**Background.** Climate change and infectious diseases, threaten animal and plant species even in natural and protected areas. To cope with these changes, species may acclimate, adapt, move or decline. Here, we test for shifts in anuran distributions in the Luquillo Mountains (LM), a tropical montane forest in Puerto Rico by contrasting occurrence probabilities from historical (1931-1989) and current data (2015/2016). **Methods.** Historical data were gathered through the Global Biodiversity Information Facility (GBIF) and published literature and the current data were collected using acoustic recorders along three elevational transects. **Results.** In the recordings, we detected the 12 native frog species known to occur in LM. Over a span of ~25 years, two species have become extinct and four species suffered extirpation in lowland areas. As a consequence, low elevation areas in the LM (< 300 m) have lost at least six anuran species. **Discussion.** We hypothesize that these extirpations are due to the effects of climate change and infectious diseases, which are restricting many species to higher elevations and a much smaller area. Three lines of evidence support our hypothesis: 1) LM is a protected reserve without any obvious land use change in the past 80 years. 2) An increase in temperature and the frequency of dry periods coincided with amphibian declines. And 3) *Batrachochytrium dendrobatidis* was found in the preserved skins of frog specimens coinciding with the beginning of anuran declines in LM. Our study confirms the general impressions of amphibian population extirpations at low elevations, and corroborates the level of threat by IUCN

41 **Abstract**

42

43 **Background.** Climate change and infectious diseases, threaten animal and plant species even in  
44 natural and protected areas. To cope with these changes, species may acclimate, adapt, move or  
45 decline. Here, we test for shifts in anuran distributions in the Luquillo Mountains (LM), a  
46 tropical montane forest in Puerto Rico by contrasting occurrence probabilities from historical  
47 (1931-1989) and current data (2015/2016).

48 **Methods.** Historical data were gathered through the Global Biodiversity Information Facility  
49 (GBIF) and published literature and the current data were collected using acoustic recorders  
50 along three elevational transects.

51 **Results.** In the recordings, we detected the 12 native frog species known to occur in LM. Over a  
52 span of ~25 years, two species have become extinct and four species suffered extirpation in  
53 lowland areas. As a consequence, low elevation areas in the LM (< 300 m) have lost at least six  
54 anuran species.

55 **Discussion.** We hypothesize that these extirpations are due to the effects of climate change and  
56 infectious diseases, which are restricting many species to higher elevations and a much smaller  
57 area. Three lines of evidence support our hypothesis: 1) LM is a protected reserve without any  
58 obvious land use change in the past 80 years. 2) An increase in temperature and the frequency of  
59 dry periods coincided with amphibian declines. And 3) *Batrachochytrium dendrobatidis*  
60 was found in the preserved skins of frog specimens coinciding with the beginning of anuran  
61 declines in LM. Our study confirms the general impressions of amphibian population  
62 extirpations at low elevations, and corroborates the level of threat by IUCN.

## 87 Introduction

88

89 The 21<sup>th</sup> century marks an era in which biodiversity is threatened at the global scale.  
90 Although habitat loss and degradation due to human activities are the main threats to animal and  
91 plant species around the world (WWF 2016), populations of many species are declining even in  
92 natural and protected areas (Hedges 1993; Stuart *et al.* 2004; Lips *et al.* 2005; Skerratt *et al.*  
93 2007; Collins, Crump & Lovejoy III 2009). To explain these declines in undisturbed habitats,  
94 scientists have focused on the widespread effects of climate change and infectious diseases.  
95 Climate change is linked to local extinctions and has altered species distributions and abundance,  
96 causing an overall shift toward higher latitudes and altitudes (Parmesan 2006; Seimon *et al.*  
97 2007; Raxworthy *et al.* 2008; Lenoir *et al.* 2008; Chen *et al.* 2011; Ficetola & Maiorano 2016).  
98 Infectious diseases, such as chytridiomycosis, have also caused local extinctions and population  
99 declines around the world, especially in cool moist environments characteristic of many upland  
100 tropical areas (Whitfield, Lips & Donnelly 2016) altering the spatial distribution of many species  
101 (Pounds *et al.* 2006; Di Rosa *et al.* 2007; Kiesecker & Skelly 2011; Lips 2016).

102 Although an increasing number of studies have documented changes in species  
103 distributions in tropical regions (Pounds, Fogden & Campbell 1999; Raxworthy *et al.* 2008;  
104 Chen *et al.* 2011; Feeley *et al.* 2011; Forero-Medina *et al.* 2011; Harris *et al.* 2012), the majority  
105 of information on range shifts comes from temperate regions, (Lenoir & Svenning 2014),  
106 resulting in large uncertainties in predicting the responses of tropical species to different global  
107 changes scenarios (Feeley & Silman 2011). Nevertheless, a recent study has shown that  
108 hundreds of species have already suffered local extinction in the tropics (Wiens 2016). In  
109 addition, tropical montane areas are among the most threatened ecosystems due to global  
110 warming (Still, Foster & Schneider 1999; Williams, Jackson & Kutzbach 2007) and the flora and  
111 fauna in these areas are expected to suffer the greatest proportion of extinctions due to climate  
112 change (Sekercioglu *et al.* 2008). From a conservation perspective, this is particularly troublesome  
113 given that tropical montane areas harbor a large portion of the world biodiversity and have high  
114 levels of endemism (Gradstein, Homeier & Gansert 2008).

115 Here we address the question: Have there been elevational shifts in anuran distributions  
116 within the largest protected area in Puerto Rico? To answer this question, we compared the  
117 historical and current elevational distributions of 12 species within the Luquillo Mountains.  
118 Specifically, we quantified species occurrence along an elevation gradient (~ 0 – 1,050 m) and  
119 tested for shifts in anuran distributions by comparing occupancy probabilities between historical  
120 (1931-1989) and current data (2015-2016). Our study provides a quantitative description of  
121 elevational shifts in anuran species in a tropical mountain, and a quantitative baseline for future  
122 studies of these species.

126

## 127 **Materials & Methods**

128

### 129 *Study site*

130

131 The study was conducted in the Luquillo Mountains (LM) in north-eastern Puerto Rico  
132 (Fig. 1). The majority of LM is protected by the El Yunque National Forest (EYNF), also known  
133 as the Luquillo Experimental Forest, which is the largest protected area (115 km<sup>2</sup>) of primary  
134 forest in Puerto Rico (Lugo 1994). The LM spans an elevational range from 100 to 1074 m and  
135 its highest peak is only 8 km from the ocean, creating a steep elevation gradient. This protected  
136 site is ideal for testing for elevational shifts for three reasons: 1) There have been no direct  
137 effects of land use change during the last 80 years in the LM; 2) The LM comprises three main  
138 peaks (Pico del Este – 1051 m, Pico del Yunque -1050 m, Pico del Toro – 1074 m) allowing the  
139 establishment of several elevational gradients; and 3) There has been extensive research  
140 documenting abiotic and biotic changes along the elevational gradient. For instance, the LM  
141 elevational gradient has a positive relationship with rainfall, runoff, humidity, cloud cover and  
142 wind velocity (Briscoe 1966; García-Martinó *et al.*, 1996; Weaver & Gould 2013) and a negative  
143 relationship with temperature, forest growth, and canopy height (Weaver & Murphy 1990;  
144 Weaver 2000; Wang *et al.* 2003; Weaver & Gould 2013). Temperature declines with elevation  
145 from ~ 26.5°C in the lowlands to ~ 20°C at the mountain top (Waide *et al.* 2013). Annual  
146 rainfall ranges from 2450 mm yr<sup>-1</sup> at lower elevations to over 4000 mm yr<sup>-1</sup> at higher elevations  
147 (Waide *et al.* 2013). In addition, the distribution of plants and animals are also affected by this  
148 elevation gradient (Gould, Gonzalez & Rivera 2006; González *et al.* 2007; Gould *et al.* 2008;  
149 Willig *et al.* 2011; Brokaw *et al.* 2012; Weaver & Gould 2013; Campos-Cerqueira & Aide  
150 2016).

### 151 *Species*

152

153 The anuran community in the LM includes 13 native species of tree frogs commonly  
154 referred to "coquis" (*Eleutherodactylus spp.*) and one native frog species from the  
155 *Leptodactylidae* family. The coquis are terrestrial-breeding, direct-development species, and  
156 calling and reproductive activity occurs year-round (Stewart & Pough 1983; Woolbright 1985;  
157 Stewart 1995; Joglar 1998). All coqui species are very vocal throughout the night and most  
158 species have a peak of vocal activity around 20:00 (Villanueva-Rivera 2014). *Eleutherodactylus*  
159 *coqui* is one the most studied species in Puerto Rico. Both males and females are strongly  
160 territorial, and they rarely move more than five meters from their retreat sites (Woolbright 1985;  
161 Woolbright 1996; Joglar 1998). Ten of the 13 species tree frogs are endemics to Puerto Rico and  
162 eight are listed in the IUCN Red List (Table 1).

163

164

165

166 **Historical data**

167 The historical data was acquired through the compilation of all available information  
168 about the species distributions in published and open sources (Table S1, Table S2, TableS3).  
169 While some data sets provided quantitative information about the presence of the species  
170 associated with a specific georeferenced location (e.g. GBIF 2016, Joglar 1998; Drewry & Rand  
171 1983), others data sets (e.g. Schwartz & Henderson 1991; Rivero 1998) provided qualitative  
172 information about species distribution range that was used to support the quantitative data. The  
173 information about species distribution from the historical data sets were acquired using different  
174 sampling methods, from opportunistic observations to mark-recapture and acoustic monitoring.  
175 Rather than being a drawback, the use of these complementary methods may increase species  
176 detectability. As far as we know, our compilation is the most comprehensible collection of  
177 historical data on anuran distributions (i.e. occurrence) in the Luquillo Mountains in Puerto Rico.

178 For a record to be included in our quantitative historical data set, it had to fulfill three  
179 criteria: 1) the record had to include a georeferenced locality or a specific geographical  
180 description that enabled us to georeference the locality; 2) the record had to be within the LM  
181 area; and 3) the record had to be before 1990. We used records before 1990 because this date  
182 coincides with the decline of many populations of coqui species in the LM (Burrowes, Joglar &  
183 Green 2004), and in addition we created a gap of ~25 years between the historical and current  
184 data sets. All geographical coordinates from the GBIF data set were checked and corrected  
185 (Table S2).

186

187 **Current data**

188

189 We collected acoustic data from 67 sites in the LM along three elevational transects (84 –  
190 1049 m) between March and May of 2015 and again in April and May of 2016. The elevational  
191 transects took advantage of roads and trails, but all audio recorders were placed more than 200 m  
192 from any road. Each elevational transects started in the lowlands and reached one of the three  
193 main mountain peaks of the Luquillo mountains (East Peak, Toro Peak, El Yunque Peak). Along  
194 each elevational transect, two audio recorders, separated at least by 200 m, were deployed at  
195 ~100-m elevational intervals. Audio recorders collected data at each site for approximately one  
196 week and were then moved to another elevation transect. Both male and female  
197 *Eleutherodactylus* species are territorial species, and *E. coqui* does not move more than five  
198 meters from their retreat sites (Stewart & Pough 1983; Woolbright 1985; Gonsler & Woolbright  
199 1995). Calls of all the anuran species from our study site were broadcasted at different distances  
200 from the audio recorder, and we estimated the detection range to be ~50 m. Therefore, a site is  
201 defined as a three-dimensional hemisphere with a radius of approximately 50 m around the  
202 recorder. Given that the recorders were separated by >200 m we assumed that they were  
203 independent samples. All recordings were analyzed, permanently stored, and available in the

204 Automated Remote Biodiversity Monitoring Network (ARBIMON) (arbimon.sieve-  
205 analytics.com/project/elevation/dashboard).

206 Audio recorders (LG smartphone enclosed in a waterproof case with an external  
207 connector linked to a Monoprice microphone) running the ARBIMON Touch application  
208 (<https://play.google.com/store>) were used to collect the audio recordings. Audio recorders were  
209 placed on trees at the height of 1.5 m and programmed to record 1 minute of audio every 10 min  
210 for a total of 144 – 1-minute recordings per day. We manually inspected all recordings from  
211 18:00 to 5:00 (65,187 1-minute recordings ) and marked the presence and absence of each focal  
212 species for each day.

213

## 214 *Analysis*

### 215 *Historical distributions - GLM models*

216

217 Within the LM, anurans were historically reported from 51 sites, ranging from 39 to 1045  
218 m. The compilation of all historical data provided valuable information about the presence of  
219 species, but no data about species absences. Since our goal was to predict species occurrence  
220 from the historical data and because predictive methods such as generalized linear models  
221 (GLM) require absence data, we generated pseudo-absence data by assigning an absence where  
222 there were no reports for species from a site. This procedure allowed us to fit GLM models,  
223 which is recommended when absence data are not available (Chefaoui & Lobo 2008). In this  
224 way, all species with a collection record from a site were listed as present, and all other species  
225 were listed as absent. This approach provides greater model performance than using randomly  
226 sampled pseudo-absence (Lütolf, Kienast & Guisan 2006). We used this dataset to fit  
227 generalized linear models (GLM) using a logistic function in R. Although we are aware that the  
228 estimation of occurrence probability using logistic regression may be unrealistic (Ward *et al.*  
229 2009; Royle *et al.* 2012) and may underestimate occupancy probability (Kéry, Gardner &  
230 Monnerat 2010; Lahoz-Monfort, Guillera-Arroita & Wintle 2014), the use of more appropriate  
231 analysis (e.g. Maxlike – Royle *et al.* 2012) were precluded for two reasons: 1) overall sparse data  
232 due to a small data set, and 2) lack of repeated visits to the same locality. Nevertheless, our  
233 historical quantitative data matches with the available qualitative information about species  
234 distribution (Schwartz & Henderson 1991; Rivero 1998), and it provides the best summary of the  
235 past distributions of these species.

236 Because we were interested in testing for elevational shifts, we included information  
237 about elevation as a standardized continuous covariate represented by a linear (*elevation*) and a  
238 quadratic (*elevation+elevation<sup>2</sup>*) function. In addition, we included a null model with only the  
239 intercept (Null model) in a total of three model parametrizations for each species, simply  
240 depicted as:

241

242 (1) *Occupancy ~ Null*

243 (2) *Occupancy ~ Elevation*

244 (3) *Occupancy ~ Elevation + Elevation<sup>2</sup>*

245

246 We used the *glmulti* package (Calcagno & de Mazancourt 2010) of R software for model  
247 selection based on the lowest AIC value. We compared models using AIC, and we estimated  
248 occupancy profiles by model-averaging all models with  $\Delta\text{AIC} < 2.0$

249

### 250 ***Current distributions - Occupancy models***

251

252 We used a detection/non-detection matrix summarized by day from the acoustic monitoring  
253 data set to fit single-species single-season occupancy models using the package *Unmarked* in R  
254 (Fiske & Chandler 2011). Because we have a relatively small number of anuran species in LM  
255 and because all the focal species were detected several times we chose to use single-species  
256 models. We also assume that the population was close between the two years to reduce model  
257 complexity and because change in occupied sites between years were very small for all species  
258 (average of 2.45 sites, SD = 2.42). We did not include *E. coqui* in occupancy analyses because  
259 the first species was present in all sampling sites.

260 The occupancy state of each sampling site was estimated taking into account imperfect  
261 detection, following the standard maximum likelihood hierarchical approach introduced by  
262 (Mackenzie *et al.* 2002). Our models contain a sampling level describing the probability of  
263 detection conditioned on occupancy ( $p$ ), and an underlying biological level describing the  
264 probability ( $\psi$ ) that a site is occupied. Both  $p$  and  $\psi$  were allowed to vary according to elevation.  
265 To estimate elevational profiles of occupancy ( $\psi$ ) for each species we constructed a set of  
266 competing hypothesis of how occupancy and detection changed over *elevation* (Kéry, Gardner &  
267 Monnerat 2010). *Elevation* is a standardized continuous covariate represented by a linear  
268 (*elevation*) and a quadratic (*elevation + elevation<sup>2</sup>*) function. In addition, we included a null  
269 model with only the intercept, resulting in a total of nine models per species (Table S4). An  
270 example of the most parametrized occupancy model can be described as:

271

272 Biological level - Occupancy ( $\psi$ )

273  $\text{logit}(\psi) = \beta_0 + \beta_1\text{elevation} + \beta_2\text{elevation}^2$

274

275 Sampling level - Detectability ( $p$ )

276  $\text{logit}(p) = \beta_4 + \beta_5\text{elevation} + \beta_6\text{elevation}^2$

277

278 We compared models using AIC, and we estimated occupancy profiles across the range  
279 of elevations sampled by model-averaging all models with  $\Delta\text{AIC} < 2.0$ . All models were fitted  
280 using the package *Unmarked* in R (Fiske & Chandler 2011). To compare changes in species  
281 distributions between historical and current data we conservatively estimated the species

282 distribution range by selecting sites with probability of occupancy equal or higher than 0.1. By  
283 using this conservative approach to determine species range limits we excluded sites with low  
284 likelihood to be occupied by the species. Only range shifts greater than 100 meters were  
285 considered significant.

286

## 287 **Results**

288

### 289 *Naïve occupancy data*

290

291 A total of 51 unique sampling localities were extracted from our historical compilation in  
292 the LM over a period of 58 years (1931 to 1989). The most widespread species was *E. coqui* (n  
293 = 27 sites) and *E. portoricensis* (n = 25 sites), while *E. hedrick* (n = 4 sites), *E. unicolor* (n = 3  
294 sites) and *E. cochranæ* (n = 3 sites) were relatively rare (Fig. 2). The total numbers of species  
295 detected varied across the sites with a maximum of eleven species detected at one low elevation  
296 site (371 m).

297 In contrast, 67 sampling localities were surveyed in 2015 and 2016 and the 12 native frog  
298 species known to currently occur in the LM were detected. These species included:

299 *Lepidodactylus abilabris*, *E. antillensis*, *E. cochranæ*, *E. brittoni*, *E. coqui*, *E. wightmanæ*, *E.*  
300 *hedricki*, *E. unicolor*, *E. gryllus*, *E. locustus*, *E. richmondi*, and *E. portoricensis*. We did not  
301 detect two species (*E. eneidae* and *E. karlschmidti*) that are considered extinct (Burrowes et al.,  
302 2004). The most widespread species was *E. coqui*, detected in all sampling sites (n = 67), and  
303 the least common species were *E. locustus* and *E. richmondi* (n = 4). The total numbers of  
304 species detected varied across the sites with a maximum of seven species detected at one high  
305 elevation site (800 m). The naïve occupancy data suggests that six species (*E. portoricensis*, *E.*  
306 *gryllus*, *E. locustus*, *E. richmondi*, *E. eneidae*, *E. karlschmidti*) no longer occur below 500 meters  
307 (Fig. 2).

308

309

### 310 *Occupancy modelling*

311

312 Elevation plays an important role in amphibian distribution because models with the  
313 covariate *Elevation* performed better ( $\Delta AIC < 2$ ) than the null model for the majority of species  
314 in the historical data set (n=11/14) as well in current data (n=9/11) (Table 1). Overall, the  
315 occurrence probability increases with the increase of elevation in four species (*E. portoricensis*,  
316 *E. gryllus*, *E. unicolor*, and *E. locustus*), while there was a negative relationship between  
317 occurrence and elevation in four species (*E. brittoni*, *L. albilabris*, *E. antillensis*, and *E.*  
318 *cochranæ*) (Table 1, Fig. 3). The occurrence probabilities of *E. richmondi* and *E. hedricki*  
319 assume a bell-shape distribution with higher occupancy probabilities at intermediary elevation.  
320 The historical occurrence distribution of *E. wightmanæ* indicates a higher occupancy probability

321 at intermediate elevations, while the current occurrence distribution shows a slight increase of  
322 occurrence with elevation.

323 The main difference between the past and present distributions of the species can be  
324 described by two features: 1) the level of the occupancy probabilities and 2) changes in the  
325 distributional range. There was a decrease in the level of occupancy probabilities in five species  
326 (*E. richmondi*, *E. wightmanae*, *E. locustus*, *E. antillensis*, and *E. cochranæ*), while there was an  
327 increase in the levels of occupancy probability for six species (*E. portoricensis*, *E. gryllus*, *E.*  
328 *unicolor*, *E. hedricki*, *E. brittoni*, and *L. albilabris*) (Fig 3). Four species showed a significant  
329 range contraction (>100m) for the lower end of the elevational distributions (Fig. 4): *E.*

330 *portoricensis* (207 to 508 m), *E. gryllus* (39 to 654 m), *E. locustus* (191 to 333 m), *E. richmondi*  
331 (39 to 654 m). There was also significant range contraction for the upper end of the elevational  
332 distribution of two species: *E. richmondi* (1045 to 800 m) and *E. antillensis* (618 to 216 m). In  
333 addition, we detected a range expansion at the low end of the elevational distribution in *E.*

334 *unicolor* (908 to 523 m) and a range expansion on the upper end of *E. hedricki* (649 to 1020 m).  
335 Overall, detection probabilities were high for all species ( $0.40 > p < 1.00$ ) indicating that  
336 our acoustic survey provides a robust methodology for detecting anuran species. Moreover, the  
337 high detection probabilities estimated provide robust evidence for the lowland extirpation of  
338 some species.

339

## 340 Discussion

341

342 In this study, we present quantitative evidence of changes in the distributions of anuran  
343 species along an elevational gradient in a protected tropical mountain. Over a span of ~25 years,  
344 two species became extinct and four species suffered extirpation in lowland areas. As a  
345 consequence, low elevation areas in the LM (< 300 m) have lost at least six anuran species. This  
346 pattern of local extinction in low elevation sites has been observed for many other species around  
347 the world, and climate change is thought to be the major culprit (Wiens 2016). Furthermore, the  
348 impacts of global warming are expected to have extensive negative impacts on species richness  
349 in lowland tropical areas (Colwell *et al.* 2008). One possible explanation for population  
350 extirpation at the lower end of species distributions is that species may be exceeding their  
351 maximum thermal tolerance (Deutsch *et al.* 2008) due to warming temperatures. Moreover, the  
352 loss of species in tropical lowlands is especially troublesome given that there are rarely species  
353 from hotter areas to colonize the lowlands (Colwell *et al.* 2008).

354 Although our results indicate changes in the elevational distributions of some species, there  
355 were two limitations with the historical data: 1) lack of information on non-detection and 2)  
356 absences of replicate visits in a short time frame. Consequently, our historical data set may have  
357 false absences, biasing our comparisons. In addition, we were not able to estimate detection  
358 probabilities, which can lead to bias and an underestimation of occupancy probabilities (Kéry,  
359 Gardner & Monnerat 2010). Misidentification error and taxonomic changes could also be a  
360 relevant source of bias. Moreover, all historical data inherently suffer from geographical

361 imprecision and survey-specific characteristics such as effort, different methodologies, and  
362 variability in observer skills (Tingley & Beissinger 2009). Despite these intrinsic limitations,  
363 our historical quantitative data set reflects the available qualitative description of species  
364 distribution range, and it offers our best knowledge about the historical distribution of the  
365 species.

366 Although these limitations limits inferences on colonization, we can provide inferences for  
367 local extinction (Tingley and Beissinger 2009). For instance, there are many records, including  
368 museum specimens, indicating that *E. gryllus* historically occurred in lower elevation sites (e.g.  
369 300 m) and now it can only be found above 600 m. Any bias and underestimation of occurrence  
370 probabilities would be more likely to affect our comparisons when the occurrence probabilities  
371 from the historical data sets are lower than the current occurrence probabilities. Therefore, the  
372 historical biases in the data results in conservative estimates of range contractions.

373 The observed pattern of species extirpation at low elevations areas is supported by long-term  
374 monitoring projects centered around the El Verde Field Station (350 - 450 m) (Stewart 1995)  
375 (Woolbright 1997). The El Verde Field Station is the most studied site in LM and there is strong  
376 evidence that of the seven species that were relatively common before 1990, only *E. coqui* and  
377 *E. hedricki* are still common, while *E. gryllus*, *E. portoricensis*, *E. richmondi*, *E. eneidae*, and *E.*  
378 *wightmanae* are now locally extinct (Drewry & Rand 1983; Woolbright 1997; Stewart 1995)  
379 (GBIF, 2016). Woolbright (1997) extended his study beyond the El Verde Field Station and  
380 noted an overall pattern of local extinctions at lower elevation sites within the Tabonuco forest.  
381 Furthermore, *E. richmondi*, *E. wightmanae*, and *E. locustus* were also described to have become  
382 locally extinct at middle (661 m) and high elevation sites (850 m) in EYNF around 1990 (Joglar  
383 & Burrowes 1996). Our study confirms the results of these two long-term studies given that *E.*  
384 *locustus*, *E. richmondi*, *E. gryllus*, *E. portoricensis* and *E. wightmanae* are now relatively rare in  
385 the LM and, with the exception of *E. wightmanae*, these species no longer occur in low  
386 elevations (< 500 m). Anecdotal descriptions of elevational shifts indicate an upward shift for *E.*  
387 *gryllus*, *E. portoricensis*, and *E. richmondi* and a downward shift for *E. hedricki* (Joglar 1998).  
388 Our results also agree with a general upward shift for *E. gryllus*, *E. portoricensis*, and *E.*  
389 *richmondi*, but there is no evidence for a downward shift for *E. hedricki*.

390 The declines and extirpations of the anurans populations in Puerto Rico between 1970 and  
391 1990 (Moreno 1991; Stewart 1995; Woolbright, 1996; Burrowes, Joglar & Green 2004), has  
392 intrigued the scientific community since many of these declines have happened in protected  
393 areas. We hypothesized that the distributions shifts documented in this study are the  
394 consequence of climate change and chytrid fungus, as previously proposed by other researchers  
395 (Joglar & Burrowes 1996; Burrowes, Joglar & Green 2004; Lips *et al.* 2005). Evidences for this  
396 hypothesis can be summarized as follow: First, there has been no obvious direct anthropogenic  
397 impact in the LM during the period of decline, and the LM remains one of the best-preserved  
398 forests in Puerto Rico. Second, studies have shown a significant increase in annual mean  
399 temperature ( $0.007^{\circ}\text{C yr}^{-1}$ ) over 62 years (1932-1994) in the lowlands (100-450m) of LM  
400 (Greenland & Kittel 2002), and a significant increase in the mean minimum temperature and a

401 decrease in mean precipitation from 1970 to 2000 in the East Peak (1051 m) (Lasso & Ackerman  
402 2003). In addition, analyses of climate data from local weather stations showed an increase in  
403 the frequency of dry periods and prolonged dry seasons between 1970 and 1990, coincident with  
404 amphibian declines (Stewart 1995; Burrowes, Joglar & Green 2004). Models also suggest that  
405 warming temperatures will continue with drier wet seasons, and drier dry seasons in the LM and  
406 the Caribbean (Scatena 1998; Campbell *et al.* 2011). Although *Eleutherodactylus* frogs do not  
407 depend on water bodies for reproduction, these species need cool temperatures and humid sites  
408 to prevent dehydration and desiccation of eggs, and prolonged periods of drought significantly  
409 decreased *E. coqui* population densities in the EYNF (Stewart 1995). Prolonged drought can  
410 also reduce foraging success of coquis (Woolbright & Stewart 1987). In addition, there is a  
411 negative impact of drought on the behavior and activity patterns of *E. coqui* (Pough *et al.* 1983;  
412 Stewart 1995), as well as on the infection levels of the pathogenic chytrid fungus (Longo,  
413 Burrowes & Joglar 2010).

414 The *Batrachochytrium dendrobatidis* fungus (Bd) is another potential cause of widespread  
415 amphibian decline. Bd has been identified in more than 700 species of amphibians, and it has  
416 been associated with species extinctions, mass mortality events, and population declines (Stuart  
417 *et al.* 2004; Lips *et al.* 2005; Lips *et al.* 2006; Skerratt *et al.* 2007; Lips 2016). Although no die-  
418 offs have been observed in Puerto Rico, there is evidence linking Bd and amphibian declines  
419 (Burrowes, Joglar & Green 2004; Longo *et al.* 2013). Bd was found in the preserved skins of *E.*  
420 *coqui* collected in 1978, and *E. karlschmidti* collected in 1976, coinciding with the beginning of  
421 declines of these species in the LM (Burrowes, Joglar & Green 2004), and it has been detected in  
422 nine *Eleutherodactylus* species as well as in *Leptodactylus albilabris* (Burrowes, Longo & Joglar  
423 2008). While Bd may pose a serious threat to frogs in EYNF, studies are needed to assess its  
424 impact on species distributions along the entire elevational gradient.

425 There is also evidence supporting the interacting effects of climate change and Bd as main  
426 cause of amphibian declines (Pounds *et al.* 2006; Grant *et al.* 2016). In Puerto Rico, the  
427 synergetic effect of climate change and disease have been proposed to explain local declines  
428 (Burrowes, Joglar & Green 2004). Climate change may act directly on the pathogen by triggering  
429 outbreaks, and in the host, it may change behavior, phenology, and physiology (Burrowes 2009),  
430 and consequently increase its susceptibility to the pathogen. For instance, coquis stressed by  
431 dehydration aggregate in humid refuges during dry periods, which likely increases the  
432 probability of disease transmission (Longo, Burrowes & Joglar 2006)

433 Although climate change and infectious diseases are the main culprit for the anuran declines  
434 in Puerto Rico (Joglar & Burrowes 1996; Burrowes, Joglar & Green 2004; Lips *et al.* 2005),  
435 hurricanes could also contribute to species declines in EYNF (Woolbright, 1991; Woolbright,  
436 1997). For instance, two coquis species (*E. portoricensis* and *E. unicolor*) may have been  
437 extirpated from El Verde area (350 m) by Hurricane Hugo in 1989 (Woolbright 1997).  
438 Nevertheless, some coqui species were apparently not affected by this hurricane, and the density  
439 of *E. coqui* rapidly recovery to pre-hurricane levels. The same pattern of increase in abundance  
440 of *E. coqui* was observed after the Hurricane Georges (1998) in Maricao, Puerto Rico, while the

441 abundance of two other species declined (*E. richmondi* and *E. brittoni*) (Vilella & Fogarty 2005).  
442 Long-term monitoring of all amphibian species is needed to understand the impact of hurricanes  
443 on their populations and distributions given that the frequency of hurricanes is expected to  
444 increase as global warming increases (O'Brien *et al.* 1992).

445 Our study provides a quantitative description of elevational shifts in anuran species in a  
446 tropical mountain, and a quantitative baseline for future studies of these species. From a  
447 conservation perspective, we identified species that may be more vulnerable to extinction due to  
448 range contractions and because these species are being pushed to higher elevations where there is  
449 much less land area. For example, our acoustic data showed that four species no longer occur  
450 below 500 m (*E. locustus*, *E. richmondi*, *E. portoricensis*, *E. gryllus*). Furthermore, *E.*  
451 *richmondi* was only found in a narrow elevational range (<350 m), and both *E. richmondi* and  
452 *E. locustus* are now relatively rare. Possibly, the most vulnerable species is *E. gryllus* that reach  
453 its highest occupancy probabilities above 900 m, only 174 m from the top of the mountain. The  
454 extremely narrow elevational ranges exhibited by these species are especially worrisome because  
455 there are only limited connections to other high elevation forest sites in Puerto Rico, and this  
456 would require extensive movement through lowland forests, agricultural lands, and urban areas.

457 These shifts in distribution along the elevation gradient are creating new ecological  
458 communities, which could impact ecosystem function given that anurans are the largest  
459 component of nocturnal biomass of all vertebrates in Puerto Rico (Stewart 1995) and are  
460 fundamental components of the food web (Beard *et al.* 2003; Whiles *et al.* 2006). While  
461 historically the distributions of 11 coqui species overlapped in the lowlands (371 m), today the  
462 elevation with the greatest richness (seven species) occurs at 800 m. Of greatest concern, is the  
463 loss of six coqui species below 500 m. This biotic attrition in the lowlands is likely to change  
464 interspecific interactions affecting the function of these biological communities (Colwell *et al.*  
465 2008).

466

## 467 **Conclusions**

468

469 In this study, we have shown how acoustic surveys can be used to monitor species, provide  
470 data to confirm general impressions of amphibian population extirpations at certain  
471 sites/elevations, and corroborate the level of threat of species as considered by IUCN. Two  
472 critically endangered species (*E. eneidae* and *E. karlschmidti*) have not been detected since 1974  
473 and 1990, despite our efforts and those of previous researchers. Two species considered  
474 critically endangered (*E. locustus* and *E. richmondi*) and two endangered species (*E. portoricensis*  
475 and *E. gryllus*) suffered range contractions > 100 m caused by extirpation in the lowlands. Here,  
476 we provide recommendations to improve the conservation of these threatened species: 1) The  
477 establishment of a long-term monitoring project to monitor species distributions. Widespread,  
478 frequent, and long-term monitoring is necessary to understand the causes and consequences of  
479 amphibian decline, and to focus conservation and management activities (Lips *et al.* 2005); 2)  
480 captive breeding of the four species that suffered lowland extirpation. Captive breeding is often

481 the easiest and most cost-effective method to manipulate and conserve the population of many  
482 species (Brooks, Wright & Sheil 2009; Zippel *et al.* 2011).

## 718 **Figures and tables**

719

720

721 Figure 1. Map of the Luquillo Mountains and their location in NE Puerto Rico. The black  
722 circles represent sites sampled in 2015/2016 and circles with a dot represent sites with historical  
723 data. Different colors represent differences in elevation (m).

724

725

726 Table 1. Comparison of elevation distribution of 14 frog species in the Luquillo Mountains,  
727 Puerto Rico. Given are IUCN status (EN = endangered; CR = Critically endangered; VU =  
728 Vulnerable; LC = Low concern, † = Extinct, \* = Endemic), the best supported occupancy model  
729 (Elev = elevation; NA = not analyzed) and the cumulative Akaike's Information Criterion weight  
730 for all models with those terms (Weight).

731

732

733 Figure 2. Comparison of raw data on species presence along the elevation gradient for 14 frog  
734 species in the Luquillo Mountains, Puerto Rico. Open circles represent positive detections from  
735 historical data and black circles represent positive detections from current data.

736

737 Figure 3: Historical (black line) and current (blue line) estimated elevation distributions of 11  
738 frog species in Puerto Rico. The observed data are show in open circles (historical) and blue  
739 circles (current). The historical and current elevation profiles were estimated by model-  
740 averaging all models with  $\Delta AIC < 2.0$ . The grey and blue shaded area represent the 95%  
741 confidence intervals. Data for the two extinct species (*E. eneidae* and *E. karlshmidt*) and *E.*  
742 *coqui*, which occur at all elevations in the historical and current data are not included.

743

744

745 Figure 4. Summary of elevational range changes for 14 species. Significant shifts (>100 m) are  
746 in red for extirpations and green for colonization, while no-significant shifts are in grey.

747

748

749

**Table 1** (on next page)

Comparison of elevation distribution of 14 frog species in the Luquillo Mountains, Puerto Rico.

Table 1. Comparison of elevation distribution of 14 frog species in the Luquillo Mountains, Puerto Rico. Given are IUCN status (EN = endangered; CR = Critically endangered; VU = Vulnerable; LC = Low concern, † = Extinct, \* = Endemic), the best supported occupancy model (Elev = elevation; NA = not analyzed) and the cumulative Akaike's Information Criterion weight for all models with those terms (Weight).

1 Table 1. Comparison of elevation distribution of 14 frog species in the Luquillo Mountains,  
 2 Puerto Rico. Given are IUCN status (EN = endangered; CR = Critically endangered; VU =  
 3 Vulnerable; LC = Low concern, † = Extinct, \* = Endemic), the best supported occupancy model  
 4 (Elev = elevation; NA = not analyzed) and the cumulative Akaike's Information Criterion weight  
 5 for all models with those terms (Weight).
