while the effect of difference in the absolute values  
 264 of dynamic ranges did not (Table 3). The significantly positive sign of the raw frequency  
 265 range difference estimates in Table 4 means that the stimuli with the rising  $f_o$  (positive  
 266 range value) tended to be judged as longer compared with the falling (or less rising) stimuli.  
 267 (Reporting an equivalence between the range difference and the other difference variables,  
 268 although straightforward to derive, would be very cumbersome and is therefore left out from  
 269 this description).

270 The standard deviations of the random slopes were 8.5 and 8.8 for duration, 0.09 and 0.08 for  
 271 frequency, 0.04 and 0.04 for intensity, and 0.03 and 0.03 for frequency range (respectively, for  
 272 the two models). That is considerably smaller than the effect size for duration, and about half  
 273 the estimate for frequency and intensity differences. This measure of inter-speaker variability  
 274 was greater than estimate for the model using difference of the absolute range values and  
 275 approximately the same as the estimate in the alternative model reported in Table 4.

276 The logistic regression models fitted for individual participants (see Appendix Tables 3 and 4)  
 277 shed further light on the degree of robustness of effects regarding the participants' judgments.  
 278 For both duration and  $f_o$  level differences, the effect is consistently positively significant for  
 279 all subjects. Somewhat surprisingly, the intensity difference effect is only significant for three  
 280 participants out of 11 (subject numbers 5, 7 and 11 for both model types); however, the  
 281 sign of the effect is also positive for all remaining participants even though the effect fails to  
 282 reach significance. A similar situation arose for the model with raw range difference as the  
 283 fixed effect (Appendix Table 4): although the estimates are positively significant for only two  
 284 participants (number 3 and 11); in all other cases (except participants 1 and 2) the effect  
 285 is also positive. On the other hand, for the model with difference in absolute range values

(Appendix Table 3), the sign of the estimate is positive and negative for approximately half of the participants each, indicating a much greater degree of qualitative variability across our participants.

Furthermore, in a hierarchical series of models for duration judgment, a model including the intensity (but not frequency) term reduced 37.6% of the model deviance, whereas the model with the frequency (but not intensity) term reduced as much as 44.5% of the model deviance compared to 45.2% for the full model. This suggests that the impact of fundamental frequency on duration judgment is not entirely explained by the impact of intensity. Additionally, when interaction terms were added to the models, they were small and not significant.

### C. Comparing the discrimination results

The two tasks were based on identically generated stimuli allowing for the models for duration and intensity discrimination to be directly compared. While the leading term in both models corresponds to the primary acoustical correlate of perceived duration and loudness respectively, the duration and loudness judgments were both influenced by other sound parameters. Some (or all) of the fundamental frequency variation could lead to variations in perceived loudness that would then lead to duration modulation.

To interpret the results, a thought experiment is carried out where the impact of loudness, as opposed to the intensity, on duration judgments is estimated from the two experiments. Assuming that the impact of loudness (perceived intensity) on perceived duration is proportional to the measured impact of intensity (since this is the leading term in the logistic regression model for loudness judgments), and assuming that a portion of fundamental frequency would impact the loudness which would then in turn impact the duration, the two logistic models can be combined by substituting the intensity term in the duration judgment model with a loudness term, which is a linear combination of duration, fundamental frequency, and intensity.

311 The quantitative estimate of fundamental frequency induced loudness effect does not support  
 312 the idea that duration modulation by fundamental frequency would be primarily generated  
 313 by intensity variations. In the loudness judgment phase, there was an equal impact of 1 dB  
 314 and 2.4 semitones raise, whereas in the duration judgment phase, there was an equal impact  
 315 of 1 dB and 0.38 semitones raise. To give an upper limit for fundamental frequency impact  
 316 on the duration judgment through the loudness, not more than 0.38 semitones could be  
 317 bundled to the loudness percept corresponding to 15.8 % ( $0.38/2.4$ ) of the total fundamental  
 318 frequency effect.

# 319 IV. DISCUSSION

320 Clearly, duration perception is closely linked to both intensity and fundamental frequency.  
 321 Higher fundamental frequency and greater intensity have been shown before to be associated  
 322 with longer perceived duration. The presented set of experiments targeted the question of  
 323 whether the impact of fundamental frequency on duration judgments is simply a confound,  
 324 i.e., whether it can be explained through the influence of frequency on perceived intensity.

325 The results strongly suggest that this is not the case, and that fundamental frequency  
 326 has an independent contribution to the perceived duration of a sound. In the light of the  
 327 design presented here, this finding is supported on several levels. First, care was paid to  
 328 neutralizing the interdependencies between intensity and fundamental frequency in our stimuli;  
 329 nevertheless, participants' judgments in the duration discrimination task were significantly  
 330 influenced by the stimulus frequency. Second, the quantitative comparison of duration and  
 331 intensity judgments demonstrates that the fundamental frequency contribution to intensity  
 332 judgments is not sufficient to fully account for its influence on perceived sound duration.  
 333 Finally, as shown by the rather low deviance reduction by the models, the discrimination  
 334 tasks were quite difficult for the participants. Still, they were able—in a statistical sense—to

perform the discriminations, and their judgments were robustly influenced by most signal properties in expected directions (with the exception of  $f_o$  dynamics).

Stimulus design parameters necessarily have an effect on the response patterns: larger variation in a primary acoustic correlate of a perceptual dimension (e.g. intensity level in loudness discrimination) makes the task easier. The differences between the two stimuli in a trial (determined by standard deviations of parameter distributions) must be detectable but not so large as to make the stimuli qualitatively incompatible with each other. Larger standard deviations in the complex stimuli would make a less difficult task and result in less guessing from participants, reducing the precision of the model estimates; however, a task that is entirely guessing is meaningless. Extreme values of the stimulus parameters could result in different behavior than those for which participants were less sure, but this was not the case in the current work (models using a subset of data within one standard deviation of the standard parameter value showed the same significant effects and effect sizes).

Fitting the models for individual participants shows remarkable robustness and consistency of the effects of signal attributes on both intensity and duration judgments. The effects of signal duration and  $f_o$  level were significantly positive for *all* participants in both tasks, and so were, naturally, the intensity effects in the intensity discrimination task. The effect of signal intensity on duration discrimination judgment was significantly positive on the group level (mixed effect model); on individual level it was primarily manifested by consistency of effect direction (estimate sign) among the participants. In fact, this difference in statistical patterns between the intensity and duration discrimination tasks, and, in particular, between the  $f_o$ -level and intensity effects for duration discrimination provides further corroborative evidence to our fundamental claim that the stimulus frequency effect on duration perception is not solely mediated through the effect of fundamental frequency on perceived intensity of the sound.

A somewhat more complex situation arises with participants' sensitivity to frequency dynamics.

361 The absolute dynamicity (the fact that one stimulus has greater range of  $f_o$  contour than the  
 362 other, regardless of the direction) had, at least for our stimuli, no significant and consistent  
 363 effect on participants' judgments in either task. The  $f_o$  slope direction also had no effect on  
 364 intensity judgments. For durational judgments, however, the (more) rising stimuli were judged  
 365 as longer than the (more) falling ones. Again, this effect was significant at the group level;  
 366 presumably, this significance arose primarily through consistency among the participants in  
 367 the direction of influence (individually, the effect was mostly non-significant). This result,  
 368 including the relative lack of robustness, is generally consistent with the findings discussed in  
 369 the Introduction: the evidence regarding this phenomenon is not unanimous and the results  
 370 reported in literature suggest a degree of influence of participants' language background on  
 371 the effect of stimulus dynamicity on durational judgments.

372 It is remarkable how well the participants were able to selectively attend to duration or  
 373 intensity in making their task-specific judgments. This requires an ability to decompose  
 374 the signal and can be quantified from the present measurements by comparing the relative  
 375 influence of acoustic dimensions across tasks. Indeed, stimulus duration had 4.5 times  
 376 stronger impact on duration judgments than loudness judgments (computed as the ratio of  
 377 estimates in the statistical models). Similarly, the stimulus intensity had 4.7 times stronger  
 378 impact on loudness judgments than on duration judgments. Hence, there is a symmetry in  
 379 the relative impact of intensity and duration on perceived loudness and length.

380 The findings presented here must be taken into account by the energy integration models  
 381 of the peripheral auditory system. The influence of fundamental frequency on perceived  
 382 duration, and more importantly, the lack of interaction between frequency and intensity  
 383 suggest an independent encoding of these signal characteristics, at least when used for  
 384 durational judgments. In general, the observed pattern fits well with the dual klepsydra  
 385 model for duration discrimination (34), assuming that the number of neural spikes entering  
 386 the dual klepsydra system depends, in possibly interconnected but cumulative way, on both

the intensity and fundamental frequency of the sound. By design, the spectral energy was concentrated on a narrow area well separated from the fundamental frequency. The individual harmonics are then indiscernible and allow for the frequency band of the signal energy and the frequency of the pitch to be almost independent of each other.

In the current experiment, artificial stimuli were used with monolingual Finnish speakers, but the effect size coefficients indicate that these participants show effects in the same direction: increasing the intensity or fundamental frequency of a sound results in a perceived lengthening. Similar experimental data (of the duration discrimination task only) from speakers of other languages reported by (30) show qualitatively identical patterns for participants with different language backgrounds. Interestingly, the relative sensitivity to individual signal characteristics significantly differs for participants with different native languages, suggesting a degree of plasticity in auditory processing. Despite these quantitative differences, both results support the existence of general auditory biases and justify a generalization of the pattern of fundamental frequency influencing duration judgment independently of an intensity confound.

Previous research has questioned whether the subtle effects of these biases have any importance for human communication, namely, whether the well documented correlations between frequency patterns and duration of syllables, associated in many languages with phonological phenomena such as tone or quantity, arise primarily from production or perception constraints (28, 44). The findings reported here yield some support to the importance of taking the properties of auditory processing, even the subtle ones, into account when investigating phonetic characteristics of different languages and their origins. Moreover, the precise nature of these interplays partly determines the relevant, perceptually grounded degrees-of-freedom space in signal characteristics available for linguistic communication.

## V. CONCLUSIONS

Intensity, fundamental frequency, and duration of a sound influence its perceived intensity (loudness) and duration. The contributions of these signal characteristics to perceived duration and loudness are mutually independent and differ quantitatively between the two tasks of intensity and duration discrimination. At least for the material used in this study, fundamental frequency dynamics do not contribute consistently to either durational or loudness judgments. Fundamental frequency contribution to duration perception cannot be fully attributed to its effect on signal intensity, i.e, stimulus intensity alone cannot be responsible for duration judgment effects.

Gratitude to Nora Fontell for helping in data collection.

# APPENDIX: DISCRIMINATION BY INDIVIDUAL SUBJECTS

The estimates and significances of duration difference, intensity difference,  $f_o$  difference and dynamic range difference (in two versions) effects obtained by fitting (simple) logistic regression models for the data for each individual speaker separately. The results for intensity discrimination task are shown in Appendix Tables 1 and 2, those for the duration discrimination tasks in Appendix Tables 3 and 4. The models reported in Appendix Tables 1 and 3 use the difference in absolute values of dynamic  $f_o$  range as a independent variable, those shown in Appendix Tables 2 and 4 use instead the alternative variable computed as a difference in raw range values.
