

# Rape and the Prevalence of Hybrids in Broadly Sympatric Species: a Case Study using Albatrosses

Conspecific rape often increases male reproductive success. However, the haste and aggression of forced copulations suggests that males may sometimes rape heterospecific females, thus making rape a likely source of hybrids between broadly sympatric species. We show heterospecific rape to be the probable source of hybrids between black-footed and Laysan albatrosses (*Phoebastria nigripes*, and *P. immutabilis*, respectively). Extensive field studies have shown that paired (but not unpaired) males of both of these albatross species use rape as a supplemental reproductive strategy. Between species differences in size, timing of laying, and aggressiveness suggest that black-footed albatrosses should be more successful than Laysan albatrosses in heterospecific rape attempts, and male black-footed albatrosses have been observed attempting to force copulations on female Laysan albatrosses. Nuclear markers showed that the six hybrids we studied were F1s and mitochondrial markers showed that male black-footed albatrosses sired all six hybrids. Long-term gene exchange between these species has been from black-footed albatrosses into Laysan albatrosses, suggesting that the siring asymmetry associated with heterospecific rape has long persisted. Hybrids sired through rape presumably would be raised and sexually imprinted on Laysan albatrosses, and two unmated hybrids in a previous study courted only Laysan albatrosses.

## Introduction

Unidirectional hybridization is common in nature. A recent review showed that 50 of 80 cases involving at least five hybrids, were predominantly unidirectional ([Wirtz 1999](#)). From a long list of alternatives, a shortage of mates for females was the only general explanation supported for unidirectional hybridization. Here we suggest that predicting siring asymmetries offers a strong way to evaluate the importance of heterospecific rape as a source of hybrids between broadly sympatric species. Although this hypothesis seems likely to apply strongly to waterfowl, where wild hybrids are more frequently reported than for any other group of birds ([Grant & Grant 1992](#); [Randler 2008](#)), we illustrate our predictions using hybrids between Laysan and Black-footed albatrosses for which we had genetic samples.

Hybridization usually arises as an epiphenomenon of mating strategies within species ([Price 2008](#)). In general, rape supplements male reproductive success when directed toward conspecifics ([Shields & Shields 1983](#); [Thornhill 1980](#); [Thornhill & Palmer 2001](#); [Thornhill & Sauer 1991](#); [Thornhill & Thornhill 1983](#)) but the urgent and aggressive nature of rape may result in males sometimes forcing copulations on heterospecific females. While they may be uncommon, hybrids generated by heterospecific rape should be found wherever the parental species breed sympatrically, rather than being confined to zones where the ranges of parapatric species pairs meet and where hybrids are often abundant. While others have suggested heterospecific rape as a source of hybrids ([Kabus 2002](#); [McKee & Pyle 2002](#); [Randler 2005](#)), the idea remains controversial, poorly tested, and little supported.

We use Laysan and black-footed albatrosses (*Phoebastria immutabilis* and *P. nigripes*, respectively) to test a predicted bias in the sire of F1 hybrids and to evaluate the effects of that bias on long-term gene exchange between these species. Paired males of both species are known to force copulations on conspecific females. If hybrids are sired through heterospecific rape, differences between these albatrosses in behavior and the timing of egg laying (detailed below) suggest that black-footed albatrosses should sire F1 hybrids. It is important that only F1 hybrids are used to evaluate siring biases predicted for heterospecific rape because siring asymmetries will be lost if backcross hybrids are generated through random mating with either parental species. Siring bias in F1 hybrids is easily assessed using mitochondrial DNA (mtDNA) to identify the maternal species.

## Study System

Laysan and black-footed albatrosses are closely related sister species ([Nunn et al. 1996](#)) that breed sympatrically in the Northwestern Hawaiian Islands. Like other albatrosses, they are long-lived, delay breeding until they five to seven years old, form life-long pair bonds, lay single eggs, and may breed for 20-50 years ([Fisher 1969](#); [Fisher 1971](#); [Fisher 1972](#); [Fisher 1975](#); [Fisher 1976](#); [Rice & Kenyon 1962](#)).

Our samples came from Midway Atoll where over 480,000 pairs of these albatrosses nest and where the beach-nesting black-footed albatross comprises about five percent of the total pairs (E. Flint, personal communication). Although interbreeding between black-footed and Laysan albatrosses is relatively rare, putative hybrids between them have been noted for decades ([Fisher 1948](#); [Fisher 1971](#); [McKee & Pyle 2002](#)) and up to 20 presumptive hybrids were observed at Midway Atoll between 1997 and 2000 ([McKee & Pyle 2002](#)).

Mature black-footed albatrosses are primarily dark brown, whereas Laysan albatrosses are largely white on the body and dark grey to black on the wings and back. Presumed hybrids are intermediate between the parental species in plumage and soft part coloration, ranging in plumage from very pale grey to fairly dark, with pale under wings ([Fisher 1972](#); [McKee & Pyle 2002](#)). The lightest presumptive hybrids can resemble the darkest Laysan albatrosses in plumage color, but the darkest putative hybrids are not as dark as black-footed albatrosses. Because both Laysan albatrosses and hybrids are variable in coloration, identifying or excluding progeny that might result from backcrosses is not possible based on plumage characteristics alone ([McKee & Pyle 2002](#)). However, calculating the hybrid index for multiple nuclear loci allowed us to assess the existence of hybrids beyond the F1 generation.

Conspecific rapes are observed in both Laysan and black-footed albatrosses ([Fisher 1971](#); [Fisher 1972](#)), and black-footed albatross males sometimes direct rape attempts at Laysan females, suggesting that hybrids could result from heterospecific rapes ([McKee & Pyle 2002](#)). In Laysan Albatrosses conspecific rape is very aggressive, often carried out by groups of males, and sometimes results in serious injury of the female ([Fisher 1971](#)). Multiple males regularly join these rape attempts, mounting other males until the pile topples over. Given that albatrosses lack the explosive penis that facilitates forced copulation by male waterfowl (Brennan et al. 2005), it seems likely that females may sometimes evert their cloaca to receive sperm just to prevent further harassment and injury by attacking males; however, we should note that Fisher 1971 found

no evidence of sperm transfer in albatrosses he examined closely following attacks by males. [Fisher \(1971\)](#) further reports no attempt by the female's mate to defend her from harassing males, as does occur in waterfowl ([McKinney & Evarts 1998](#)). Although [Fisher \(1972\)](#) reports failing to observe interspecific rape attempts, [McKee & Pyle \(2002\)](#) observed male black-footed albatrosses attempting to rape female Laysan albatrosses and believed these events to be the source of hybrids. Neither [Fisher \(1972\)](#) nor [McKee & Pyle \(2002\)](#) observed mixed pairs.

Importantly, differences in the timing of breeding, body size, and aggressiveness all suggest that F1 hybrids are sired when the larger and more aggressive male black-footed albatrosses force copulations on female Laysan albatrosses. Particularly important is that black-footed albatrosses arrive at the breeding colonies and lay earlier than do Laysan albatrosses ([Fisher 1969](#); [Rice & Kenyon 1962](#)), with the result that Laysan females are fertile and vulnerable to insemination through heterospecific rape by black-footed albatross males whose females are incubating.

We evaluated the F1 status of hybrids using fixed and near-fixed differences in their nuclear genome, and we assessed siring bias using mtDNA from the hybrids. We also used an isolation-migration (IM) model to assess asymmetries in long-term gene flow between these species since their divergence approximately 1.03 million years ago ([Nunn et al. 1996](#)).

## Materials and Methods

### *Sampling*

Blood was sampled from 29 breeding black-footed albatrosses, 28 Laysan albatrosses, and six presumed hybrids (morphologically intermediate between the two species in plumage coloration) at Midway Atoll National Wildlife Refuge (28°13' N, 177°22' W). Genomic DNA was extracted from blood samples either by a standard phenol:chloroform procedure ([Sambrook et al. 1989](#)) or using the Wizard SV Genomic DNA Purification System (Promega). All work was conducted in accordance with University of Washington Institutional Animal Care and Use Committee (protocol 2846-13).

### *Molecular methods*

To assess gene flow between the parental species, we collected DNA sequence data for eight anonymous nuclear loci, one coding nuclear locus (a fragment of a Major

Histocompatibility Complex (MHC) gene ([Walsh & Edwards 2005](#)), and the mtDNA *cytochrome-b* (*cyt-b*) locus ([Bretagnolle et al. 1998](#); [Nunn et al. 1996](#)). Anonymous loci were derived from a fosmid library for black-footed albatross (Table 1). “FWD” and “REV” designations indicate loci that were taken from opposite ends of a fosmid insert, and therefore are separated by ~ 35 kb in the genome. We followed standard protocol to amplify and purify PCR products.

We assigned quality scores to base calls in sequence trace files using Phred ([Ewing & Green 1998](#); [Ewing et al. 1998](#)) and aligned homologous sequences using Phrap ([Green 1994](#)). Polymorphic sites were identified using the program PolyPhred ([Nickerson et al. 1997](#)). Assemblies were visualized in Consed ([Gordon et al. 1998](#)) and single nucleotide polymorphisms (SNPs) and genotypes at each locus were confirmed by eye. Nuclear haplotypes were resolved using PHASE v.2.1.1 ([Stephens & Donnelly 2003](#); [Stephens et al. 2001](#)). All sequences have been deposited in GenBank (accession numbers KF475302-KF475698).

Putative hybrids were sexed using primers 2550F and 2718R ([Fridolfsson & Ellegren 1999](#)); sex was scored by eye, with two bands indicating female and a single-band indicating male. Sexing the hybrids enabled us to assess whether hybrid females (the heterogametic sex in birds) were inviable, which could be expected under Haldane’s rule ([Haldane 1922](#)).

### *Hybrid Identification*

We computed two hybrid indices, both varying from 0 (pure Laysan albatrosses) to 1 (pure black-footed albatrosses). The first is most intuitive and includes only loci with fixed or near-fixed sequence differences between black-footed and Laysan albatrosses (Table 1). Using these same loci, we also computed the probability that the six phenotypically intermediate specimens were first generation (F1) hybrids or backcrosses (Table 2). For the second hybrid index we used maximum likelihood in the introgress package implemented in R ([Gompert & Buerkle 2009](#)), and included all of the nuclear loci.

Siring asymmetries for the hybrids were assessed using a binomial test on mtDNA data.

### *Migration Estimation*

To assess effective population sizes and the rate and direction of gene flow between black-footed and Laysan albatrosses, we used the IM model implemented in IMA2 ([Hey & Nielsen 2004](#)). We applied the HKY mutation model of nucleotide substitution and nuclear mutation rate

scalars were free to vary in the model. The nuclear and mitochondrial genes were assigned an inheritance scalar of 1.0 and 0.25, respectively. To avoid violating the assumptions of no recombination and neutrality of markers, we tested for within locus recombination using the four-gamete test ([Hudson & Kaplan 1985](#)) for each locus and within each species; we tested neutrality of markers using Tajima's D implemented in R package PEGAS ([Paradis 2010](#)) (Table 1).

We ran 12 replicate IMA2 analyses, each using different starting seeds and 40-50 concurrent chains, for 10-50 million steps after an initial burn-in phase of 50,000-100,000 generations. To rescale estimates of population size and migration parameter into demographic units, we used the geometric mean of previous mtDNA rate estimates for albatrosses of  $3 \times 10^{-5}$  substitutions per locus per year for our fragment of *cyt-b*; ([Nunn & Stanley 1998](#)), and a generation time of 25 years ([Cousins & Cooper 2000](#)). We evaluated a total of 25 nested models of the full migration model (all migration rates and all population sizes estimated as different parameters). Models of population divergence were compared using likelihood ratio tests and ranked based on the information-theoretic criterion ([Carstens et al. 2009](#)).

## Results

### *Hybrid Indices and probability of hybrid genotypes*

All six putative hybrids were heterozygous at five diagnostic nuclear SNPs (Table 1). Using just these diagnostic loci the hybrid index for a true F1 hybrid is expected to be 0.51 because Laysan albatrosses share in low frequency (10%) a single diagnostic SNP (dSNP2 in Tables 1) that is fixed in black-footed albatrosses (Fig. 1).

In Table 2 we use the observed population allele frequencies to calculate the probability of producing the genotype found in all six hybrids, under the assumption that they were either F1 hybrids or first generation backcrosses. The probability of producing the observed hybrid genotype was 0.90 for a parental cross. The probability that the hybrid genotype resulted from a backcross to either of the parental species varies by the sex of the hybrid and the sex and species of the backcross parent. Because all hybrids carried Laysan mtDNA haplotypes, the probability of a backcross to a female Black-footed albatross is 0. For the three other backcross combinations, the probability of observing the hybrid genotype is either 0.028 or 0.034 (Table 2). These calculations, based on the five diagnostic SNPs, show that the six hybrids are almost certainly F1s and not backcross individuals.

We also evaluated the status of the six hybrids using a maximum likelihood estimator ([Gompert & Buerkle 2010](#)), including in this analysis the four nuclear SNPs that were not diagnostic (Table 1). All six hybrids received a score of 0.56, with a 95% confidence interval of 0.22 – 0.85.

#### *Siring bias and sex for the hybrids*

All six hybrids carried the Laysan albatross mtDNA haplotype, indicating that F1 hybrids result from male black-footed albatrosses inseminating female Laysan albatrosses ( $p = 0.031$ ). Three of the hybrids were male and three were female, suggesting no inviability of the heterogametic sex ([Haldane 1922](#)).

#### *Gene flow*

Tajima's D values showed no significant deviation from neutrality for any of the loci examined (Table 1) and no evidence of recombination within loci was found.

Under the IM model, the rate of gene flow was significantly higher from black-footed albatrosses into Laysan albatrosses ( $p=0.028$ ). The mean rate of gene flow ( $2Nm$ ) was 0.09 gene copies per generation from black-footed albatross into Laysan albatross (95% HPD 0.024 - 0.23), whereas this rate was zero in the reverse direction (95% HPD 0 - 0.10). Migration from Laysan to black-footed albatross was constrained to zero in the top four models, which, together, account for 55% of the variation in the weighted AIC models (Table 3).

#### **Discussion**

Using diagnostic nuclear loci, we show that all six presumed hybrids between Laysan and black-footed albatross were F1 hybrids. All six carried Laysan mtDNA haplotypes, indicating that male black-footed albatrosses were their sires. This contradicts the hypothesis that a scarcity of mates for females of the rare species results in hybrid pairings ([Wirtz 1999](#)) because all six hybrids had Laysan albatross mothers, instead of mothers of the much less abundant black-footed albatross. Finally, we found limited, but significant gene flow from black-footed albatrosses into Laysan albatrosses, suggesting that past F1 hybrids have backcrossed to Laysan albatrosses. As we discuss below, this further supports to our hypothesis that forced copulations are asymmetrical.

# 199 *Effects of Phenology and Behavior on Insemination Biases*

200 Black-footed albatrosses lay 10 days to two weeks earlier than Laysan albatrosses ([Fisher](#)  
201 [1969](#); [Rice & Kenyon 1962](#)), so most female black-footed albatross have begun incubating when  
202 Laysan females are fertile. This difference in breeding schedules undoubtedly contributes strongly  
203 to the asymmetry in inseminations that generate hybrids because only paired males have been  
204 reported to engage in rape attempts in these albatrosses ([Fisher 1971](#); [McKee & Pyle 2002](#)).  
205 Unmated males spend their time at breeding colonies courting females and have not been  
206 observed attempting rapes ([Fisher 1971](#)). Other factors may also contribute to the observed siring  
207 asymmetry. Notably, female Laysan albatrosses are 5-10% smaller than male black-footed  
208 albatrosses ([Dunning 2007](#)), and male black-footed albatrosses are much more aggressive in  
209 conspecific rape attempts than are male Laysan albatrosses ([Fisher 1972](#)). Finally, because black-  
210 footed albatrosses constitute only 5% of the population of these two species breeding at Midway  
211 Atoll, they have far more opportunity to engage in forced heterospecific copulations than do  
212 Laysan albatrosses. These differences suggest that male black-footed albatrosses are more likely  
213 to sire hybrids through rapes, and all reported heterospecific rape attempts have involved male  
214 black-footed albatrosses and female Laysan albatrosses ([McKee & Pyle 2002](#)).

215 The asymmetry in gene exchange revealed by the isolation-migration model suggests a  
216 long history of unidirectional gene flow from Black-footed Albatrosses into Laysan Albatrosses.  
217 Although modern hybrids appear to have no success in attracting mates ([Fisher 1972](#); [McKee &](#)  
218 [Pyle 2002](#); [Rice & Kenyon 1962](#)), two carefully observed hybrids (unsuccessfully) addressed all  
219 courtship attempts at Laysan albatrosses ([Fisher 1972](#)). Hybrids sired by male black-footed  
220 albatrosses raping female Laysan albatrosses would be raised by and sexually imprinted on  
221 Laysan albatrosses ([Slagsvold et al. 2002](#); [ten Cate & Vos 1999](#)); further, courting individuals of  
222 both species spend a great deal of time focusing on the breast color of their dance partners ([Fisher](#)  
223 [1972](#)). Thus, when plumage differences between these species were likely less dramatic, F1  
224 hybrids, generated by heterospecific forced copulations, may have resembled the darkest Laysan  
225 albatrosses well enough to pair and breed with them in the past.

## 226 *Alternative Explanations for Asymmetric Gene Flow*

We can think of two alternatives to our hypothesis of heterospecific rape as the cause of the observed asymmetry in gene flow between black-footed and Laysan albatrosses. First, is the possibility that F1 backcrosses into the black-footed albatross population have not been viable. Definitively addressing this alternative this would require breeding experiments, but the observation that hybrids court only Laysan albatrosses renders this alternative moot ([Fisher 1971](#)).

Second, if hybrids were intermediate in their breeding schedule relative to the parental species, then hybrids may have had greater opportunity to mate with Laysan albatrosses, which return later to the breeding colonies than black-footed albatrosses. However, this explanation untenably assumes that hybrids form life-long pair-bounds and breed the first year that they return to their breeding islands. Instead, pre-breeding Laysan albatrosses typically spend one or two years choosing mates ([Fisher 1972](#)), making the two-week difference in laying dates unlikely to bias the pattern of backcross matings toward Laysan albatrosses.

It seems most likely to us that the gene flow revealed by the IM analysis reflects gene exchange that took place as the species were diverging in coloration. This is supported by the fact that courting birds focus their attention of the breasts of their dance partners, where the two species differ most in color ([Fisher 1972](#)), and by the failure of field workers to find any hybrids that were paired ([Fisher 1972](#); [McKee & Pyle 2002](#)).

#### *Tests with other groups*

The contrast between species in which conspecific Extra-Pair Copulations (EPC) are forced, as opposed to species in which females accept or solicit such copulations, is critical to our thesis that hybrids between broadly sympatric species will be more common in groups where forced copulations are frequent. Although EPC are common in many passerines, they are mostly unforced and apparently controlled by females to increase the genetic quality of offspring ([Dunn & Cockburn 1998](#); [Dunn & Cockburn 1999](#); [Spottiswoode & Møller 2004](#); [Stutchbury & Neudorf 1998](#)). Unfortunately, whether EPC are forced or accepted is rarely described in the literature (although there are good descriptions of rape in albatrosses, waterfowl, bee-eaters, swallows and the New Zealand hihi, (*Notiomystis cincta*) ([Brekke et al. 2013](#); [Emlen & Wrege 1986](#); [Kabus 2002](#); [Martin 1980](#)). Improved behavioral descriptions of whether or not conspecific EPC are forced are required to predict whether heterospecific rape can be a source of hybrids in most groups.

Naturally occurring hybrids are abundant in waterfowl ([Grant & Grant 1992](#); [Randler 1998](#); [Randler 2008](#)) and male ducks are known to direct rape attempts at females of other species ([Muñez-Fuentes et al. 2007](#); [Randler 2002](#); [Seymour 1990](#)). However, we could find no genetic assessments of insemination biases in the generation of hybrids between naturally sympatric waterfowl. An obvious test would be to compare insemination bias when one parental species is characterized by forced copulations and the other is not. For example, hybrids between northern shovelers (*Anas clypeata*) and both mallards (*A. platyrhynchos*) and pintails (*A. acuta*) are reported from North America and Eurasia ([McCarthy 2006](#)). Because shoveler males are territorial, and seldom attempt conspecific rapes, F1 hybrids should be sired by mallards or pintails ([McKinney & Evarts 1998](#)). Siring bias can also be predicted for the abundant hybrids between common pochards and tufted ducks (*Aythya ferrina* x *A. fuligula*, respectively) ([Randler 2008](#)). Because conspecific rape is unreported in common pochards but frequent in tufted ducks ([McKinney & Evarts 1998](#)), F1 hybrids should be sired by tufted ducks if they were produced through heterospecific rape. Heterospecific rape probably accounts for the frequent hybrids reported between barn swallows and house martins in Europe and between barn swallows and cliff swallows (*Petrochelidon pyrrhonota*) in North America. Barn swallows are characterized by many EPCs, but females choose whether or not to accept these EPCs, and they are almost never forced ([Møller 1994](#)). In contrast, conspecific rape is frequently observed in both cliff swallows and house martins at communal mud-gathering sites ([Brown & Brown 1996](#); [Møller 1994](#)). That male cliff swallows and house martins are characterized by conspecific rape, presumably, renders female barn swallows vulnerable to heterospecific rape when they gather mud at sites frequented by males of these two species. When identified as nestlings, hybrids between barn swallows and house martins were always found in barn swallow nests, had barn swallow siblings, and had two barn swallow parents; similarly, nestling hybrids between barn swallows and cliff swallows or cave swallows (*P. fulva*) were found, in all cases but one, in barn swallow nests, attended by two barn swallow parents ([Martin 1980](#)). These are likely F1 hybrids sired through heterospecific rapes.

#### *Broader implications*

Two comparative studies have addressed the role of EPC in the generation of avian hybrids. In a survey of open nesting birds [Randler \(2006\)](#) found EPC to be uncorrelated with the

production of hybrids; however, this study failed to distinguish forced and unforced extra pair copulations and failed to consider whether hybrids were rare or common. In another study [Randler \(2005\)](#) assessed the roles of forced EPC and brood amalgamation on the production of hybrid waterfowl, and found a significant effect only of brood amalgamation when both factors were included in the model. However, both causal variables were treated as binary characters, which masks their importance in species pairs where either factor causes the production of many hybrids. For example, over 800 common pochard x tufted duck hybrids have been reported from Europe ([Randler 2008](#)), yet these were treated as equivalent to a single report of a natural hybrid between other species pairs. Testing for siring asymmetries in F1 hybrid waterfowl would generate a stronger test of the heterospecific rape hypothesis.

In some cases evaluating siring asymmetries can generate tests of the hypothesis that heterospecific brood parasitism results in ducks forming heterospecific pair bonds ([Randler 2005](#)). For example, redheads (*Aythya americana*) are facultative brood parasites of canvasbacks (*Aythya valisineria*), whereas canvasbacks do not parasitize redhead nests ([Sorenson et al. 2010](#)). Redhead ducklings raised by canvasback females in broods of mostly canvasback ducklings should be sexually imprinted on canvasbacks and, therefore, be more willing to pair or at least mate with canvasbacks ([Sorenson et al. 2010](#)). An excess of adult males in both species predicts the siring bias: Female redheads imprinted on canvasbacks ([Sorenson et al. 2010](#)), should be able to attract unmated male canvasbacks as mates. In contrast, male redheads imprinted on canvasbacks would be unlikely to attract canvasback mates because canvasback females have many unmated males to choose from. Thus canvasback males should sire F1 hybrids between these species. In contrast, Barrows (*Bucephala islandica*) and common (*B. clangula*) goldeneyes parasitize each other, so males of both species are expected to be sires of hybrids. Although rare, hybrids between both of these species pairs are regularly reported ([McCarthy 2006](#)), and none of the parentals is characterized by conspecific rape.

Among *Anas* ducks gene sharing through hybridization apparently has strongly affected effective population sizes. For pintails and green-winged teal, census population sizes are too small for certain shared alleles to have persisted for more than 2 and 2.6 million years. But these alleles, which are shared with mallards, are estimated to have persisted for 6.2 and 7.9 million years, respectively, suggesting a long history of horizontal gene exchange with mallards, which have a much larger effective population size ([Kraus et al. 2012](#)). Heterospecific rapes may be

responsible for generating F1 hybrids between these ducks and, unlike long-lived albatrosses, F1 hybrid females in these short-lived ducks probably do form pair-bonds and breed. Hybrid female ducks should be sexually imprinted on the species that raised them ([ten Cate & Vos 1999](#)) and the strong male bias in the breeding sex ratios of north temperate ducks should facilitate pairing and breeding by hybrid females.

## Conclusion

Although unidirectional hybridization often predominates in nature, only a shortage of mates for females previously had emerged from a long list of alternative hypotheses as a general explanation for asymmetric hybridization ([Wirtz 1999](#)). In this case study of hybrid albatrosses, we attempt to make the general point that, when hybrids result from heterospecific rape, differences in behavior and life history of the parental species can be used to predict the direction of crosses. Predicting the mother and father species of F1 hybrids from different parental combinations has the potential to considerably refine our understanding of the importance of heterospecific forced copulation (and brood parasitism), in the generation of hybrids ([McKee & Pyle 2002](#); [Møller 1994](#); [Randler 2005](#)). Although heterospecific rape is unlikely to be adaptive, it has the potential to explain differences in the prevalence of F1 hybrids between broadly sympatric species pairs according to whether or not they are characterized by conspecific forced copulations.

Several authors have suggested that heterospecific rape may be an important source of avian hybrids ([McKee & Pyle 2002](#); [Møller 1994](#); [Randler 2005](#)), but a comparative study of waterfowl found only weak support for this hypothesis ([Randler 2005](#)). We believe that testing for siring asymmetries will provide a stronger assessment of this hypothesis in waterfowl and game birds, groups for which wild hybrids between a many pairs of broadly sympatric species ([Grant & Grant 1992](#)). Forced copulations have been reported for various insects ([Arnqvist 1989](#); [Thornhill 1980](#); [Thornhill & Sauer 1991](#)), fish ([Valero et al. 2008](#)), lizards ([Cooper 1985](#); [Olsson 1995](#); [Rodda 1992](#)) and mammals ([Harris et al. 2010](#)), but whether or not forced copulations generate hybrids in these groups has not yet been addressed.

## Acknowledgements

Nancy Hoffman and Peter Pyle collected and provided hybrid blood samples for this study, and S. Edwards provided blood samples for black-footed and Laysan albatrosses. E. Flint and N. Hoffman engaged in helpful discussions. A. Møller provided information on swallows and helped with references. W. Swanson provided workspace, and J. Felsenstein, S. Edwards, and members of the Rohwer, Leaché and Klicka lab groups commented on the manuscript. Thanks to all for their help.

# Figure 1

Hybrid scores based on the five diagnostic SNPS (Table 1), with pure black-footed albatrosses scored as 0 and pure Laysan albatrosses scored as 1.

The six putative hybrids all scored as 0.51, rather than 0.50, because Laysan albatrosses share a rare allele with Black-footed albatrosses at one of our diagnostic loci.

# Table 1 (on next page)

Primer and locus information.

Diagnostic nuclear loci (dSNP) that provided at least a 90% probability of distinguishing between the parental species are starred. Tajima's D of NA indicates no variation occurring at that locus; BF = black-footed albatross, LA = Laysan albatross.

## Table 2<sub>(on next page)</sub>

Primer and locus information.

Diagnostic nuclear loci (dSNP) that provided at least a 90% probability of distinguishing between the parental species are starred. Tajima's D of NA indicates no variation occurring at that locus; BF = black-footed albatross, LA = Laysan albatross.

<b>F1 genotype</b>		
<b>F1</b>	<b>mtDNA</b>	<b>Probability</b>
<b>combinations</b>		
LA f x BF m	LA (1.0)	0.90
LA m x BF f	BF (1.0)	0.00 <sup>1</sup>
<b>Backcross genotype</b>		
<b>Backcross</b>	<b>mtDNA</b>	<b>Probability</b>
<b>combinations</b>		
F1 f x BF m	LA (1.0)	0.028
F1 f x LA m	LA (1.0)	0.034
F1 m x LA f	LA (1.0)	0.034
F1 m x BF f	BF (1.0)	0.00 <sup>1</sup>

<sup>1</sup>Probability is 0 due to the absence of BF mitochondrial haplotype in the observed hybrid genotype.

### Table 3<sub>(on next page)</sub>

AIC ranking of the six best models using IMA2 based on ~ 300,000 sampled genealogies.

Model subscripts of population size (q) and migration (m) parameters identify populations used in the analysis; 0, 1, and 2 represent the estimated population sizes for black-footed albatrosses, Laysan albatrosses, and the ancestral population, respectively. In each model brackets denote fixed parameters; other parameters were estimated.

Model	log(P)	k	AIC	$\Delta$ AIC	$\omega$	q0	q1	q2	m0>1	m1>0
Pop. size BF = LA; Mig. from LA to BF = 0	2.48	3	1.04	0	0.16	0.24	[q0]	0.01	[0]	0.22
Mig. from LA to BF = 0	3.39	4	1.22	0.18	0.15	0.22	0.07	0	[0]	2.56
Ancestral pop. size = BF pop. size; Mig. from LA to BF = 0	2.16	3	1.68	0.64	0.12	0.3	0.11	[q0]	[0]	1.82
Ancestral pop. size = LA pop. size; Mig. from LA to BF = 0	2.16	3	1.69	0.65	0.12	0.3	0.11	[q1]	[0]	1.76
Mig. from BF to LA = mig. from LA to BF	2.99	4	2.03	0.99	0.1	0.25	0.13	0	0.2	[m0>1]
Pop. size LA = BF	2.48	4	3.04	2	0.06	0.24	[q0]	0.01	0	0.22
