In freshwater environments, chemosensory cues play an important role in predator/prey interactions. Prey use a variety of chemosensory cues to detect and avoid predators. However, whether predators use the chemical cues released by disturbed or stressed prey has received less attention. Here we tested the hypothesis that the disturbance cue cortisol, informs predatory behaviour when presented with prey. We presented predators (perch, *Perca fluviatilis*) with three chemosensory choice tests and recorded their location, orientation, and foraging behaviour. We compared the responses of our predators when provided with (i) visual cues of prey only (two adjacent tanks containing sticklebacks); (ii) visual and natural chemical cues of prey vs. visual cues only; and (iii) visual cues of prey with cortisol vs. visual cues only. Perch spent a significantly higher proportion of time in proximity to the prey, and orientated towards prey more, when presented with a cortisol stimuli plus visual cues, relative to natural chemical cues of prey, or visual cues of prey only. In addition, there was a trend that perch showed increased predatory behaviour (lunges) towards sticklebacks when presented with a cortisol stimuli plus visual cues, relative to visual cues only. This is the first evidence that water-borne cortisol, in conjunction with visual cues of prey, results in a directional preference and a possible increase in predatory behaviour toward prey. Our results support our hypothesis that cortisol can act as public information about prey state and/or disturbance, and that it may be involved in predator decision-making.

Abstract

In freshwater environments, chemosensory cues play an important role in predator/prey interactions. Prey use a variety of chemosensory cues to detect and avoid predators. However, whether predators use the chemical cues released by disturbed or stressed prey has received less attention. Here we tested the hypothesis that the disturbance cue cortisol, informs predatory behaviour when presented with prey. We presented predators (perch, *Perca fluviatilis*) with three chemosensory choice tests and recorded their location, orientation, and foraging behaviour. We compared the responses of our predators when provided with (i) visual cues of prey only (two adjacent tanks containing sticklebacks); (ii) visual and natural chemical cues of prey vs. visual cues only; and (iii) visual cues of prey with cortisol vs. visual cues only. Perch spent a significantly higher proportion of time in proximity to the prey, and orientated towards prey more, when presented with a cortisol stimuli plus visual cues, relative to natural chemical cues of prey, or visual cues of prey only. In addition, there was a trend that perch showed increased predatory behaviour (lunges) towards sticklebacks when presented with a cortisol stimuli plus visual cues, relative to visual cues only. This is the first evidence that water-borne cortisol, in conjunction with visual cues of prey, results in a directional preference and a possible increase in predatory behaviour toward prey. Our results support our hypothesis that cortisol can act as public information about prey state and/or disturbance, and that it may be involved in predator decision-making.

Key-words: *Gasterosteus aculeatus*; *Perca fluviatilis*; hormone; predation, sensory ecology

42 Introduction

43

44 The outcomes of predator-prey interactions are largely influenced by the ability of predators and
 45 prey to detect and respond to one another (Lima & Dill, 1990; Endler, 1991). An organism that
 46 perceives a predatory threat or potential prey before being detected itself gains a perceptive
 47 advantage that can influence the result of a given encounter (Lunt & Smee, 2015). Prey can
 48 successfully avoid predators when they have the sensory advantage, by detecting and avoiding
 49 predators before being consumed (Mirza & Chivers, 2002). In contrast, predators prevail when
 50 they hold the perceptual advantage and detect prey before they are detected and prey can escape.
 51 There is a built-in imbalance between predator and prey in regard to the penalty of failure during
 52 an encounter. This asymmetry in the selective pressure on predators and prey, known as the ‘life-
 53 dinner’ principle (Dawkins & Krebs, 1979), is reflected in the greater research effort given to
 54 prey responses over predator behavior (Ferrari, Wisenden & Chivers, 2010). While we know a
 55 great deal about the sensory cues involved in the antipredator defences of prey, we know less
 56 about the cues that predators use during foraging (Vavrek & Brown, 2009; Ferrari, Wisenden &
 57 Chivers, 2010).

58

59 Prey use different sensory channels to detect predators, including visual, acoustic, chemical,
 60 electrical and/or tactile cues (Ferrari, Wisenden & Chivers, 2010). Chemical cues are especially
 61 common in aquatic systems (DeBose & Nevitt, 2008; Ferrari, Wisenden & Chivers, 2010). These
 62 chemical cues can be produced directly by predators (e.g., kairomones), by prey that have been
 63 injured by predators (e.g., damage released alarm cues, Mathis & Smith, 1993; Harvey & Brown,
 64 2004; Chivers, Brown & Ferrari, 2012; Lonnstedt, McCormick & Chivers, 2012), and by prey

that have been disturbed or stressed by predators, without being injured or consumed (e.g. disturbance cues, Chivers, Brown & Smith, 1996; Ferrari, Wisenden & Chivers, 2010). Prey increase anti-predator behaviours in response to the chemical cues of predators, as well as the chemical cues released by conspecifics in response to predatory attack (Ferrari, Wisenden & Chivers, 2010). By responding to these chemical cues of predators, prey have increased chances of survival during predator encounters (Mirza & Chivers, 2002). In contrast the responses of predators to prey cues have received less research focus (but see Wisenden & Thiel, 2002; Harvey & Brown, 2004; Elvidge et al., 2012). Predators that do not respond appropriately to sources of information about their prey's location and state are likely to pay the costs of either missed foraging opportunities, or time wasted pursuing vigilant prey. Therefore, a greater understanding of how predators respond to the chemical cues released by prey would provide insight into the selective forces that shape the chemical ecology of predator-prey interactions.

Given that water is a universal solvent, a vast number of chemicals released by prey could act as potential chemical cues for predators (DeBose & Nevitt, 2008; Ferrari, Wisenden & Chivers, 2010). Predators are able to localise prey using the cues released by prey after attack (Mathis & Smith, 1993; Harvey & Brown, 2004; Chivers, Brown & Ferrari, 2012; Lonnstedt, McCormick & Chivers, 2012). However, there has been less research on cues that are released by disturbed or stressed prey, and the response of predators to any such cues (Vavrek & Brown, 2009; Chivers, Brown & Ferrari, 2012).

Disturbance cues, have been suggested to exist in a variety of systems, including invertebrates, amphibians, and freshwater fish (Hazlett, 1990; Wisenden, Chivers & Smith, 1995; Kiesecker et

al., 1999; Bryer, Mirza & Chivers, 2001; Mirza & Chivers, 2002; Jordão, 2004; Brown et al., 2012). It has been suggested that nitrogenous compounds in urine, and respiratory byproducts could act as disturbance cues (Hazlett, 1990; Kiesecker et al., 1999; Vavrek & Brown, 2009; Brown et al., 2012). One potential disturbance cue that has received less research focus is the stress hormone cortisol (Olivotto et al., 2002; Vavrek & Brown, 2009), the principal glucocorticoid in teleost fish (Brown, Gardner & Braithwaite, 2005).

Prey fish show an acute elevation of their circulating cortisol concentrations in response to the presence of predators (Breves & Specker, 2005; Barcellos et al., 2007). Cortisol can pass across the gills into the surrounding water (Scott & Ellis, 2007; Sebire, Katsiadaki & Scott, 2007), and influences the stress responses of conspecifics (Barcellos et al., 2011). Elevated cortisol concentrations are associated with reduced body mass and growth, as well as increased parasite loads in fish species (Jentoft et al., 2005; Fast et al., 2006). These factors in turn have been linked to reduced predator avoidance in prey (Sogard, 1997; Ness & Foster, 1999). It is therefore possible that cortisol could act as source of public information about prey state and/or disturbance, and that predators could become attuned to this physiological response of prey. However, whether predators can detect and respond to the presence of cortisol released by prey, or use the presence of the hormone to inform their foraging decisions is unknown.

To answer this question we investigated whether predatory fish show a preference for prey fish associated with cortisol over prey fish with no chemical cue. We used the piscivorous European perch (*Perca fluviatilis*) as model predator, and three-spined stickleback (*Gasterosteus aculeatus*) as prey. We presented each perch with three chemosensory prey choice tests (i) prey

visual cues only, (ii) prey visual cues plus the natural chemical cues of prey, and (iii) visual cues of prey plus a cortisol chemical cue. We predicted that if predators use cortisol to inform predation decisions, a) if the presence of cortisol indicates prey that are vulnerable to attack, that predators should show a preference for prey associated with cortisol over prey without the chemical cue; (b) be indicative of prey that have increased vigilance, and so predators should avoid such prey because of the reduced likelihood of attack success. We also hypothesise that (c) if cortisol does not inform predator behaviour, predators would show no difference in preference between the three treatments, or alternatively prefer the natural chemical cues of prey compared to no chemical cues or cortisol. It is also possible that cortisol does not alter predatory behaviour, but instead raises the predator's endogenous levels of cortisol. If this is the case then we predicted that (d) the predator may show an undirected change in behaviour; i.e. increased overall activity.

Materials and Methods

All fish were collected from water-bodies located in west central Scotland. Three-spined sticklebacks ($n = 150$, ~ 1 g) were collected in October-November 2011 from Balmaha Pond, a small water body that does not contain piscivorous fish. Perch (~ 16 -20cm length, 52.5 ± 9.8 g), a natural predator of sticklebacks (Gross, 1978), were collected in October 2010 and 2011 from Howend Trout Fishery. Perch were likely to have had experience of sticklebacks at Howend Trout Fishery.

Fish were housed at indoor aquaria at the University of Glasgow, UK. Fish were fed daily with frozen bloodworm (*Glycera dibranchiate*), and kept under a light regime of 12L:12D. Mains tap water was used for holding water and water temperature was $16.5 \pm 1^\circ\text{C}$ with a pH of 8-8.4.

All experiments were conducted between December 2011 and January 2012, using a tank design that allows transfer of chemical and visual cues between fish (Le Vin, Mable & Arnold, 2010), while preventing physical interaction for ethical reasons (Fig. 1)(Animal Behaviour, 2006).

Each perch was introduced into a 45x20x25cm experimental tank ~20h before a test to allow for acclimation and to standardize hunger between individuals. Adjacent to the experimental tank on either side were two flow-through stimulus tanks (10x20x25cm), each maintained with 2l of water. Five sticklebacks were introduced into each stimulus tank, also ~20h before a test. Flow-through stimulus tanks were used to avoid accumulation of cortisol in the water during acclimation and after capture and handling (Pottinger et al., 2011; Archard et al., 2012). Removable opaque barriers were positioned between the experimental and stimulus tanks to prevent the perch and sticklebacks from seeing each other during acclimation. These were removed at the start of a test to allow predators and prey to see one another.

Predator responses to chemical cues

To test the influence of hormonal cues on predator behaviour, each perch participated in three chemosensory choice tests (number of perch = 18, total number of tests = 54): (i) a control test, where fresh water was dripped into the perch tank on both sides directly in front of the stimulus tanks holding sticklebacks (Fig. 1a); (ii) a natural chemical test, where water from one of the

stimulus tanks containing naïve sticklebacks (no previous exposure to perch) was dripped into one side and fresh water dripped into the other (Fig. 1a and b); and (iii) a cortisol test, where we provided our putative disturbance cue at a concentration that a predator might encounter in nature (0.2ng/ml of cortisol; Sigma) on one side and fresh water on the other (Fig. 1a). Sticklebacks have been documented to release up to 0.26ng/ml/hr cortisol into holding water after capture and handling (Sebire, Katsiadaki & Scott, 2007; Pottinger et al., 2011).

The order of chemosensory tests and the side placement of the chemical stimulus were randomized. Water was drawn from neighbouring tanks through a pump system with a flow rate of 1.6 ml/min, which has been shown to induce a reaction to the chemical stimulus in other fish species (McLennan & Ryan, 1997; Le Vin, Mable & Arnold, 2010). A previous study has shown using colour-dyed water, that water dripped into a focal tank remained mainly localized within the zone (13x8x19) immediately adjacent to where the water was dripped (Le Vin, Mable & Arnold, 2010). Experimental tanks that held perch and sticklebacks were then drained and cleaned between each test, and each perch had a two-day break between tests.

At the start of each test the opaque barriers were removed, the stimulus pumps were started and the flow-through system in the stimulus tanks was stopped. We observed the perch for 60min from behind a blind to avoid any effect of the observer on fish behaviour. We visually divided the perch tank into three equal zones (15cm length), two ‘preference zones’ (chemical stimulus zone and the opposite non-chemical stimulus zone) located adjacent to the front of each stimulus tank and a ‘non-preference’ zone in between them (Fig. 1). For analysis in the control tests where

there were no chemical stimuli, the chemical stimulus zone was allocated to the left side in 50% of tests and to the right for the other 50%.

To assess predatory behaviour, we used Observer 8 software to record the duration spent by perch in each zone; the duration spent orientating towards sticklebacks; the number of predatory attacks made towards the sticklebacks (hereon termed lunges, which were defined as rapid forward movements towards sticklebacks); and the number of movements by perch between zones.

Cortisol concentration in experimental tanks

To assess the concentration of cortisol released by stickleback into their holding water we collected the water from their tanks in the natural chemical cue tests, 60min after presentation of the perch ($n = 9$). To measure the level of cortisol released by perch into their holding water in the experimental tanks, we collected water after 60mins when no stimulus water was being pumped ($n = 4$).

To determine the cortisol concentrations in the water samples, cortisol was extracted by pulling 100ml under vacuum at a rate of ca. 5ml/min through primed SPE cartridges containing octadecylsilane (Sep-pak Plus, Waters Ltd., Watford, UK). Water samples were not pre-filtered. Priming involved 5ml methanol followed by 5ml distilled water. After the samples had been pulled through, the cartridges were washed with 5ml distilled water followed by 20ml air (to remove as much moisture as possible). The free steroids (not conjugated (Ellis et al., 2004)) were eluted with 5ml ethyl acetate. This was collected in a glass tube and evaporated at 45°C under a

stream of air. Samples were then re-suspended in 250µl of assay buffer (tris buffered saline) and cortisol concentrations were established using a Cortisol ELISA Kit (Enzo Life Sciences, Inc.). Samples were run within two assays, all samples run in triplicate and recoveries calculated after a known amount of cortisol was added to samples were >96% and the mean intra-and inter-assay coefficient of variation were 8.6% and 8.4% respectively. 100ml water samples were used as cortisol is found at low concentrations in holding water (Scott & Ellis, 2007), and this methodology allowed the amount of cortisol to be concentrated so that values were measured on the linear phase of the standard curve (sample value range: 14.2-4.4ng/ml, standard curve: 100-0.78ng/ml). As the 100ml water samples were re-suspended in 250µl of buffer for the assay (x400 concentration), cortisol values from the assay were divided by 400 to get the concentration in the holding water (ng/ml).

Statistical analyses

To investigate whether perch behaviour differed between the three chemosensory tests, we calculated the proportion of total time that perch spent in the chemical stimulus zone, the proportion of time that perch spent orientating towards the sticklebacks in the chemical stimulus zone, and the proportion of total lunges at sticklebacks in the chemical stimulus zone. We calculated proportions as the total time spent in the chemical stimulus zone divided by the sum of the time spent in or orienting towards sticklebacks in all zones. For lunges at stickleback we calculated the proportion of lunges in the chemical stimulus zone divided by the sum of lunges in the chemical stimulus zone and the opposite stimulus zone. All proportions were arcsine-transformed to normalize data.

Linear Mixed Models (LMMs) were used to assess whether chemosensory test type (control, natural cues, cortisol) influenced the location, orientation and lunging preference of perch, with perch identity as a random factor (to account for repeated measures). The order chemosensory tests were presented to perch did not influence their behaviour ($P > 0.70$), and so was not included in final models. Chemosensory test type did not influence whether perch began the test in the chemical stimulus zone (binomial GLMM $z = -0.76$, $P = 0.45$). At the start of each trial perch could be located in any zone within the tank. Therefore, if the focal perch did not move for the entire test, this could mask the effect of the chemosensory tests upon behaviour in actively responded individuals, by assigning 100% of time to a single zone, and 100% of time orientating in a single direction. Due to this, for behavioural analysis we only included trials where perch were actively moving. Total movements between zones was square root transformed to normalize data. All analyses were conducted in R 2.12.2 (R core team 2012). The data used for analyses can be found in supporting information S1.

Ethics statement

This study was performed under a UK Home Office licence (60/4292) and was subject to review by the University of Glasgow ethics committee. All experiments were conducted using a tank design that allows transfer of chemical and visual cues between fish, while preventing physical interaction for ethical reasons. The hormone concentrations used in this study are within the natural levels experienced by fish in the wild. Prey fish were provided with shelter while in visual contact with the predator. Permission was gained for catching perch from a privately owned trout fishery (Howend) and sticklebacks were collected from Balmaha pond after obtaining permission from the Scottish government. This study did not involve endangered or

protected species. This work was funded by an Association for the Study of Animal Behaviour grant awarded to HMR.

Results

Predator behaviour

9 of 18 perch did not move during an entire test ($n = 12$ tests), and this was marginally, but non-significantly, more likely to occur in trials when cortisol was the chemical cue (binomial GLMM $z = 1.82$, $P = 0.06$). We removed these 12 tests from further analyses, so that only actively moving individuals were included in the analyses of location, orientation, and movement. This is because the fish that remained immobile could be located in any zone within the tank and could therefore skew the analyses.

Perch spent a significantly higher proportion of their time in the chemical stimulus zone when cortisol was added compared to natural chemical cues of sticklebacks and the water control (Table 1 & Fig. 2a, LMM $t = 3.61$, $P = 0.001$). Perch also oriented towards sticklebacks for a significantly higher proportion of time in the chemical stimulus zone when cortisol was added compared to natural chemical cues of sticklebacks and the water control (Table 1 & Fig. 2b, LMM $t = 3.93$, $P < 0.001$). There was a marginally non-significant trend that perch lunged more frequently at sticklebacks at the side of the tank where the chemical stimulus was dripped in the cortisol tests relative to the water control (Table 1 & Fig. 2c, LMM $t = 1.93$, $P = 0.07$). Perch moved around the tank a similar amount in each chemosensory test (Table 1 & Fig. 2d, LMM $t = 0.30$, $P = 0.77$).

Concentration of cortisol in experimental tanks

The mean concentration of cortisol in the natural chemical tests was an order of magnitude lower than the cortisol test; 0.02 ng/ml vs. 0.2 ng/ml, and was lower than the mean concentration of cortisol in the perch holding water; 0.05 ng/ml.

Discussion

We tested the hypothesis that cortisol elevates predatory behaviour, in the presence of visual cues of prey (Vavrek & Brown, 2009). We found that predators showed increased prey inspection behaviour (spending more time in close proximity, as well as more time orientated towards prey) when prey were associated with cortisol, compared to prey with natural chemical cues or prey with a water control. We also found that predators were marginally more likely to increase their attack behaviour towards prey in the presence of cortisol compared to the other chemical cues. We observed that some predators became inactive, and that this was marginally more likely to occur in response to prey associated with cortisol. Despite the differences in responsiveness of our predators to cortisol, the change in their behaviour supports our hypothesis that cortisol can act as public information about prey disturbance (Wisenden, Chivers & Smith, 1995), but predatory fish may show a context-dependent behavioural response.

Our results are in line with the findings of other research that has shown predators respond to chemical information to detect prey (Chivers, Brown & Smith, 1996; Wisenden & Thiel, 2002; DeBose & Nevitt, 2008; Ferrari, Wisenden & Chivers, 2010; Elvidge & Brown, 2012; Lonnstedt, McCormick & Chivers, 2012). Predators can use chemical information such as damage-released alarm cues to capitalise on circumstances when the defences of prey are compromised

(Lonnstedt, McCormick & Chivers, 2012). Our study provides, to our knowledge, the first evidence that cortisol could also provide cues to predators of disturbed or stressed prey.

Fish species show a behavioural and physiological response to the stress responses of conspecifics (Toa, Afonso & Iwama, 2004; Barcellos et al., 2011; Oliveira et al., 2013) and cortisol has been suggested to act as a disturbance cue to conspecific prey (Olivotto et al., 2002; Vavrek & Brown, 2009). Prey fish retreat from water conditioned with chemical cues released by stressed conspecifics, and it is proposed that these cues are interpreted by conspecifics as threatening, unsafe, and/or undesirable situations (Abreu et al 2016). This is despite the fact that cortisol is likely to be ubiquitous within the environment (Hazlett, 1990; Kiesecker et al., 1999; Ferrari, Wisenden & Chivers, 2010). However, this is also the case for nitrogenous waste products that are also suggested to act as disturbance cues, but are abundant within the environment (Hazlett, 1990; Kiesecker et al., 1999; Ferrari, Wisenden & Chivers, 2010; Brown et al., 2012).

Stressed prey may represent an easier target for predators because prey with higher levels of cortisol also show reduced predator avoidance (Sogard, 1997; Ness & Foster, 1999). Therefore, the presence of chemical cues such as cortisol may ‘label’ valuable food patches (Lonnstedt, McCormick & Chivers, 2012), and piscivores may exploit these cues as a means to locate prey. But a number of our perch predators responded to cortisol with immobility (freezing). It is possible that cortisol could also indicate that other predators are already foraging in an area, and that prey, having been disturbed, are now more vigilant. In this case, the costs of foraging competition or of lost foraging opportunities may explain the difference in this subset of

predators who froze. The strength of both predator responses (attraction and freezing) was greater in the cortisol test than the natural chemical test, supporting a role for the hormone in predatory behaviour.

Our predators did not change their behaviour in the natural chemical test compared to the water control. The concentration of cortisol in the natural chemical tests was an order of magnitude lower than the cortisol test (0.02 vs. 0.2ng/ml), and was lower than the concentration of cortisol in the perch holding water (0.05ng/ml). Therefore, the responses may be proportional to the concentration of disturbance cue detected. This kind of graded response has also been shown in prey (Vavrek & Brown, 2009; Brown et al., 2012). Alternatively, the responses of our predators may have only occurred when the cue rose above the background levels of cortisol ('noise'). This is supported by the background noise hypothesis proposed by Vavrek and Brown (2009). This hypothesis states that background levels of cues dictate how much cue is required to actually elicit a response. Although this hypothesis relates to prey behaviour, we see that it could also apply to predators.

An alternative explanation for our results is that cortisol does not increase predatory behaviours *per se*, but that it elevated the endogenous cortisol levels in our perch due to uptake of the water-borne cortisol across the gills (Scott & Ellis, 2007). Glucocorticoids are known to rapidly affect behaviour (Moore & Evans, 1999). But perch moved around the tank a similar amount in each chemosensory test, and it was specifically inspection and predatory behaviours that we elevated in the cortisol tests. This finding is contrary to our expectation that predators would exhibit undirected changes in behaviour if endogenous concentrations were elevated. Furthermore, the

concentration used in our cortisol tests is within the range released by sticklebacks after handling stress (Both et al., 2004; Sebire, Katsiadaki & Scott, 2007; Pottinger et al., 2011), and could be experienced by perch in the wild, so should be biologically meaningful (Sebire, Katsiadaki & Scott, 2007; Pottinger et al., 2011). To establish whether cortisol strictly increased predatory behaviour, rather than exploratory behaviour, it would be interesting to look at the behaviour of perch when they are exposed to conspecifics rather than prey.

A limitation of our study is that we used predator naïve sticklebacks as prey. We found that sticklebacks released less cortisol into their holding water following visual exposure to a predator than sticklebacks that had experienced a handling stress (Sebire, Katsiadaki & Scott, 2007; Pottinger et al., 2011). This is likely because our sticklebacks originated from a water body that did not contain piscivorous fish. Many prey species do not show innate recognition of potential predators (Mathis, Chivers & Smith, 1993; Chivers & Smith, 1994), so a lack of experience of predatory fish may explain the attenuated stress response. We did not examine whether perch responded if given the choice between visual cues of sticklebacks when presented with both elevated cortisol and natural “signature” chemical cues of experienced sticklebacks (Wyatt, 2010). If experienced sticklebacks release cortisol at higher concentrations than the naïve sticklebacks in our experiment (Mathis, Chivers & Smith, 1993; Chivers & Smith, 1994), we could have explored the potential for graded responses, and the responses to chemical mixtures. We also did not test whether perch showed a behavioural response to chemical cues alone. But as perch are sight-dependent diurnal predators, they likely require both visual and chemical cue to target prey (Turesson & Brönmark, 2004; Elvidge & Brown, 2012). Although this could have provided information on the relative importance of visual and chemical cues, our design still

allowed for us to detect how chemical cues augment the behaviour of predators in comparison to visual cues only.

The behavioural response of perch to a cortisol stimulus does suggest that this hormone could influence predatory behaviour; therefore, there is the intriguing potential of a chemosensory arms race between predator and prey. Populations of sticklebacks differ in their behavioural profiles due to predation pressure (Bell, 2005; Bell & Sih, 2007), and fish from high predation populations have been shown to have a lower cortisol release rate than those from low predation populations (Archard et al., 2012). This has been suggested to be beneficial as it could prevent excessive energy expenditure due to repeated stress responses caused by the presence of predators (Brown, Gardner & Braithwaite, 2005). However, a reduced stress response could have evolved due to predators selectively predating individuals that have a higher stress response.

Conclusions

Traditionally research has focused on the function of the stress response experienced by prey animals during a predation event. However, in this study we show how an improved understanding of how predators respond to the stress responses of their prey could be useful when investigating the complexity of predator–prey interactions.

Figure 1(on next page)

Schematic of experimental tanks.

Figure 1: Schematic of experimental tanks. Pump system A allowed transfer of fresh water or cortisol solution into the perch tank. Pump system B allowed transfer of the natural chemical cues from the stickleback holding water.

Figure 2 (on next page)

Bar charts showing how chemical cues influenced perch behaviour

Bar charts and captions showing mean \pm se of (a) the proportion of total time spent by perch in chemical stimulus zone, and duration in chemical stimulus zone (secs), (b) the proportion of time spent by perch orientating toward sticklebacks in the chemical stimulus zone, and duration orientating toward sticklebacks in chemical stimulus zone (secs), (c) the proportion of lunges at sticklebacks in the chemical stimulus zone, and the number of lunges in the chemical stimulus zone, and (d) total movements between zones by perch. Letters indicate significant differences (a: $P < 0.01$), and statistical trends (c: $P = 0.07$).

Table 1(on next page)

Table of LMMs results

Linear Mixed Models testing the effect of chemical trial upon proportion of time in chemical stimulus zone, proportion of time orienting in chemical stimulus zone, proportion of lunges in chemical stimulus zone, and total movements between zones. Individual ID was included as a random factor in all models. Values in bold denote statistically significant factors, * denotes marginally non-significant factor.

	Fixed effects				Random intercept
	β	s.e.	<i>t</i>	P	% σ
Proportion of time in chemical stimulus zone	0.33	0.09	3.61	0.001	35.8
Proportion of time orienting in chemical stimulus zone	0.62	0.16	3.93	< 0.001	2.0e-03
Proportion of lunges in chemical stimulus zone	0.32	0.17	1.93	0.07*	50.8
Movements between zones	0.35	1.18	0.30	0.77	30.6
