Infrared thermal imaging has emerged as a valuable tool in veterinary medicine, in particular for evaluating reproductive processes. Here, we explored differences in skin temperature of twenty female chimpanzees in Budongo Forest, Uganda, four of which were pregnant during data collection. Based on previous literature in other mammals, we predicted increased skin temperature of maximally swollen reproductive organs of non-pregnant females when approaching peak fertility. For pregnant females, we made the same prediction because it has been argued that female chimpanzees have evolved mechanisms to conceal pregnancy, including swellings of the reproductive organs, conspicuous copulation calling, and solicitation of male mating behaviour, to decrease the infanticidal tendencies of resident males by confusing paternity. For non-pregnant females, we found slight temperature increases towards the end of the swelling cycles but no significant change between the fertile and non-fertile phases. Despite their different reproductive state, pregnant females had very similar skin temperature patterns compared to non-pregnant females, suggesting little potential for males to use skin temperature to recognise pregnancies, especially during maximal swelling, when ovulation is most likely to occur in non-pregnant females. We discuss this pattern in light of the concealment hypothesis, i.e., that female chimpanzees have evolved physiological means to conceal their reproductive state during pregnancy.

11 **ABSTRACT**

12 Infrared thermal imaging has emerged as a valuable tool in veterinary medicine, in particular for
13 evaluating reproductive processes. Here, we explored differences in skin temperature of twenty
14 female chimpanzees in Budongo Forest, Uganda, four of which were pregnant during data
15 collection. Based on previous literature in other mammals, we predicted increased skin
16 temperature of maximally swollen reproductive organs of non-pregnant females when
17 approaching peak fertility. For pregnant females, we made the same prediction because it has
18 been argued that female chimpanzees have evolved mechanisms to conceal pregnancy, including
19 swellings of the reproductive organs, conspicuous copulation calling, and solicitation of male
20 mating behaviour, to decrease the infanticidal tendencies of resident males by confusing
21 paternity. For non-pregnant females, we found slight temperature increases towards the end of
22 the swelling cycles but no significant change between the fertile and non-fertile phases. Despite
23 their different reproductive state, pregnant females had very similar skin temperature patterns
24 compared to non-pregnant females, suggesting little potential for males to use skin temperature
25 to recognise pregnancies, especially during maximal swelling, when ovulation is most likely to
26 occur in non-pregnant females. We discuss this pattern in light of the concealment hypothesis,
27 i.e., that female chimpanzees have evolved physiological means to conceal their reproductive
28 state during pregnancy.

29

30 INTRODUCTION

31 Infrared thermal imaging (IRT) has emerged as a promising tool for studying animal behaviour.
32 For instance, research employing this methodology has helped cast light on affective processing
33 in a variety of species, including macaques (*Macaca mulatta*) (Nakayama et al., 2005; Kuraoka
34 & Nakamura, 2011; Ioannou, Chotard & Davila-Ross, 2015), chimpanzees (*Pan troglodytes*)
35 (Kano et al., 2016; Dezechache et al., 2017) and dogs (*Canis lupus familiaris*) (Travain et al.,
36 2015; Riemer et al., 2016; Travain et al., 2016). In these studies, IRT has been used to detect
37 changes in emissivity of the skin caused by shifts in blood flow at the body surface, a
38 physiological process controlled by the autonomic nervous system (see Ioannou, Gallese &
39 Merla, 2014 for a comprehensive review). One important asset of this technique is its non-
40 invasive character, since measurements can be made at a reasonable distance from free-ranging
41 animals and without hindering their on-going natural behaviour.

42

43 IRT has also been used as a non-invasive technique to study reproductive processes of animals
44 (Cilulko et al., 2013). For example, Hilsberg-Merz (2008) noticed that female Asian elephants
45 (*Elephas maximus*) and Black rhinoceroses (*Diceros bicornis*) showed increased surface
46 temperature in the area of their reproductive organs during oestrus, a pattern associated with
47 increased attractiveness to males. In pigs, vulvar skin temperatures were higher during oestrus
48 compared to dioestrus (Sykes et al., 2012), a pattern related to increased blood flow towards the
49 vulva due to oestrogen secretion in the ovarian follicles (Stelletta et al., 2013). Heightened
50 temperature of the area of the reproductive organs can be used as a tool to detect oestrus in cows,
51 with vulva temperature peaks around 24 hours before ovulation, followed by a slight decrease
52 towards ovulation (Talukder et al., 2014). Furthermore, it has been suggested that thermo-

53 reception may constitute a sensory strategy used by males in mammal species in order to detect
54 ovulation in females (Hilsberg-Merz, 2008), possibly in conjunction with other cues.

55 In sum, most current research using IRT has been performed on domestic and farm mammals,
56 usually in the context of veterinary diagnosis (Cilulko et al., 2013), with only little systematic
57 use in studying natural patterns, including sexual behaviour.

58

59 Here, we were interested in the skin temperature of wild female chimpanzees (*Pan troglodytes*)
60 throughout the swelling cycle. The swelling cycle can be defined as the cyclical change during
61 which a female's anogenital region gets progressively swollen and increases in size before
62 reaching maximal tumescence, followed by detumescence, whereby the swelling area shows a
63 rapid decrease in size and the skin becomes loose (Wallis, 1992; Deschner et al., 2004). In
64 chimpanzees and other catarrhine species living in multi-male societies, females tend to develop
65 exaggerated anogenital swellings during the periovulatory phase of their menstrual cycles (Nunn,
66 1999). There has been considerable debate on the biological function of exaggerated swellings,
67 particularly in regard to whether swelling size, or tumescence, constitutes a reliable indicator of
68 fertility. In chimpanzees, males show most interest in females during maximal tumescence
69 (Wallis, 1992; Deschner et al., 2004) when ovulation is most likely to occur (Deschner et al.,
70 2004). Gradual swelling tumescence is caused by increased oestrogen concentrations, while its
71 sudden decrease is caused by increased progesterone secretion (Graham et al., 1972; Emery &
72 Whitten, 2003; Emery Thompson, 2005). However, swelling size is only a probabilistic indicator
73 of fertility in chimpanzees, because maximal swelling can last up to 21 days with a mean of
74 about 13 days and thus maximal tumescence may exceed the phase of peak fertility (Emery
75 Thompson, 2005). This has been interpreted as an evolved female strategy to prolong the period

76 of sexual attractiveness and, by increasing the number of copulations with different males, to
77 confuse paternity (Nunn, 1999; Alberts & Fitzpatrick, 2012). Such a strategy is adaptive in
78 species where males commit infanticide, as is commonly observed across chimpanzee
79 communities (Williams et al., 2008; Goodall, 1986; Nishida & Kawanaka, 1985; Watts &
80 Mitani, 2000; Wilson et al., 2014).

81

82 As a first step, we were interested in whether the period of maximum tumescence, if compared to
83 earlier phases, can be identified by a unique temperature profile. In a second step, we were
84 interested in the temperature profiles of pregnant females, who have been suggested to conceal
85 their gestation in an attempt to remain attractive to males (Wallis, 1982). Pregnant chimpanzee
86 females continue to be sexually active and display sexual swellings despite being no longer able
87 to conceive. It has been suggested that the maximal anogenital swelling during pregnancy may
88 account for one fourth of the total time female chimpanzees display maximal tumescence during
89 their reproductive lifetime (Wallis & Goodall, 1993). Pregnant females are, in some instances,
90 even more sexually active than non-pregnant females (Wallis, 1982). One functional explanation
91 of this behavioural pattern is that pregnant females attempt to confuse paternity in the males of
92 their group, which may lower the infanticidal tendencies of males once an infant is born (Wallis
93 & Goodall, 1993).

94

95 Based on these findings, we hypothesised that variation in skin temperature may provide cues
96 about the three main reproductive stages of a female, that is to say, pregnancy, oestrus, non-
97 oestrus. However, based on the literature reviewed, female chimpanzees appear to have evolved
98 ways to conceal their true reproductive stage, particularly pregnancy, but also the exact time of

99 ovulation (Townsend, Deschner & Zuberbühler, 2011). If males perceive changes in skin
100 temperature, then selection should favour individuals with skin temperature profiles that do not
101 reveal their reproductive condition.

102 To address these hypotheses, we investigated skin temperature of female chimpanzees in the
103 Sonso community of Budongo Forest, Uganda. We inspected the thermal patterns of pregnant
104 and non-pregnant females to test the following predictions. First, for non-pregnant females, we
105 expected higher temperatures (particularly of the genital area) during the fertile phase (when
106 females show peak swelling sizes and when sexual proceptivity is highest [Wallis, 1992])
107 compared to non-fertile phases (when swellings are not maximally inflated and sexual
108 proceptivity is comparably lower [(Wallis, 1992)]. This was expected because, in farm animals,
109 the skin temperature of the vulva can be influenced by oestrogen secretion through increased
110 blood flow (Stelletta et al., 2013).

111

112 Second, if pregnant females follow an evolved strategy to conceal their pregnancy when showing
113 sexual tumescence, we predicted similarity in skin temperature at maximum tumescence between
114 pregnant and non-pregnant females (when male mating efforts are typically concentrated, see
115 Wallis [1992]), compared to earlier swelling stages, when copulation is comparatively rarer and
116 ovulation unlikely.

117

118 **METHODS**

119 *Ethical statement* Permission to conduct the study was granted by the Ugandan Wildlife
120 Authority (UWA) (UWA/TDO/33/02) and the Uganda National Council for Science and

121 Technology (UNCST) (NS-475). Ethical approval was given by the University of St Andrews'
122 ethics committee.

123 **Study site** The study was carried out in the Budongo Forest Reserve, a moist semi-deciduous
124 tropical forest in western Uganda, covering 428 km² at an altitude of 1,100 m, between 1° 35'
125 and 1° 55' N and 31° 08' and 31° 42' E (Eggeling, 1947). Data were collected from the
126 Sonso community between November 2011 and May 2012, and between August 2013 and June
127 2014. Habituation of this community to humans began in 1990, with the majority of individuals
128 (approximate N = 70) well habituated to human observers at the time of the study (Reynolds,
129 2005).

130

131 **Materials** Surface skin temperature measurements were taken with a Testo (881-2) thermal
132 imager, which operates between 8 and 14 µm with a thermal sensitivity of <80 mK at 30°C.
133 Emissivity was set at 0.98, a value typically used for human skin (Steketee, 1973). A telephoto
134 lens was used for all images (9° x 7° / 0.5 m). The device emits no light or sound and is thus
135 ideal for working with wild animals.

136

137 **Pregnancy status** We initially used HCG pregnancy tests (which respond to the presence of >25
138 mIU/ml human chorionic gonadotropin in the urine, a hormone produced by the placenta about
139 one week after fertilisation). We later decided to estimate pregnancy status depending on the
140 presence or absence of offspring up to 229 days after the recording was taken (assuming a mean
141 gestation period of 229 days in chimpanzees [Reynolds, 2005]). This was done because it was
142 only possible to perform one or two pregnancy tests for each individual, over a short time frame,

143 so it is possible that some females may have been pregnant temporarily before or after testing.
144 Additionally, a more recent pilot study suggested that HCG pregnancy tests are unreliable in
145 wild chimpanzees, with pregnant females testing negative around their fifth month of gestation
146 (Caroline Asimwe, personal communication).

147 As we relied upon the presence/absence of offspring after the average gestation period of
148 chimpanzees, it is possible that some females we designated as 'not pregnant' may have been in
149 the early stages of pregnancy when thermal images were recorded, without carrying the
150 pregnancy to term. Stillbirths and miscarriages are difficult to distinguish in the wild (Courtenay
151 & Santow, 1989) (but see Tutin [1975]). Studies in captivity indicate that miscarriages may
152 happen in around 8% of the pregnancies (Courtenay, 1987) and fetal wastage (miscarriage and
153 stillbirths) may occur following 14% of all conceptions (Littleton, 2005).

154 ***Thermography data collection*** Data collection took place between 07:00 and 16:30 local time.
155 On a given morning, a female was selected as the focal animal and followed throughout the day
156 with IRT photographs taken whenever the individual was in clear view, and photographs taken
157 of surrounding individuals ad libitum. Although we considered all females during data
158 collection, we later excluded 64 images of females with dependent infants (<4 years). Although
159 some of them may have been cycling, we excluded them because of difficulties in determining
160 their reproductive status.

161

162 All sampled individuals (20 females, 4 of which were pregnant during parts of data collection)
163 were sufficiently tolerant to observer presence within 10m. Each body part (face, ears, nose,
164 hands and feet, and swelling/genitals) was sampled only once every half hour with females
165 contributing differently to the dataset (see Table 1). For an image to be taken, the focal had to be

166 within a distance of 15m (range: less than 1m–15m) and less than 5m above ground. They had to
167 be in unobstructed view, with a body part clearly visible to the observer and in dry conditions
168 (water alters the temperature and emissivity of skin) and not exposed to direct sunlight. Readings
169 were taken from body parts that were exposed and free of hair. For each image, we estimated the
170 distance to the focal individual (in metres). Ambient temperature and humidity data were
171 collected using an electronic recorder, as these may affect infra-red readings. Swelling
172 tumescence was determined by experienced field assistants from stage 0 (absence of tumescence)
173 to stage 4 (maximum tumescence) as judged by the degree of wrinkling (Furuichi, 1987)
174 (adapted for chimpanzees: Townsend et al. [2008]). Note that the field assistants were blind to
175 the aims and hypotheses of the study.

176 ***Image analysis*** Thermal images were analysed using the Testo IRSoft analysis software. A
177 polygon image selection tool was used on each image to select specific body parts of interest for
178 subsequent thermal analysis. For each selected region of interest, we obtained the mean
179 temperature (see Figure 1 for example). Two coders (GD and CW) performed the image
180 analysis. To test for inter-observer reliability, we examined measurements of N=408 thermal
181 images taken by two coders. There was a mean difference of 0.15 +/- 0.43°C (mean difference
182 between the two sets of measurements +/- SD) between the two sets of measurements, with high
183 internal consistency (Cronbach's alpha, $\alpha = 0.99$), suggesting that our method of calculating the
184 average temperature of an area of interest was consistent.

185 ***Statistical analysis*** We used a linear mixed model with Gaussian error structure and maximum
186 likelihood estimation to assess how swelling stage and pregnancy affected skin temperature of
187 female chimpanzees. In our initial model, we fitted the two-way interaction between swelling
188 stage and reproductive state. This also allowed us to specifically address the possibility that

189 variation in temperature between swelling stages may show different patterns in pregnant and
190 non-pregnant females. In addition, we controlled for ambient temperature, humidity and distance
191 between camera and subject. Because some images allowed simultaneous measurement of
192 several body parts, we fitted image ID nested in subject ID as random intercept. In this way, we
193 also accounted for multiple measurements of the same female. We fitted body part as random
194 intercept and in addition, allowed the effects of swelling stage and pregnancy state on skin
195 temperature to vary between body parts by incorporating random slopes for these variables (Barr
196 et al., 2013). Ideally, we would have incorporated similar random slopes for female ID, thereby
197 allowing between subject variation in the effects of swelling and pregnancy on temperature.
198 Unfortunately, we had to forego this step because the resulting model structure was too complex
199 for our data set. Before model fitting, we inspected distributions of variables and transformed
200 them to achieve symmetric distributions (see Supplementary Information). In addition, we scaled
201 all numeric variables to mean=0 and standard deviation=1 (Schielzeth, 2010). We checked for
202 homogeneity and normality of model residuals visually and calculated variance inflation factors
203 (Fox & Weisberg, 2010). Neither check indicated serious deviations from modelling
204 assumptions. We then calculated Cook's distance as a measure for the influence of each single
205 individual in our data set on our model results. Here we found a number of individuals with
206 substantial influence on our results. Specifically, Cook's distance for all four females in our data
207 set that were pregnant during the study exceeded the critical threshold (c.f. Nieuwenhuis, te
208 Grotenhuis & Pelzer [2012]). Furthermore, we tested full models against our null models (see
209 below) in a leave-one-out fashion to assess the potential influence of single females: we fitted the
210 full and null model with a data set from which one female was excluded per turn. Here,
211 exclusion of one female (OK – see Table 1) led to the full model not being significant ($p > 0.05$),

212 although the signs of the parameter estimates remained unchanged. Despite this consistency in
213 the direction of our results, the interaction between swelling stage and pregnancy must be
214 interpreted with some caution, as their statistical significance hinges on one individual. However,
215 the signs of our major result concerning the differences between pregnant and non-pregnant
216 females remained consistent, regardless of which female we excluded.

217

218 To test the significance of our full model, we built an informed null model, which contained the
219 random effects structure as described above and the three control fixed effects (ambient
220 temperature, humidity, distance). We then tested our full model against this null model using a
221 likelihood ratio test (LRT, Dobson & Barnett, 2008). Similarly, we tested the interaction by
222 comparing the model including the interaction (i.e. the full model) against a model without the
223 interaction (swelling stage and reproductive state as main effects only). We calculated marginal
224 and conditional R^2 following (Nakagawa & Schielzeth, 2013) and (Johnson, 2014), using the
225 MuMIn package (Bartoń, 2016). We fitted all models in R 3.3.0 (R Core Team, 2016), using the
226 lme4 package (v. 1.1-12, Bates et al. [2015]).

227

228 From the existing literature (Hilsberg-Merz, 2008; Scolari et al., 2011; Sykes et al., 2012;
229 Talukder et al., 2014), we predicted an increase in temperature throughout the swelling cycle in
230 non-pregnant chimpanzees, with a peak temperature at full tumescence, in particular at the area
231 of the reproductive organs, when females are fertile. Second, and following the hypothesis that
232 female chimpanzees have evolved physiological and behavioural strategies to conceal
233 pregnancy, we predicted pregnant females to show similar patterns of skin temperature changes
234 at peak tumescence when the probability of conception is at its highest for non-pregnant females.

235

236 To address the two predictions, we assessed skin temperature associated with swelling and
237 reproductive state, at various body parts, controlling for ambient temperature, humidity and
238 recording distance.

239

240 RESULTS

241 Our full model (containing swelling stage and reproductive state and their interaction plus the
242 control terms: distance, humidity and ambient temperature) was significantly different from the
243 null model (containing the control terms only) (LRT: $\chi^2_9 = 19.48$, $p = 0.0214$, $R^2_m = 0.33$, $R^2_c =$
244 0.90 , Table 2). Concerning our variables of interest – reproductive state and swelling stage – we
245 found that the model containing the interaction between the two was significantly different from
246 a model from which the interaction term was removed (LRT: $\chi^2_4 = 9.72$, $p = 0.0455$). Thus, our
247 results indicate that skin temperature showed greater variability in pregnant females (N=4) than
248 non-pregnant females (N=20). Generally, pregnant females had lower skin temperatures than
249 non-pregnant females when deflated and during smaller swelling stages (stages 0 – 2, Figure 2),
250 of less than 1°C overall. This pattern changed later in the cycle, with pregnant females having
251 higher skin temperature compared to non-pregnant females (stage 3, Figure 2), again with a
252 magnitude of less than 1°C. During maximum tumescence (swelling stage 4), temperatures of
253 non-pregnant and pregnant females appeared most similar compared to all other swelling stages.
254 This was true for all body parts measured (Figures 3 and 4).

255

256 Finally, and contrary to our predictions, we did not find a clear increase in temperature
257 throughout the swelling cycle (Figure 2), at the area of the reproductive organs and elsewhere

258 (Figure 3). There was a modest increase in skin temperature between stages 1-2 and stages 3-4,
259 in both pregnant and non-pregnant females, in particular around (but not restricted to) the vulvar
260 area (Figure 3). Yet, we did not find a clear difference between the skin temperature at maximal
261 swelling (where female proceptivity is higher [Wallis, 1992]) and reduced swelling stages.
262 Finally, skin temperature seems comparable or even slightly higher during detumescence than at
263 maximum tumescence.

264

265 **DISCUSSION**

266 Our aim was to assess whether skin temperature may reveal the reproductive state of female
267 chimpanzees, using IRT, a well-developed technique in veterinary medicine, with yet little
268 application so far in the field of behavioural ecology. We compared wild female chimpanzees
269 throughout their swelling cycle and predicted that (i) non-pregnant females should show higher
270 skin temperature when oestral than when anoestral, as well as an increase in skin temperature
271 (with maximal temperature at the end of the swelling cycle, particularly at the area of the
272 reproductive organs), following previous observations in other species (Hilsberg-Merz, 2008;
273 Scolari et al., 2011; Sykes et al., 2012; Talukder et al., 2014). We also predicted that (ii) pregnant
274 females should approximately overlap with the temperature patterns exhibited by non-pregnant
275 females, despite their radically different hormonal state at maximum swelling (stage 4) when
276 males are sexually interested in them. This second prediction is based on the hypothesis that
277 pregnant females have evolved gestation concealing strategies, as they incur an adaptive
278 advantage in concealing pregnancy, to enhance the benefits of paternity confusion by
279 promiscuous mating as long as possible.

280

281 Our results were consistent with the first prediction, by showing slightly higher temperatures of
282 the anogenital regions when transitioning from stages 1-2 to 3-4 (Figure 2), consistent with what
283 has been found in other mammal species (Hilsberg-Merz, 2008; Scolari et al., 2011; Sykes et al.,
284 2012; Stelletta et al., 2013; Talukder et al., 2014). However, this pattern was true for most body
285 parts considered, not solely for the anogenital region (Figure 3). Although it is hard to directly
286 compare our results to previous studies using IRT because of different definitions and methods,
287 the differences we found in our results are of similar magnitudes (about 1°C) compared to other
288 studies (Scolari et al., 2011; Sykes et al., 2012). In both human and non-human female primates,
289 skin colour and tone can change during the fertile period (Roberts et al., 2004; Dubuc et al.,
290 2009), and such variation may be perceived by males (Higham et al., 2011). Variation in skin
291 colour, presumably caused by blood flow and associated temperature changes, may affect the
292 entire body, including the face, and not be restricted to the periovulatory area.

293

294 Regarding our second prediction, we found smaller changes in skin temperature in non-pregnant
295 compared to pregnant females. Crucially, for stage 4, we observed more similar skin
296 temperatures between pregnant and non-pregnant females, compared to the other swelling stages
297 (Figure 2), a pattern true for all body parts considered (Figure 3). Our data is therefore consistent
298 with the prediction that, during gestation, chimpanzee females approximate behavioural and
299 physiological cues that characterise non-pregnant females, which functions to conceal their
300 reproductive state. This could be part of an evolved strategy to deceive males by remaining
301 sexually attractive to them and ultimately to confuse paternity and lower infanticide risk after
302 parturition. Alternatively, the overlap in anogenital temperature could be the by-product of
303 physiological mechanisms involved in anogenital swelling. In the context of the concealment

304 hypothesis, it is worth mentioning that pregnant females show less clear transitions between
305 swelling stages compared to non-pregnant females. Instead, swelling sizes appear to change
306 more erratically, and hence a probably simpler means for males would be to attend to gradation
307 of swelling changes. Previous work has already shown that females show irregular swelling
308 patterns during the early stages of pregnancy (Wallis & Goodall, 1993).

309

310 Sexual swellings during pregnancy have also been reported in other non-human primates, such as
311 sooty mangabeys (*Cercocebus atys*) (Gordon et al., 1991) and Barbary macaques (*Macaca*
312 *sylvanus*) (Möhle et al., 2005), but in these species the swelling patterns between pregnant and
313 non-pregnant females seem to differ. Whether males are responsive to non-monotonic changes in
314 swelling and, if so, whether this affects their mating behaviour and future infanticidal tendencies,
315 would be worth exploring.

316

317 The important question of whether temperature changes are perceivable by males remains
318 unresolved. In humans, thermal discrimination has been investigated in the domain of
319 psychophysics, using tasks where participants are presented with pairs of materials and
320 instructed to choose the cooler of two objects. Thermal discrimination varies with the nature and
321 size of contact sites as well as the baseline temperature of the skin around the contact site (Ho &
322 Jones, 2006). Also, the rate and magnitude of temperature changes play a considerable role in the
323 discrimination of thermal increments (Jones & Berris, 2002; Ho & Jones, 2006). The thenar
324 eminence at the base of the thumb is one of the most sensitive body parts with reported thermal
325 discrimination of less than 0.1°C (Ho & Jones, 2006). If chimpanzees possess temperature

326 discrimination capacities similar to humans, then males should be able to perceive the
327 temperature changes reported in this study.

328

329 It is also worth mentioning that primate males almost certainly use additional signs to make
330 fertility assessments of females during their sexual swelling cycles, particularly olfactory signals
331 (Michael & Zumpe, 1982). In humans (*Homo sapiens*), female body odour during highly fertile
332 days is preferred by males (Gildersleeve et al., 2012). In other primate species, olfactory cues
333 may also play a role (Ziegler et al., 1993; Converse et al., 1995; Clarke, Barrett & Henzi, 2009),
334 but, to our knowledge, relevant systematic research in chimpanzees has not been conducted (Fox,
335 1982). Regarding visual signals, skin colour and tone can change during the fertile period in
336 human and non-human primate females (Roberts et al., 2004; Dubuc et al., 2009), and such
337 variation may be perceived by males (Higham et al., 2011). In humans, facial redness has been
338 linked to the vasodilatation caused by oestradiol (Jones et al., 2015), a pattern in blood flow
339 around the facial area that may be associated with increase in skin temperature. Finally, female
340 sexual behaviour itself can reveal the most fertile period of the swelling cycle (Engelhardt et al.,
341 2005). Future studies should also investigate whether non-pregnant vs. pregnant female
342 chimpanzees show reliable differences in those areas.

343

344 We acknowledge several limitations to our research. First, we did not find a clear increase in skin
345 temperature when comparing anogenital areas of females in fertile and non-fertile stages.
346 Second, only four pregnant females contributed to our dataset, so it would be important to
347 replicate these findings with a larger sample of pregnant females. Third, we did not collect any
348 hormonal data and were therefore unable to determine the point of likely ovulation. A validation

349 study is necessary and would moreover be feasible in captive settings. Finally, we had no
350 behavioural data to show that males are directly responsive to changes in skin temperature, and
351 can be deceived by pregnant females who may have similar skin temperature profiles as fertile
352 individuals. Such behavioural data could have also helped to control for other potential factors
353 that may have affected skin temperature, such as the amount of physical activity when resisting
354 solicitations from males (Stumpf & Boesch, 2005). Nevertheless, we consider it plausible that
355 males can be affected by pregnant females' skin temperature, mainly because shifts in blood
356 flow, and their corresponding changes in skin temperature, may affect skin colouration in the
357 face.

358

359 In sum, our data appear consistent with the prediction that, during gestation, chimpanzee females
360 approximate skin temperature as well as behavioural and visual cues that characterise non-
361 pregnant females. Yet, it is still possible that skin temperature does not constitute a deceptive
362 signal in chimpanzees. Rather, skin temperature may simply be a by-product of the physiological
363 mechanisms driving anogenital tumescence. Furthermore, we offer inconclusive evidence of a
364 thermal pattern associated with fertility. Skin temperature seems to increase throughout the
365 swelling cycle, but with no clear differences in skin temperature compared to when females are
366 anoestral. Our research offers a tentative exploration of changes in skin temperature associated
367 with fertility and pregnancy in wild female chimpanzees, which future research can build on,
368 using IRT to tackle important questions in the field of behavioural ecology.

369

370 **ACKNOWLEDGMENTS**

371 We are grateful for comments from by Lydia Hopper, Katherine Cronin and two anonymous
372 reviewers. We thank the Uganda Wildlife Association and the Uganda National Council for
373 Science and Technology for permission to conduct the study. Our gratitude goes to Geoffrey
374 Muhanguzi, Caroline Asimwe, Geresomu Muhumuza, Bosco Chandia and Sam Adué for their
375 support in the field. We further thank Cat Hobaiter, Roman Wittig, Dave Perrett, William
376 Paterson, Dominic McCafferty, Ross Whitehead, Amanda Hahn, Brittany Fallon and Zanna Clay
377 for helpful discussions and/or comments on the manuscript.
