Two digging decapod crustaceans, the sand crab species *Lepidopa benedicti* and the mole crab species *Emerita benedicti*, both live in the swash zone of fine sand beaches. They were examined for two parasites that infect decapod crustaceans in the region, an unidentified nematode previously shown to infect *L. benedicti*, and cestode tapeworm larvae, *Polypocephalus* sp., previously shown to infect shrimp (*Litopenaeus setiferus*). *Lepidopa benedicti* were almost always infected with both parasite species, while *E. benedicti* were rarely infected with either parasite species. This difference in infection pattern suggests that tapeworms are ingested during sediment feeding in *L. benedicti*, which *E. benedicti* avoid by filter feeding. Larger *L. benedicti* had more *Polypocephalus* sp. larvae. The thoracic ganglia, which make up the largest proportion of neural tissue, contained the largest numbers of *Polypocephalus* sp. larvae. Intensity of *Polypocephalus* sp. infection was not correlated with how long *L. benedicti* remained above sand in behavioural tests, suggesting that *Polypocephalus* sp. do not manipulate the sand crabs in a way that facilitates trophic transmission of the parasite. *L. setiferus* may be a primary host for *Polypocephalus* sp., and *L. benedict* may be a secondary, auxiliary host.

INTRODUCTION

Parasites can generalize and infect many host species, or specialize to infect only a small number of host species (only one host species in extreme cases). A benefit of being a specialist may be increased adaptation to a host species. Specialization should be favoured in endoparasites that manipulate host behaviour (Adamson & Caira 2011; Fredensborg 2014), because the nervous systems generating behaviour are probably anatomically and physiologically more variable than other types of tissue (Bullock 1993; Bullock 2004; Bullock 2006).

Sand crabs (*Lepidopa benedicti*) and mole crabs (*Emerita benedicti*) are digging anomuran crustaceans in the same superfamily (Hippoidea), which are both found in the swash zones of sandy beaches in the Gulf of Mexico. Given that they are related and found in the same habitat, it is reasonable to predict that they might have similar parasites to each other. *Lepidopa benedicti* is often infected by an unidentified nematode species that does not appear to manipulate host behaviour (Joseph & Faulkes 2014), which might suggest the nematode is a generalist that would also infect *E. benedicti*.

Other parasites that infect decapod crustaceans where these two species live are larval cestode tapeworms in the genus *Polypocephalus*, which infect white shrimp (*Litopenaeus setiferus*) (Carreon, Faulkes & Fredensborg 2011; Carreon & Faulkes 2014). Although the life cycle of species in this genus is not completely worked out, it seems likely that it has a two part life cycle (Figure 1): crustaceans (Villella, Iversen & Sindermann 1970; Owens 1985; Shields 1992; Hudson & Lester 1994; Brockerhoff & Jones 1995; Payne 2010) and other invertebrates (Cake 1979) for the larval stage, and

elasmobranch fishes (e.g., skates and rays) as the definitive hosts for adults (Butler 1987; Call 2007; Koch 2009). *Polypocephalus* spp. larvae infect multiple species from at least two phyla (Cake 1979; Owens 1985; Brockerhoff & Jones 1995), suggesting that species in this genus are generalists. *Polypocephalus* sp. inhabit the nervous system of crustaceans, and appear to manipulate behaviour in *L. setiferus* (Carreon, Faulkes & Fredensborg 2011), which are factors that suggest species in this genus are specialists.

Polypocephalus sp. is also a candidate for studying the manipulation of host behavior, because the larval stage infects the neural tissue of their decapod crustacean hosts. Being in or near the nervous system would seem to make such manipulation easier for parasites. In white shrimp, increased infection was correlated with increased activity of the host (Carreon, Faulkes & Fredensborg 2011), which was hypothesized to be a case of parasite-induced trophic transmission (PITT). A trophically transmitted parasite in a digging crustacean might be expected to change the behaviour of its host so it spends more time above sand (Joseph & Faulkes 2014). *Litopenaeus setiferus* do dig into sand (Eldred et al. 1961; Fuss 1964; Pinn & Ansell 1993), and their increased activity with infection would be consistent with the prediction above.

This paper compares the patterns of infection in *L. benedicti* and *E. benedicti* for both nematode and cestode parasites, and tests whether *Polypocephalus* sp. manipulates the behaviour of either of these species as they do with shrimp (Carreon, Faulkes & Fredensborg 2011).

METHODS

Sand crabs (*Lepidopa benedicti*) and mole crabs (*Emerita benedicti*) were collected from the beaches of South Padre Island, Texas. Individuals were sexed by

57 examining pleopod size (longer in females) and the carapace length was measure with
58 digital calipers. Different individuals were used to study nematodes and *Polypocephalus*
59 sp.

60 Individuals were anaesthetised by chilling for ~20 minutes on crushed ice,
61 dissected in sea water, and the nerve cord was removed. The nerve cord was cut into
62 smaller sections, which were pinned in dishes lined with Sylgard (Dow Corning). The
63 nerve cords were dehydrated in a progressive ethanol series (70% ethanol for 5
64 minutes, 90% ethanol for 5 minutes, 100% ethanol for 5 minutes, then 100% ethanol
65 again for 10 minutes), cleared in methyl salicylate on a depression slide, viewed under a
66 compound microscope (Olympus CX41), and photographed (Olympus C-5050 Zoom
67 digital camera). In some cases, consecutive images at different focal points in the Z axis
68 were compiled into a single image using Helicon Focus v. 6.7.1 Lite (Helicon Soft Ltd.).

69 Initial observations of 10 individuals of each species indicated that variation in
70 numbers of parasites infecting *L. benedicti* was sufficient to test whether there was a
71 correlation between infection and host behaviour. Because *E. benedicti* had very little
72 variation in the number of parasites, their behaviour was not examined.

73 Behavioural tests were similar to those described in Joseph & Faulkes (2014).
74 Individuals were video-recorded digging in a tank 300 mm wide × 150 mm deep × 200
75 mm high, filled with ~75 mm of sand from South Padre Island covered by ~75mm of
76 seawater. Video was recorded with an iPad 3 using Coach My Video v. 4.4
77 (<http://www.coachmyvideo.mobi>). Individuals were released at the top of the tank, and
78 was filmed until the carapace was covered by sand. The total time was calculated by
79 subtracting the submergence times from release time (rounded down to whole

seconds). Individual made three digging trials, each separated by a 5 minute rest period when the animal was not disturbed to minimize habituation. The average of the three trials was used for analysis.

The behaviour of crabs fell into three basic categories. An individual could (1) immediately dig into sand ("direct"), (2) stay above sand by tailflipping and rowing its legs (Faulkes & Paul 1997) before digging ("swim"), or; (3) remain on the top of the sand, immobile, before digging ("sit"). "Swim" and "sit" are not mutually exclusive. An individual could do both in one trial, in either order. For simplicity of analyses, individuals that both swam and "sat" in their three trials were omitted from analyses that examined individuals (i.e., Figure 8).

Parametric statistical analyses and graphs were made in Origin 2017 (OriginLab Corporation). Nonparametric tests were used for infection intensity and behavioural analysis because of nonhomogenous variation in data distribution. Nonparametric statistical analyses were performed in SPSS v. 23 (IBM).

RESULTS

The previously reported prevalence of nematodes in *L. benedicti* (87.0%, n = 46) (Joseph & Faulkes 2014) was higher than in *E. benedicti* (0.0%, n = 22) (Figure 2A). Similarly, the prevalence of *Polypocephalus* sp. infection in *Lepidopa benedicti* (98.0%, n = 50) was higher than in *E. benedicti* (18.2%, n = 22) (Figure 2B). The mean intensity of *Polypocephalus* sp. infection (Figures 2B, 3) was significantly greater in *L. benedicti* (mean = 34.5, SD = 33.0, n = 49) than *E. benedicti* (mean = 1.5, SD = 1.0, n = 4). These differences are not because of the overall size of individuals examined: the average size of *L. benedicti* was smaller than *E. benedicti* (Table 1) in both cases. Because there

were so few parasites of either species in *E. benedicti*, all further analyses concern only *L. benedicti*.

Polypocephalus sp. larvae were closely associated specifically with neural tissue, including peripheral nerves to appendages (Figure 3). The larvae often appeared on the surface of ganglia and could sometimes be seen on the dissected nerve cord using a stereomicroscope. In *L. setiferus*, larvae appeared to be more deeply embedded in neural tissue and were rarely visible until the nerve cord was either squashed or cleared.

There is a significant correlation ($r = 0.31$, $n = 49$, $p = 0.03$) between *L. benedicti* size and mean intensity of *Polypocephalus* sp. infection (Figure 4).

Like other anomurans, *L. benedicti* have shorter abdomens than familiar decapods like shrimp and crayfish. Because *L. benedicti* are specialized for digging and swimming with thoracic legs 1 through 4, the legs are proportionately more robust. Thoracic leg 5 is very small and used for grooming. These anatomical features are reflected in the relative sizes of the ganglia in *L. benedicti* compared to other decapod crustaceans. The thoracic ganglia associated with thoracic legs 1-4 are substantially larger than the abdominal ganglia. The fourth and fifth thoracic ganglia and the first abdominal ganglion are fused. The number of larvae in the ganglia differed significantly across the nervous system (Kruskal Wallis = 16.71, $df = 6$, $p = 0.01$), with thoracic ganglia containing the most larvae, particularly in highly infected individuals (Figure 5).

Contrary to the prediction that more heavily infected animals would spend more time above sand, the mean intensity of *Polypocephalus* sp. infection was not significantly correlated ($r = -0.25$, $p = 0.13$, $n = 38$) with overall digging time (Figure 6).

The three main behaviours of *L. benedicti* (directly digging into sand, swimming, or remaining stationary, or “sitting”) were significantly different (Kruskal-Wallis 70.76, df = 2, $p < 0.01$) in how long individuals remained above sand (Figure 7). Swimming above sand and remaining stationary on top of it did not differ significantly in the duration of exposure for sand crabs, although “sitting” times had greater variation, resulted in the longest times that sand crabs were exposed.

Individuals showing different behaviour patterns had significantly different mean intensities of infection (Kruskal Wallis = 8.72, df = 2, $p = 0.013$): animals that “sat” at least once had lower infection intensities than those that swam at least once or always dug directly into sand (Figure 8).

DISCUSSION

Two parasite species, an unidentified nematode (Joseph & Faulkes 2014) and *Polypocephalus* sp., infect *Lepidopa benedicti* with much higher prevalence and intensity than in *Emerita benedicti*. In the case of *Polypocephalus* sp., a high prevalence and intensity also occurs in white shrimp (*L. setiferus*) which also dig into sand (Eldred et al. 1961; Fuss 1964; Pinn & Ansell 1993) What distinguishes *E. benedicti* from both *L. benedicti* and *L. setiferus* is the feeding mode. *Emerita* species are filter feeders (Efford 1966), which *L. benedicti* and *L. setiferus* are not. *Lepidopa* species are probably sediment feeders (Boyko 2002). This suggests that ingestion is a common route of *Polypocephalus* sp. infection for *L. benedicti* and *L. setiferus*.

The lack of parasites in *E. benedicti* in this population is usual not only because the sympatric *L. benedicti* is infected, but because other populations of *Emerita* species

are infected with other parasites (Smith 2007; Oliva et al. 2008; Kolluru et al. 2011; Violante-Gonzalez et al. 2015; Violante-González et al. 2016).

In *L. setiferus*, the greatest number *Polypocephalus* sp. larvae is in the abdominal ganglia (Carreon, Faulkes & Fredensborg 2011), but in *L. benedicti*, the greatest number is in the thoracic ganglia. This probably reflects which region has the proportionately greater mass of neural tissue available in the two species, although neural mass does not entirely explain distribution patterns across the nervous system (Carreon & Faulkes 2014).

Polypocephalus sp. does not seem to manipulate *L. benedicti* in a way that would facilitate trophic transmission. Intuitively, one would predict that if *Polypocephalus* sp. were manipulating sand crabs to make them vulnerable to predators, animals with more *Polypocephalus* sp. would be more likely to swim or remain immobile on the top of the sand. In anything, the evidence points towards more heavily infected individuals being more likely to dig into sand immediately. Nevertheless, this result can be viewed as consistent with the results in *L. setiferus*, where higher levels of infection increased activity (Carreon, Faulkes & Fredensborg 2011). Digging directly into sand and swimming could both be considered higher activity by *L. benedicti*.

The apparent difference in parasite-induced behavioural manipulation in *L. setiferus* and *L. benedicti* has several potential explanations. First, the *Polypocephalus* species infecting *L. setiferus* may not be the same species as the one infecting *L. benedicti*. Genetic testing will eventually be able to determine if there is one cestode species or multiple. Second, *L. setiferus* may be the preferred primary host for *Polypocephalus* sp. (perhaps along with other shrimp species), and *L. benedicti* is a

non-preferred auxiliary host. The intensity of *Polypocephalus* sp. larvae in *L. setiferus* (mean = 97.7, SD = 102.6; maximum 397; n = 53; (Carreon, Faulkes & Fredensborg 2011) is approximately triple that of *L. benedicti* (mean = 34.5, SD = 33.0; maximum 170; n = 49). *Litopenaeus setiferus* may be more abundant than *L. benedicti*. *Litopenaeus setiferus* is commercially fished, and annual catches from trawling in the Texas waters of Gulf of Mexico average 7 million pounds per year (Texas Parks and Wildlife 2002). In contrast, 10 m transects of beach often yields less than 10 *L. benedicti* individuals (Faulkes ; Murph & Faulkes 2013). *L. benedicti* populations have only been sampled in the swash zone (Faulkes ; Faulkes 2014) and its abundance in deeper waters is unknown (it has been recorded up to 60 m depth; (Boyko 2002). Nevertheless, it seems plausible that the biomass for *L. benedicti*, and thus its potential as host for *Polypocephalus* sp., is lower than *L. setiferus*. Thus, there may be greater selection pressure for *Polypocephalus* sp. to manipulate its primary host but not secondary ones.

ACKNOWLEDGEMENTS

Different individual than C. Anterior towards top in A, and towards left in B-D.

Figure 4

Relationship between size of *L. benedicti* and intensity of *Polypocephalus* sp. infection.

Dashed line = linear regression; shaded area = 95% confidence intervals.

Figure 5

Number of *Polypocephalus* sp. larvae in different regions of the nerve cord in *L. benedicti*.

Summary statistics shown on left: square = mean; line dividing box = median; box = 50% of data; whiskers = 95% of data; triangles = minimum and maximum. Raw data shown on right. Groups sharing a letter do not differ significantly from each other. Sample sizes vary because some ganglia were damaged during dissection.

Figure 6

Relationship between intensity of *Polypocephalus* sp. infection and digging time in *L. benedicti*.

Dashed line = linear regression; shaded area = 95% confidence intervals.

Figure 7

Time above sand for different behaviours by *L. benedicti*.

Duration of individual behaviour trials, grouped by different behaviours. N = 110 trials. Four trials involved combinations of sitting and swimming, and are not shown due to their rarity. Summary statistics shown on left: square = mean; line dividing box = median; box = 50% of data; whiskers = 95% of data; triangles = minimum and maximum. Raw data shown on right. Groups sharing a letter do not differ significantly from each other.

Figure 8

Infection intensity of *L. benedicti* individuals showing different behaviours.

Individuals categorized into three groups: those that always dug directly; those that swim at least once, but never sat; those that “sat” at least once (i.e., remaining immobile on the surface), but never swam. Summary statistics shown on left: square = mean; line dividing box = median; box = 50% of data; whiskers = 95% of data; triangles = minimum and maximum. Raw data shown on right. Groups sharing a letter do not differ significantly from each other.
