43 **Abstract**

44

45 Chemical communication of predation risk is a common trait in fish. Prey fish under risk of
46 predation can signal the risk to conspecific fish that display defensive reactions. Fish also assess
47 predation risk by visual cues and change behavior accordingly. Here, we wonder if these
48 behavioral changes act as visual alarm signal to conspecific fish that are not initially under risk.
49 We show that shoals of zebrafish visually exposed to a predator display antipredator behaviors. In
50 addition, these defensive maneuvers trigger antipredator in conspecific and, concomitantly,
51 stimulate the hypothalamus-pituitary-interrenal axis, leading to cortisol increase. Thus, herein, we
52 show that zebrafish defensive behaviors act as visual alarm cues that induce antipredator and stress
53 response in conspecific fish.

54

55

56 **1. Introduction**

57 Prey-predator interaction occurs throughout the animal kingdom (Cresswel, 2010) with
58 peculiar and general characteristics in every interaction. We can say that this interaction occurs in
59 every direction (prey to predator, predator to prey, prey to prey and even predator to predator)
60 (Barcellos et al., 2014, Mullan et al., 2015; Dunlop-Hayden & Rehage, 2011). The prey can access
61 the predator trough a diversity of signals that can be visual, olfactory, acoustic, vibration,
62 (Barcellos et al., 2014, Barreto et al., 2003). In fish, we have a vast literature citing these types of
63 perceptions (Wisendem et al., 2004, Barcellos et al., 2011) of a predator or even of a conspecific
64 fish treated by a predator (Jordão, 2000). The different combination of this different signals of the
65 presence of a predator, or even about diverse ways of communication about predator threatening,
66 between conspecifics prey, have different effects in anti-predator maneuvers (O'Connor et al.,
67 2015).

68 During prey-predator interaction, the early detection of a predation risk is crucial for prey
69 survival (Allen, 1975) and chemical communication plays a key role on risk assessment (Chivers
70 & Smith, 1998). Prey fish display antipredator behaviors when perceive the odor of a predator
71 (direct perception; *e.g.* Miyai et al., 2016) or when are alerted by chemical cues released by other
72 preys (indirect perception; *e.g.* Barcellos et al., 2011 and 2014; Barreto et al., 2013;Oliveira et al.,
73 2014). Regarding chemical communication of risk of predation, there is a huge body of evidences,
74 although there are still many unanswered questions. On the other hand, prey fish also detect
75 predators by visual cues and act properly with defensive reactions to deal with these threats
76 (Kalluef et al., 2014), but, in this case, it is far less explored in the literature.

77 The visual presence of a predator induce changes in prey behavior and physiology (Barreto
78 et al., 2003; Gerlai, 2003; Barcellos et al., 2007; Miller & Gerlai, 2007; Gebauer et al., 2011). As

79 a diurnal fish species, we can cite zebrafish, who clearly uses this sensorial modality for
80 communication with conspecifics. Eavesdropping is one type of visual communication, wherein
81 individual use the available visual public information based on conspecific fish behaviors (Abril-
82 de-Abreu et al., 2017). These visual cues allow them to evaluate the context and adjust their
83 behavior appropriately. The zebrafish are able to change their behavior via eavesdropping (Abril-
84 de-Abreu et al., 2017).

85 In this context, we suppose that predator-induced behavioral changes could act as a visual
86 alarm signal that provoke defensive reactions in conspecific fish. Herein, we show in zebrafish
87 (*Danio rerio*) that antipredator behavior is a visual alarm cue for conspecific zebrafish unexposed
88 to a predator that induces defensive maneuvers and, also, act as a stressor that induce a cortisol
89 surge.

90

91 **2. Materials and Methods**

92 **2.1. Ethical note**

93 This study was approved at protocol #20/2016, by the Ethics Commission for Animal Use of
94 Universidade de Passo Fundo (Passo Fundo, RS, Brazil) and all methods were carried out in
95 accordance with the guidelines of National Council of Animal Experimentation Control
96 (CONCEA).

97 **2.2. Zebrafish and housing conditions**

98 Wild-type zebrafish (*Danio rerio*), adults (± 8 months), both sexes, with an average of ± 5
99 cm and ± 0.4 g), were maintained under a photoperiod of ~ 14 h L/10 h D in indoor holding tanks
100 (2 fish/L). The water was maintained as follows: 28.0 ± 2.0 °C; pH of 7.0 ± 0.6 ; dissolved oxygen
101 at 6.8 ± 0.4 mg/L; total ammonia at <0.01 mg/L; total hardness at 6 mg/L; and alkalinity at 22

102 mg/L of CaCO₃. The fish were fed twice a day (09:00 h and 16:00 h), until satiation, with
103 commercial flakes (TetraMin®, Tetra, Melle, Germany). The dimension of the aquarium of stock
104 is 13 x 30 x 40 cm (length, width and height), total water volume of 13 L and the stocking density
105 similar to holding tank of 2 fish/L. The experimental chambers have the dimension of 40x30x30
106 (length, width and height) replete with 30 L of water and the stock density in this was 1 fish per 3
107 liters.

108 All experiments were conducted in quadruplicate. Ten zebrafish were used to form the
109 sender (SF) and 10 to form receiver (RF) fish shoals in respectively groups: control, predator, and
110 non-predator situations. The same was done for additional controls with 10 fish for predator
111 treatment and 10 fish for non-predator. During the experiment, we used a total of 300 zebrafish for
112 analyses.

113

114 ***2.3. Experimental design and procedures***

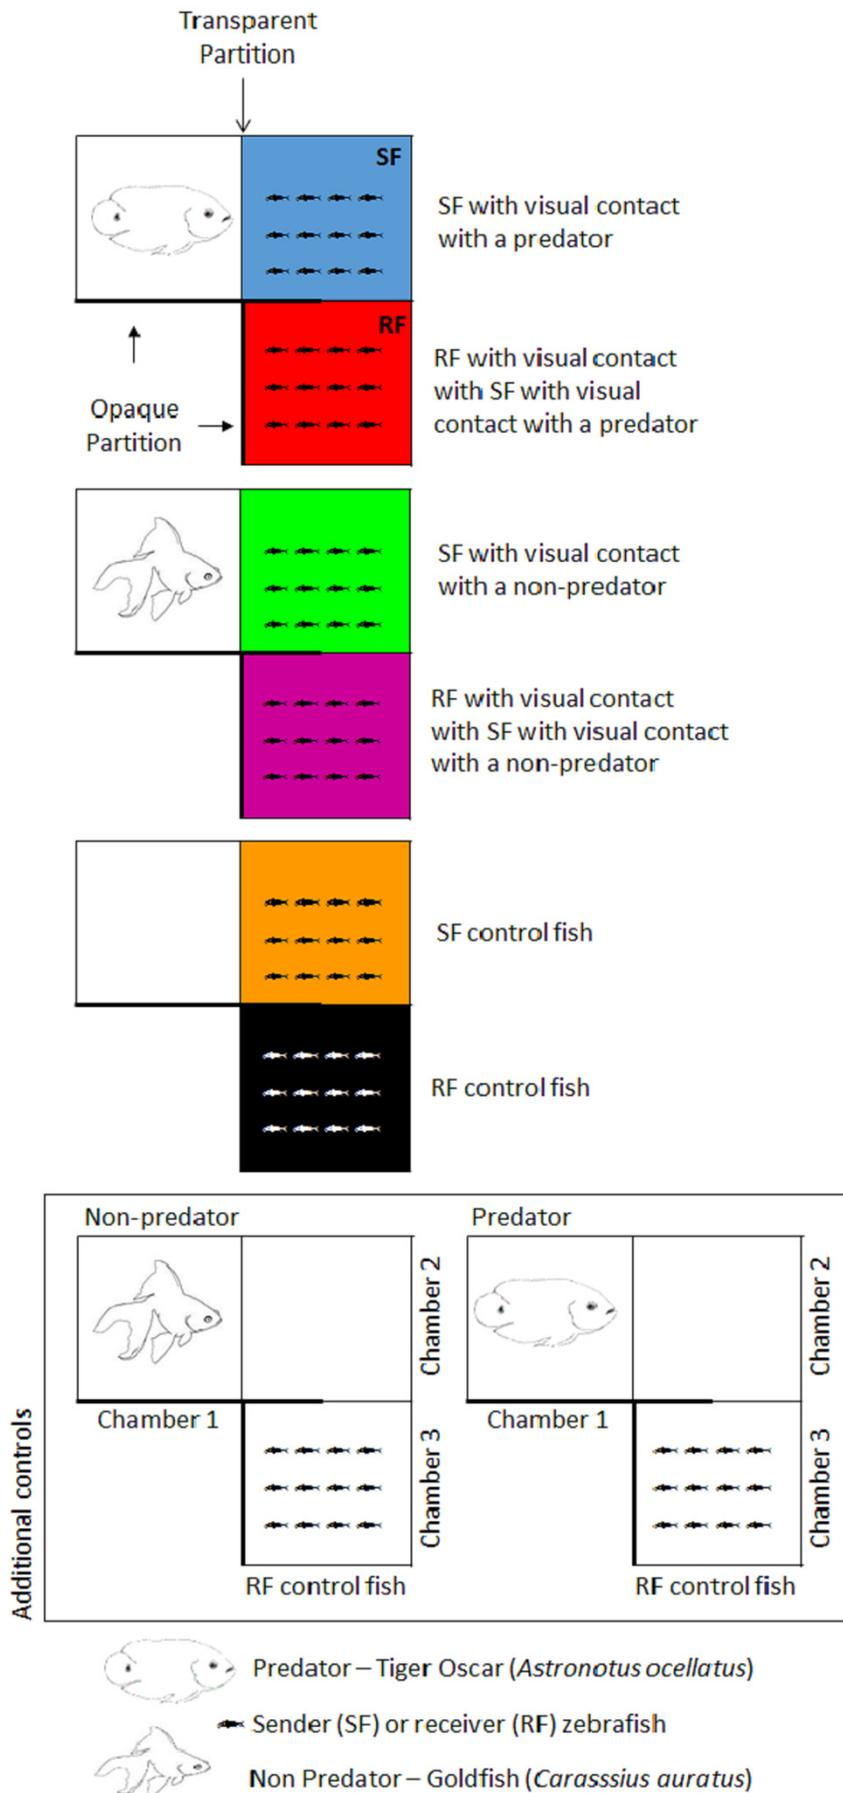

115 As our study strategy, we kept zebrafish shoal in a chamber that allowed visualization of a
116 predator or non-predator fish, or a tank with only water. This condition was called (hereafter) as
117 sender fish (SF, Fig. 1). In an adjacent chamber, we placed other zebrafish shoals, named as
118 receiver fish (RF, Fig. 1), that permitted only the visualization of the SF shoal.

119 The three chambers were completely sealed to avoid any water/chemical communication
120 between chambers. Therefore, we set up three experimental conditions. In the first condition, RF
121 was evaluated during SF exposure to the view of a predator (the tiger oscar *Astronotus ocellatus*).
122 In the second condition, we used a harmless fish (the goldfish, *Carassius auratus*) to test whether
123 the effect of the view of any fish produced behavioral changes in SF and, consequently, in RF. In

124 the last condition, SF was exposed to the view of an aquarium with water but without any fish,
125 controlling lab-handling processes.

126 Moreover, we conducted two additional control conditions (Fig. 1) to show that RF are not
127 capable of seeing directly the predator, two groups of receiver fishes were evaluated isolated
128 (without the visual cues emanating from conspecific fish), one staying in their chamber 3, while
129 the predator stayed in his respective chamber 1. Another group of receiver fish stayed in their
130 chamber 3, while the non-predator stayed in his respective chamber 1. We set up a sample size of
131 $n = 10$ / each condition. Initially, SF and RF zebrafish shoals and stimulus fish (non-predator and
132 predator) were introduced in their respective chambers to an adaptation period of 24h. In this
133 period, SF fish could not visualize the stimulus chamber (predator fish, harmless fish, or tank with
134 only water) and RF could visualize SF during all adaptation and experiment period. Visual contact
135 was blocked using an opaque plastic plaque. After this adaptation period, the plaque was removed
136 allowing the visualization between stimulus chamber and SF for 60 min, integrally video recorded
137 for behavioral analysis. After the visualization period, both SF and RF fish were captured, killed
138 by immediate spinal section, frozen in liquid nitrogen and stored at $-20\text{ }^{\circ}\text{C}$ until required to whole-
139 body cortisol assay.

140 Chambers were always completely cleaned before a new replicate was set up. During the
141 experiments, the aquaria were not cleaned, the water was not changed, and the fish were not feed
142 to avoid the effects of handling procedures, because fish stayed into the chambers only for 24 h.
143 We guaranteed that no exchange of water occurred between each chamber. We previously filled
144 the chambers with water individually and observed that the adjacent chamber remained totally dry.
145 With this procedure, we ensured that the communication between fish of each chamber occurred
146 just via visual sensory.

148 **Figure 1.** Schematic representation of the experimental conditions. The fish drawings in the
149 graphics were drawn by LB.

150

151 ***2.4. Cortisol extraction and determination***

152 To extract and determine the whole-body cortisol we used 4 to 6 fish of each experimental
153 group of each replicate, totalizing 16-24 fish. There is a variation among cortisol “n” samples
154 because whole-body cortisol analysis requires a minimum of 0.5g of tissue extract, so since fish
155 were small, we used pooled samples of two or three fish, aiming to attain the final “n” number of
156 8 samples.

157 Tissue cortisol levels were used as an indicator of the stress response. To prevent a possible
158 handling-induced stress response, the time period between capture and killing was < 30 s. Each
159 fish was weighed, minced and placed in a tube containing 3 ml of phosphate buffered saline (PBSg,
160 pH 7.3). The contents were then transferred to a tube containing ethyl ether and subjected to
161 vortexing for then centrifuged after immediately frozen in liquid nitrogen. The thawed portion
162 (cortisol containing diethyl ether) was decanted and transferred to a new tube and evaporated
163 completely, to yield a lipid extract containing cortisol, which was then stored at - 20°C.

164 The tissue extracts were resuspended in PBSg and the whole-body cortisol levels were
165 measured using a commercially available ELISA kit (EIAgen™ cortisol test,
166 BioChemImmunosystems). This kit is fully validated for zebrafish tissue extracts using the
167 methodology proposed by Sink et al. (2007). The accuracy was tested by calculating the recovery
168 in samples spiked with known amounts of cortisol. The precision was tested by calculating the
169 intra-assay coefficient of variation (CV) of 12 repeated assays in 7 randomly chosen samples on

170 the same plate, and reproducibility was tested by assaying the same samples on different plates
171 and calculating the inter-assay CV.

172 To test for linearity and parallelism, serial dilutions of tissue extracts were performed in
173 the buffer provided with the kit. We detected a strong positive correlation between the curves (R^2
174 = 0.892) and determined that the samples displayed low inter- and intra-assay CVs (7–10 % and
175 5–9 %, respectively).

176 ***2.5. Behavioral quantification***

177 We repeated the methodology employed in Oliveira et al. (2014). Briefly, the water column
178 was divided into three areas of equal size, from the bottom to the surface. The time that fish spent
179 in the bottom area was observed and manually recorded by a single experienced observer without
180 knowing what group was being assessed, and the % of the session time for each of these behaviors
181 was calculated later on. The rationale for quantifying fish behavior via observation and manual
182 registration was based on the findings of Speedie & Gerlai (2008), which clearly show that
183 zebrafish responses to alarm substances can be reliably quantified by visual-manual recording as
184 well as through computerized video tracking methods. We quantified the time spent near the tank
185 bottom as an indicator of defensive reactions (Gerlai & Csányi, 1990; Gerlai et al., 2000; Quadros
186 et al., 2016). The duration of this behavior was expressed as a percentage of the total observation
187 session duration. The onset of the time at tank bottom was considered when at least 3 out of the
188 10 zebrafish remain in the bottom area based on previous method and data (Speedie & Gerlai,
189 2008).

190 ***2.6. Statistics***

191 For whole-body cortisol and behavior values, we compare all treatments and also
192 proceeded two specific comparisons between zebrafish senders and between receiver zebrafish of

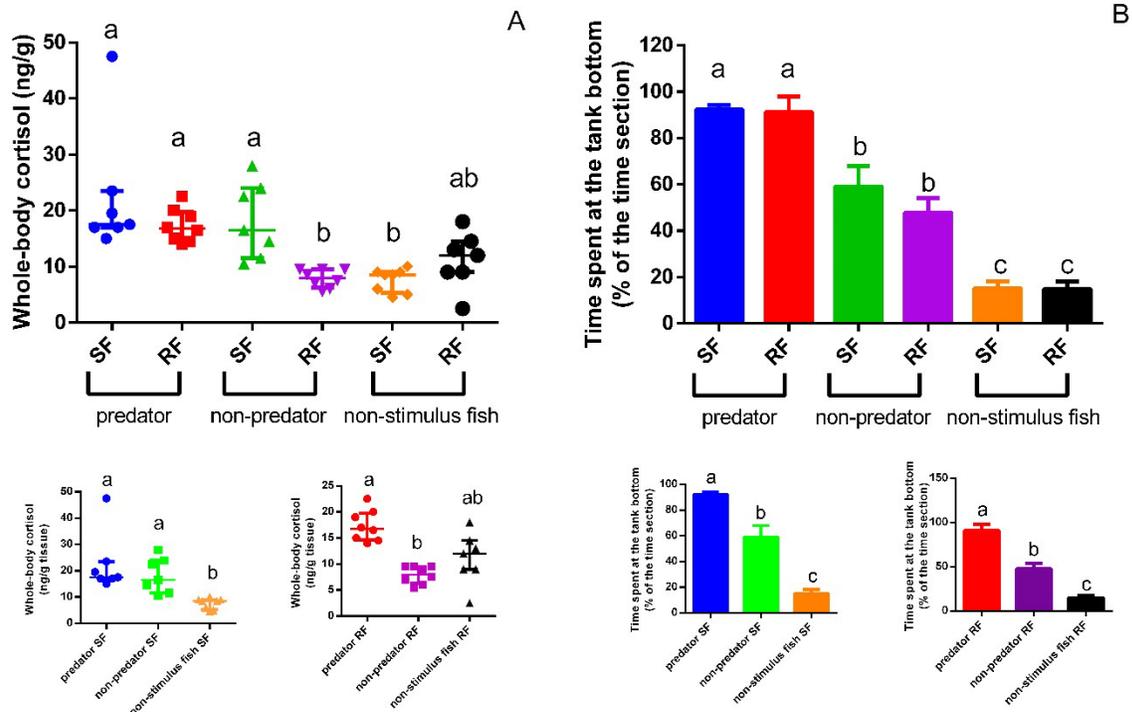

193 experimental conditions. Regarding cortisol values, a Kolmogorov-Smirnov test showed that the
194 samples were derived from populations that did not follow normal distributions. A Bartlett test
195 indicated that the SDs of the samples in the same experiment were statistically indistinguishable.
196 Therefore, we applied the Kruskal-Wallis test followed by Dunn's multiple comparison test.
197 Regarding time spent at the bottom aquaria, the data passed in Kolmogorov-Smirnov test and
198 Bartlett test and, therefore, we applied an one-way ANOVA, followed by Tukey's multiple
199 comparison test to compare the means in each experiment. Significant differences were set at $\alpha =$
200 0.05.

201 **3. Results**

202 We found that visual perception of the predator increased whole-body cortisol in the SF
203 and RFs in relation SF control ($P < 0.0001$, $K = 30.68$, SF comparison $P = 0.0006$, $K = 14.92$ and RF
204 comparison $P = 0.001$, $K = 13.74$). This effect did not occur for SF and RF in the non-predator fish
205 treatment, in which only SF increased cortisol in relation to the SF control. The tank with only
206 water elicited no significant cortisol response (Figure 2A).

207 Regarding defensive behavior, for fish exposed to the predator, both SF and RF had
208 augmented the time spent close to the tank bottom. In fish exposed to a non-predator fish, this
209 variable was also increased for SF and RF, but this response was less intense (statistically lower)
210 than those SF and RF observed in predator exposure treatment, considering the comparison of both
211 groups (non-predator and predator treatment) with the control group (non-stimulus fish). The
212 aquaria with only water induced no significant change in the defensive behavior (Figure 2B,
213 $P < 0.0001$, $F_{5,18} = 38.66$, SF comparison $P < 0.0001$, $F_{2,9} = 50.17$ and RF comparison $P < 0.0001$,
214 $F_{5,18} = 46.63$). Zebrafish from the two additional controls presented very low cortisol concentrations

215 (2.88 ± 0.74 and 3.63 ± 0.59 ng/g tissue), typically found in non-stimulated control fish (Barcellos
 216 et al., 2007; 2014).

217

218

219 **Figure 2.** Whole-body cortisol response (A) and time spent in the tank bottom (B) of SF and RF.
 220 Data were expressed as median (± interquartile range) in the panel A and as mean (± S.E.M.) in
 221 the panel B. Data were compared by Kruskal-Wallis complemented by a Dunn's Multiple
 222 Comparisons Test (panel A) and by one-way Anova followed by Tukey's multiple range test (n =
 223 7 – 8 for cortisol and 4 for behavioral analysis). Different letters above medians or means indicate
 224 the statistical difference.

225

226

4. Discussion

227 We showed that zebrafish visually exposed to predator display antipredator behaviors. that
228 in turn acted as visual alarm cue for conspecific fish. Zebrafish, unexposed to a predator, showed
229 defensive maneuvers when watched their conspecific displaying defensive behaviors. In addition,
230 these visual cues induced activation of hypothalamus-pituitary-interrenal axis (stress response),
231 culminating with a whole-body cortisol increase. These endocrine and behavioral responses might
232 be associated with stress events, like predation risk, since they are well described in the biological
233 interaction between prey and predator in some species (Barton 2002; Clinchy et al., 2011; Archard
234 at al., 2012). Based on our data, we can affirm that eavesdropping occurs via visual sensory system
235 in zebrafish facing their conspecifics in a context of predation risk. Zebrafish in a direct visual
236 contact with a harmless fish, that had an interpretation of a false predation risk, initiated a short-
237 term alteration in their behavior and an irreversible stress response. Here we named an irreversible
238 stress response because we postulated that this cortisol response once triggered shows a typical
239 increase in cortisol levels, that we realized for this group of fish, whereas the behavioral response
240 can be quickly adjusted to the moment. Contrastingly, their conspecifics observing their altered
241 behavior had the capability of interpret and process the information as a non-dangerous situation,
242 evidenced by the lack of alterations in behavioral and endocrine stress responses in receiver fish.

243 Sender and Receiver fish presented elevated cortisol in response to a context where a
244 predator was visually present, hence, a condition of potential imminent predation risk. When in
245 visual contact with a non-predator or with an empty tank, this cortisol increase was not observed
246 in receiver fish. Another interesting result and a response described as an anti-predator behavior
247 (Gerlai, 2003) is the time spent near to the tank bottom, which increased in sender fish when in
248 visual contact whit a predator and also in their respective receiver fish. We can affirm that zebrafish
249 just viewing the behavior of their conspecifics reacting to the predator presence, is able to interpret

250 as a predation imminent risk, and triggers an anti-predatory response. These results indicate a
251 complex form of communication in zebrafish when dealing with predators because further the
252 direct visualizing of the predator induce defensive and stress responses, this risk can be
253 communicated and stress conspecifics that are not seeing a predator, an indirect response to a risk
254 of a predator attack. It indicates the occurrence of a net of communication based on visual cue that
255 can lead shoals of zebrafish deal with predators. It could take place by a chain reaction when a
256 single fish detect a predator and respond to this threat. Consequently, the defensive behavior
257 propagates throughout the entire shoal. Based on the same logic, a shoal displaying anti-predator
258 responses can induce fish in another shoal to do the same and so on. It is plausible because, in a
259 shoal of fish, copying is a behavior that has been observed: it is common, for instance, the leader
260 of a shoal to “command” the group during foraging navigation (Reebs, 2000). The same can occur
261 during defensive reactions and this hypothesis deserves future investigations.

262 The increased whole-body cortisol in zebrafish when in visual contact with a predator was
263 previously described (Barcellos et al., 2007). Surprisingly, zebrafish with a visual contact with the
264 non-predator fish, presented a similar increase in cortisol levels. We can highlight that the cortisol
265 response for this group (SF-non-predator treatment) was also a response of smaller magnitude
266 compared to zebrafish viewing a predator. Nonetheless, receiver fish viewing these conspecifics
267 had no elevated cortisol. The cortisol value of SF exposed to non-predator fish was higher, but the
268 behaviour (time in the tank bottom) was similar. Thus, since RF receive only visual cues, this
269 similar behaviour cannot elicit a cortisol response. In the non-predator treatment, both sender and
270 receiver fish had an augmented time spent near the tank bottom when compared with the control
271 group (without a stimulus fish). However, this response was smaller when compared with the
272 predator exposure treatment.

273 We affirm that the anti-predator response showed for fish directly visualizing the predator
274 (Sender fish) was a determinant factor for triggering an anti-predatory behavior in receiver ones,
275 confirming that communication of a threat occurred by visual cues in a context of an interpretation
276 of anti-predator behavior displayed by sender fishes. The unexpected behavioral and stress
277 response in non-predator treatment may be due to the limitations assessment of the non-predator
278 fish, since zebrafish have only visual contact with it. The recognition by fish of a real predation
279 risk when it is not completely obvious might depend on upon also the perception of other cues,
280 such as fish odor (Korpi&Wisenden, 2001) or mechanical cues (Hegab & Wei, 2014). A visual
281 recognition of a predator by the prey fish is based on movement characteristics of the predator
282 (Barcellos et al., 2007). Since our non-predator goldfish was very active, zebrafish might be
283 momentarily interpreted as a predator. In our experiment, fish received only visual stimulus. The
284 absence of the combination of different cues may be induced a ‘misinterpretation’ of a harmless
285 stimulus by zebrafish. This supposed ‘misinterpretation’ of predation risk would have caused the
286 observed cortisol increase in sender fish. Interestingly, zebrafish viewing their conspecific that
287 view a non-predator did not alter their behaviour and did not trigger a cortisol response. This
288 suggests that the explanation of ‘misinterpretation’ might make sense.

289 Our findings also highlight the importance to be careful in relation to visual cues in
290 zebrafish, mainly in those who will be used in experiments. Others visual stimulus, (*e.g.* humans
291 presence, other fish species or even other animals) can be interpreted like a threatening cue, having
292 effects on the behavioral and hormonal patterns in zebrafish and, consequently influencing
293 experimental results. Thus, our study brings a better comprehension about the predator-prey
294 interaction and the communication along conspecifics submitted to a predator threatening in
295 aquatic environment.
