Taxonomic uncertainty of the Asian tree frog *Polypedates leucomystax* complex presents the challenging task of inferring its biogeographical history. Here, we describe its dispersion and the genetic relationships among different populations in Thailand, where we connect the population of the *P. leucomystax* complex of the Sunda Islands to the Indochina (mainland) population based on analyses of 266 sequences of the mitochondrial cytochrome c oxidase subunit I (*COI*) gene. Our maternal genealogy implies that there are four well-supported lineages in Thailand, consisting of Northern A (clade A: *Polypedates* sp.), Nan (clade B: *P. cf. impresus*), Southern (clade C: *P. cf. leucomystax*) and Northern B (clade D: *P. cf. megacephalus*), with Bayesian posterior probability >0.9. Phylogeny and haplotype networks indicate that clades A, B and D are sympatric. In contrast, clade C (*P. cf. leucomystax*) and clade D (*P. cf. megacephalus*) are genetically divergent due to the geographical barrier of the Isthmus of Kra, resulting in an allopatric distribution. Climatic conditions, in particular differences in rainfall on each side of the Isthmus of Kra, may play an important role in limiting the immigration of both clades. For the within-populations of either clades C or D, there was no significant correlation between geographic and genetic distance by the isolation-by-distance test, indicating intraspecific-dispersal of each clade. Population expansion occurred in clade C, whereas clade D showed a constant population. Taken together, the *P. leucomystax* complex in South East Asia may have diversified under climatic pressure, leading to allopatric and/or sympatric speciation.

12 **ABSTRACT**

13 Taxonomic uncertainty of the Asian tree frog *Polypedates leucomystax* complex presents the  
14 challenging task of inferring its biogeographical history. Here, we describe its dispersion and the  
15 genetic relationships among different populations in Thailand, where we connect the population  
16 of the *P. leucomystax* complex of the Sunda Islands to the Indochina (mainland) population based

17 on analyses of 266 sequences of the mitochondrial cytochrome c oxidase subunit I (*COI*) gene.  
18 Our maternal genealogy implies that there are four well-supported lineages in Thailand,  
19 consisting of Northern A (clade A: *Polypedates* sp.), Nan (clade B: *P. cf. impresus*), Southern  
20 (clade C: *P. cf. leucomystax*) and Northern B (clade D: *P. cf. megacephalus*), with Bayesian  
21 posterior probability >0.9. Phylogeny and haplotype networks indicate that clades A, B and D are  
22 sympatric. In contrast, clade C (*P. cf. leucomystax*) and clade D (*P. cf. megacephalus*) are  
23 genetically divergent due to the geographical barrier of the Isthmus of Kra, resulting in an  
24 allopatric distribution. Climatic conditions, in particular differences in rainfall on each side of the  
25 Isthmus of Kra, may play an important role in limiting the immigration of both clades. For the  
26 within-populations of either clades C or D, there was no significant correlation between  
27 geographic and genetic distance by the isolation-by-distance test, indicating intraspecific-  
28 dispersal of each clade. Population expansion occurred in clade C, whereas clade D showed a  
29 constant population. Taken together, the *P. leucomystax* complex in South East Asia may have  
30 diversified under climatic pressure, leading to allopatric and/or sympatric speciation.

## 31 INTRODUCTION

32 Southeast Asia contains a substantial genetic diversity of amphibians. Recent molecular  
33 phylogenetic analyses have disclosed many anuran lineages that contain cryptic species.  
34 Historically, complex changes in the region's geology and climate (e.g., Pleistocene climatic  
35 oscillations) altered the topology and environmental conditions, resulting in an initial  
36 fragmentation of habitat. These mechanisms generated the high species richness observed today  
37 (Hall, 1998; Woodruff, 2010). Of interest to our research were the numerous frog species in  
38 Southeast Asia whose taxonomy is still controversial, such as *Microhyla fissipes* (Yuan et al.,  
39 2016), *Staurois tuberilinguis* (Matsui et al., 2007), *Microhyla ornata* (Matsui et al., 2005) and  
40 *Polypedates leucomystax* (Kuraishi et al., 2013; Rujirawan, Stuart & Aowphol, 2013). Accurate  
41 species delimitation is essential to better understand their speciation and diversification and their  
42 biogeography for conservation purposes.

43         The Asian tree frog, the *Polypedates leucomystax* (Gravenhorst, 1829) complex, is an  
44 Asian Rhacophoridae frog. These species are widely distributed in Southeast Asia, South China  
45 and India. In addition, this species has phenotypic plasticity and exhibits high adaptation to the  
46 local environment, leading to its existence in diverse habitats such as forests and even buildings.  
47 These high levels of phenotypic plasticity present a great challenge for classification.  
48 Phylogenetic and taxonomic relationships of the *P. leucomystax* complex throughout Southeast  
49 Asia exhibit adaptive radiation (Kuraishi et al., 2013; Pan et al., 2013; Rujirawan, Stuart &  
50 Aowphol, 2013). At least six valid species, including *P. braueri*, *P. leucomystax*, *P. macrotis*, *P.*  
51 *megacephalus*, *P. mutus* and *P. impresus*, have been delimited from the *P. leucomystax* complex  
52 based on their morphology, advertisement calls and molecular data (Matsui, Seto & Utsunomiya,  
53 1986; Brown et al., 2010; Kuraishi et al., 2011; Kuraishi et al., 2013; Pan et al., 2013). Five

54 species, *P. leucomystax*, *P. mutus*, *P. macrotis*, *P. colletti* and *P. megacephalus*, can be found in  
55 Thailand (Taylor, 1962; Heyer, 1971; Frost, 2013; Kuraishi et al., 2013; Pan et al., 2013;  
56 Rujirawan, Stuart & Aowphol, 2013). A study by Brown et al. (2010) indicated that much of the  
57 genetic divergence of the *P. leucomystax* complex was discovered in mainland rather than insular  
58 populations distributed throughout thousands of islands of the Malay Archipelago, presumably  
59 resulting from range expansion mediated by transportation of agricultural products. Recently, a  
60 new species, *P. discantus*, belonging to the *P. leucomystax* species complex from southern  
61 Thailand was discovered using data on morphological characteristics, advertisement calls and  
62 molecular evidence, which showed that this species was highly dissimilar to *P. leucomystax* and  
63 *P. megacephalus* (Rujirawan, Stuart & Aowphol, 2013). Several studies have confirmed the  
64 existence of highly cryptic species of the *Polypedates leucomystax* complex (Matsui, Seto &  
65 Utsunomiya, 1986; Kuraishi et al., 2011; Blair et al., 2013; Kuraishi et al., 2013; Pan et al.,  
66 2013).

67         Understanding the phylogenetic relationships among species can give insight into how  
68 lineages diverged and how new species arose. The process of speciation can be understood based  
69 on the geographic overlap of emerging species during divergence. In this study, we investigated  
70 the genetic variation, phylogenetic relationships and other relevant factors that limit the dispersal  
71 of the *P. leucomystax* complex in Thailand. The present results illustrate the range of distribution  
72 of putative *P. leucomystax* and putative *P. megacephalus*, which is influenced by climatic  
73 conditions.

## 74 **MATERIALS AND METHODS**

### 75 **Sample collection, DNA extraction and sequencing**

76 In this study, a total of 266 adult *Polypedates leucomystax* complex individuals were collected  
77 from 15 different localities in Thailand (Table 1). All samples were dissected to obtain the liver,  
78 which was then stored in absolute ethanol. Sample collection and euthanization were approved by  
79 the Center For Animal Research Naresuan University under project number NU-AE591028.  
80 Genomic DNA was extracted from liver tissue using a DNA extraction kit (RBC Bioscience,  
81 Singapore) and kept at  $-20^{\circ}\text{C}$  for further use. Individual DNA was used as a template for PCR  
82 amplification of the mitochondrial COI gene using Taq DNA polymerase in a total volume of 25  
83  $\mu\text{L}$  under the following conditions: an initial denaturation at  $94^{\circ}\text{C}$  for 5 min, followed by 35–40  
84 cycles at  $94^{\circ}\text{C}$  for 30 s,  $50^{\circ}\text{C}$  for 30 s and  $72^{\circ}\text{C}$  for 1 min, and a final extension step at  $72^{\circ}\text{C}$  for  
85 7 min. PCR products were visualized on 1.5% agarose gel under UV illuminator. The expected  
86 size of the partial mitochondrial COI gene sequence was 688 bp. Subsequently, all PCR products  
87 were purified using a QIAquick PCR Purification Kit (Qiagen, Germany) and then sequenced  
88 (Macrogen, South Korea).

## 89 **Phylogeny**

90 Bayesian inference (BI) and maximum likelihood (ML) were independently employed for  
91 constructing a phylogenetic tree based on the following partial COI sequences of the *Polypedates*  
92 *leucomystax* complex that were retrieved from GenBank: *P. impresus*: KP996822 (China),  
93 KP996846 (China), KP087862-70 (Laos); *P. leucomystax*: KR087871-2 (Thailand); and *P.*  
94 *megacephalus*: KR087879, KR087881 (Thailand). First, the best-fit model of DNA sequence  
95 evolution for this locus was identified with the Akaike information criterion (AIC) implemented  
96 in MrModeltest v2.3 (Nylander, 2004), resulting in the GTR+I+G model as the best fit with AIC  
97 Subsequently, a Bayesian tree was constructed based on the base substitution calculated from the

98 GTR+I+G model through MrBayes 3.1.2 (Ronquist & Huelsenbeck, 2003) with two independent  
99 searches with random starting trees for 5 million generations, in which the diagnostic was  
100 calculated every 1,000 generations and compared using four Markov chain Monte Carlo chains  
101 (temp = 0.2). The log-likelihood scores were used for plotting the convergence in Tracer v1.5  
102 (Rambaut et al., 2013) and building a consensus tree, which was completed by the removal of the  
103 first 25% of the generations from each run. For maximum likelihood analysis, RAxML 7.0.4 was  
104 carried out (Stamatakis, Hoover & Rougemont, 2008) using the GTR+I+G model for nucleotide  
105 substitution (same as the BI analysis) with 1,000 bootstrap replicates.

#### 106 **Population genetics and structure**

107 A total of 266 sequences of mitochondrial *COI* were aligned using ClustalW (implemented in  
108 MEGA 6.0 with default parameters). The number of polymorphic sites, the parsimony-  
109 informative sites, singleton sites, the number of haplotypes, haplotype diversity ( $H_d$ ), and  
110 nucleotide diversity for each clade were calculated using DnaSP v5.0 (Librado & Rozas, 2009).  
111 Genetic distances among taxa were calculated using the corrected  $p$ -distance model in MEGA 6.0  
112 (Tamura et al., 2011). Furthermore, we detected a boundary line in the genetic landscape between  
113 the Northern B clade and the Southern clade using Barrier 2.2 (Manni, Guérard & Heyer, 2004).  
114 A minimum spanning network was constructed using PopART (Population Analysis with  
115 Reticulate Trees) population genetics software to define the relationships among haplotypes and  
116 the distribution of haplotypes in each locality (Bandelt, Forster & Röhl, 1999). To evaluate the  
117 effect of geographic distance on the genetic divergence among populations of the Northern B  
118 clade and among populations of the Southern clade, a linear regression model was carried out.

## 119 Demographic history

120 To investigate the demographic history of *P. megacephalus* and *P. leucomystax* populations in  
121 Thailand, multiple approaches were explored using DnaSP (Librado & Rozas, 2009). Neutrality  
122 tests of Tajima's  $D$  (Tajima, 1989) and Fu's  $F_s$  (Fu, 1997) for the two species were completed. A  
123 significantly positive value indicates a process of subdivision or a recent population bottleneck,  
124 whereas a population expansion results in a significantly negative value. Pairwise mismatch  
125 distribution was used assuming a constant population size (Roger & Harpendin, 1992).  
126 Multimodal mismatch distribution implies stability of the population, while unimodal mismatch  
127 distribution reflects an expanding population. In addition to these methods, the raggedness index  
128 ( $r_g$ ) of the observed distribution was calculated (Harpending, 1994). A small  $r_g$  indicates a  
129 demographic expansion.

## 130 RESULTS

### 131 Sequence characteristics

132 A total of 266 samples of the *P. leucomystax* complex yielded 688 bp fragments of the  
133 mitochondrial *COI* gene. All new sequences in this study were deposited in the GenBank  
134 database (MG583020-MG583285). After multiple alignment of all *COI* sequences, the sequences  
135 were trimmed to the same length (437 bp) before downstream analysis. We observed 82  
136 polymorphic sites, which are also 82 parsimony-informative sites without a singleton site,  
137 resulting in the acquisition of 15 haplotypes (Table 2). Overall nucleotide and haplotype diversity  
138 were 0.0664 and 0.9000, respectively (Table 2).

### 139 **Phylogenetic analyses and haplotype distribution**

140 Based on 266 mitochondrial *COI* sequences of the *P. leucomystax* complex, a matrilineal  
141 genealogy was generated, and our results indicated that the *P. leucomystax* complex in Thailand  
142 could consist of four clades: clade A (Northern A), *Polypedates* sp.; clade B (Nan), *P. cf.*  
143 *impresus*; clade C (Southern), *P. cf. leucomystax*; and clade D (Northern B), *P. cf. megacephalus*  
144 (Fig. 1). With respect to phylogenetic inference, clade A was treated as a sister group of clade B,  
145 which was found in Nan. Clade A, however, can be seen in genetic samples obtained from the  
146 Kanchanaburi (KCB), Mae Hong Son (MHS) and Phetchaburi (PCB) provinces and shared a  
147 habitat with clade D, which was recognized as *P. cf. megacephalus*; its distribution range was in  
148 the far north of the Isthmus of Kra at Chiang Mai (CM), MHS, KCB, PCB, Saraburi (SRB), Loei  
149 (LPR), Nakhon Ratchasima (NRS) and Prachuap Khiri Khan (PKK). The dispersal areas of the  
150 clade C population, as represented by *P. cf. leucomystax*, included Chumphon (CP), Nakhon Si  
151 Thammarat (NST), Phuket (PK) and Ranong (RN), which are south of the Isthmus of Kra (Fig.  
152 2). Barrier 2.2 was employed to determine a barrier for immigration between clade C and clade D  
153 populations based on the dataset of genetic distance (Kimura's two-parameter model). Likely, the  
154 Isthmus of Kra (IOK) represents a significant barrier to restrict immigration based on the great  
155 genetic distance that was noted around IOK (Fig. 3)

156 A minimum spanning network among the mitochondrial haplotypes was also constructed  
157 as shown in Fig. 1. The haplotypes of each group showed unique features, and each group had a  
158 different number of haplotypes. Clade D exhibited the highest number of haplotypes at seven ( $H_d$   
159 = 0.746), followed by clade C with five haplotypes ( $H_d = 0.7526$ ) (Table 2). Haplotypes A and B,  
160 seen in clade A, and haplotype C found in clade B were unique haplotypes. Haplotypes D–I were  
161 noted in clade D, while populations of northern, western and upper southern Thailand (KCB,  
162 PCB and PKK, respectively) shared haplotype J. We noted that the haplotypes F and G of clade

163 D1 in NRS were highly divergent from the congeners. Clade C (*P. cf. leucomystax*) had high  
164 haplotype diversity and contained three unique haplotypes (M, N and O) and two shared  
165 haplotypes (K and L).

166 Analyses of the linear regression model between the genetic distance of the mitochondrial  
167 *COI* gene sequence and the geographical distance found no significant isolation-by-distance  
168 effect among populations of clade C (*P. cf. leucomystax*) and clade D (*P. cf. megacephalus*) (Fig.  
169 4).

## 170 **Demographic history**

171 When we defined a significant barrier around the Isthmus of Kra (IOK) leading to the genetic  
172 divergence between clade C (*P. cf. leucomystax*) and clade D (*P. cf. magacephalus*), neutrality  
173 tests (Tajima's  $D$  and Fu's  $F_s$ ) of both species were not significantly positive, whereas Fu's  $F_s$  of  
174 clade C was significantly positive (Table 3). Furthermore, the mismatch distribution was tested as  
175 a result of a left-skewed multimodal mismatch distribution for clade D with moderate  $r_g$  (0.2031)  
176 but a unimodal mismatch distribution for clade C with a low  $r_g$  (0.0569) (Fig. 5). Overall, these  
177 results suggested a constant population size of clade D and a population expansion of clade C.

## 178 **DISCUSSION**

179 The taxonomy of the Asian tree frog of the *Polypedates leucomystax* complex is contentious due  
180 to the species' widespread distribution from Nepal to South East Asia and similar morphologies.  
181 To better understand the population structure and biogeography of the *P. leucomystax* complex in  
182 Thailand, where there is a substantial area for their genetic dispersal, the *COI* mitochondrial gene  
183 sequences of these species were analysed. Our matrilineal genealogy implied four well-supported

184 lineages, consisting of a Northern B clade (clade D), a Southern clade (clade C), a Nan clade  
185 (clade B) and a Northern A clade (clade A); based on their sequences and distributions, they  
186 might be treated as *P. megacephalus*, *P. leucomystax*, *P. impresus* and *Polypedates* sp.,  
187 respectively. However, our study did not perform morphological, call advertisement, ecological  
188 habitat, and nuclear DNA analyses for species justification; therefore, it is difficult to confirm the  
189 phylogenies with certainty. These would need to be investigated in future work.

190           Based on our phylogenetic tree, Northern A and Nan seemed to share the latest common  
191 ancestor with the Southern clade; however, they showed a significant genetic difference against  
192 Northern B. The matrilineal haplotype network showed that haplotype C of the Nan clade  
193 (putative *P. impresus*) seemed to be related to haplotype N and O of the Southern clade.  
194 Moreover, haplotypes A and B within the Northern A clade (*Polypedate* sp.) seem to have  
195 evolved from haplotype C. These results indicate that both the Nan clade and the Northern A  
196 clade are more closely related to the Southern clade (restricted in south of IOK) than the Northern  
197 B clade (restricted in north of IOK) and that the Nan and Northern A clades may even be  
198 sympatric. Although mtDNA seemed to offer cleanly split clades with a unique haplotype in each  
199 clade, mtDNA introgression/hybridization between the closely related species can occur. This can  
200 occur particularly in sympatric populations or at the boundaries of species distributions resulting  
201 from incomplete reproductive isolation. Therefore, the use of only mitochondria DNA data is not  
202 adequate for species justification. For instance, some populations of European newts *Triturus*  
203 *montandoni* have an mtDNA haplotype of *Triturus vulgaris* in an area where their distributions  
204 are connected, most likely as a result of historical or ongoing hybridization and multiple  
205 introgression of mtDNA from *T. vulgaris* to *T. montandoni* (Babik et al., 2005). Thus, nuclear  
206 DNA must be required for species delimitation to explain the lineage history with accuracy and  
207 reliability. A recent study by Kuraishi et al., (2013) found one sample of *P. leucomystax* complex

208 from Indochina shared nuclear BDNF and Rag1 haplotypes with one sample from the south of  
209 IOK, possibly suggesting deep coalescence or incomplete lineage sorting.

210 Bayesian inference strongly supported the geographic distinction of species in the  
211 Northern B clade and the Southern clade. Furthermore, Monmonier's algorithm suggested that  
212 the Isthmus of Kra (IOK; located between 11 and 13 °N along the Thai Peninsula) forms a  
213 significant region separating them as evidenced by the large genetic divergence between the  
214 populations on either side of the isthmus. Kuraishi et al. (2013) explored the population structure  
215 of *P. leucomystax* complex in South East Asia and revealed that *P. megacephalus* is restricted to  
216 Indochina (the northern Thailand, Laos, Vietnam and southern China) (Kuraishi et al., 2013; Pan  
217 et al., 2013), while the expansion range of *P. leucomystax* is restricted to the Sunda regions  
218 (southern Thailand and Malay Archipelago) (Brown et al., 2010; Kuraishi et al., 2013). Based on  
219 their distribution, we assumed that the northern B clade and the Southern clade might be *P.*  
220 *megacephalus* and *P. leucomystax*, respectively. The Isthmus of Kra has been well-characterized  
221 as a remarkable biogeographic boundary of both faunal and floral assemblages that are limited on  
222 either side. Bruyn et al (2005) used genetic evidence from *Macrobrachium rosenbergii*  
223 (freshwater shrimp with a broad distribution) to suggest a hypothesis that the existence of a  
224 seaway across the IOK over 1 Myr contributed to its geographically discontinuous distribution. In  
225 contrast, Hughes et al. (2011), based on marine fossils and geological data, proposed that the  
226 occurrence of species with distinct distributions in the north and south of the IOK is related to the  
227 influence of the climatic zone rather than either marine inundation or breaches at any point near  
228 the IOK. In addition, flying animals such as birds and bats also have a restricted species  
229 distribution which is bounded by the IOK (Hughes et al., 2011). This indicates that the  
230 geophysical barriers at the IOK, such as the waterway, are unlikely to be significant  
231 biogeographical boundaries causing vicariance of various species at the IOK. A study by Hughes

232 et al. (2011) also determined the climatic zone in Indochina and the Malay Peninsula is the result  
233 of four climatic zonations, which are displayed as similar climatic zones found in each time  
234 period from the Last Interglacial Period to the current conditions. Of interest is the climatic  
235 divergence in precipitation, temperature and seasonality between the central zone (north of IOK)  
236 and the southern zone (south of IOK). Additionally, data on rainfall in Thailand by the Thai  
237 Meteorological Department indicates a difference in the amount of rainfall between areas to the  
238 north and south of the isthmus (Fig. 3). Based on this, we believe that climate may be a  
239 significant factor in shaping the spatial distribution of the genetic lineage between the Northern  
240 and Southern clades. Moreover, the matrilineal haplotype network provides strong evidence for  
241 the suppression of migration between the Northern and Southern clades (Fig. 1). The haplotype  
242 network also shows that the Northern B clade and the Southern clade have the highest genetic  
243 diversity and a wide range distribution in Thailand, although the most recent divergence time  
244 between *P. megacephalus* (putative Northern B clade) and *P. leucomystax* (putative Southern  
245 clade) was estimated to be in the late Pliocene or early Pleistocene (1.4–4.0 MYBP). We assumed  
246 that the populations of the Southern clade (putative *P. leucomystax*) expanded and colonized the  
247 northern part of Indochina, leading to the diversification of the species. This hypothesis may be  
248 partially supported by the results of the unimodal pairwise difference and the small value of the  
249 raggedness index in the Southern clade (Fig. 4).

250 A previous study revealed the range expansion of insular populations of *P. leucomystax*,  
251 characterized by small genetic distances among islands of the Malay Archipelago, as they can  
252 migrate from one island to another through anthropogenic means, particularly through  
253 transportation of agricultural products (Brown et al., 2010). Therefore, it was postulated that  
254 climatic conditions might be the key barrier restricting the distribution range of the modern frog  
255 populations. One hypothesis to support the limit of both Northern A and southern populations

256 may result from the adaptation in biological features such as behaviour, reproductive timing or  
257 specific niche for a specific climatic zone having a notable difference in different zones,  
258 according to Hughes et al. (2011). A previous study revealed that the variation of breeding season  
259 length of the *P. leucomystax* complex of Thailand (putative *P. megacephalus*; 6 months a year for  
260 breeding) and Singapore (putative *P. leucomystax*; every month) led to an adaptation to shortened  
261 breeding season length by increasing clutch size (Sheridan, 2009). It is clear that climate can  
262 influence the alteration in phenotypes of frogs (Sheridan, 2009; Todd et al., 2011).

263         Within the population of the northern B clade, maternal genealogy demonstrated that the  
264 genetic samples from Nakhon Ratchasima province (NRS) seemed to represent a naturally  
265 occurring divergence because of the emergence of endemic haplotypes; however, it was a low-  
266 supported lineage, with 0.7 Bayesian posterior probability (BPP). When we considered the  
267 topography of this region, the population of NRS as clade D1 is partitioned from the other  
268 populations within clade D by the two mountain ranges, Dong Phaya Yen and Sankamphaeng.  
269 This may be a possible barrier to gene flow among the modern populations of Northern B  
270 between eastern (clade D1) and western (clade D2; NRS) Thailand. Unfortunately, only a limited  
271 number of populations from the east of Thailand were investigated in this study. Further work for  
272 validating whether Dong Phaya Yen and Sankamphaeng are a great barrier to gene flow in *P.*  
273 *megacephalus* is required. According to the demographic history, the population of Northern B  
274 was a stable population, but the population of Southern clade showed a relatively similar  
275 unimodal distribution with a small raggedness index, possibly indicating a population expansion.  
276 This result was similar to that observed in the population of *P. leucomystax* in the northern  
277 Philippines (Brown et al., 2010). This scenario implied a genetically homogenous population,  
278 especially in the population of Phuket Island, which shared a haplotype with NST, probably

279 caused by a recent population expansion due to the founder effect. Although the population of the  
280 Northern B clade expanded, it was limited to localities south of the Isthmus of Kra.

## 281 CONCLUSIONS

282 Our matrilineal genealogy of the *Polypedates leucomystax* complex in Thailand suggested four  
283 lineages, i.e., Nan (putative *P. impresus*), Northern B (putative *P. megacephalus*), Southern  
284 (putative *P. leucomystax*) and Northern A (*Polypedates* sp.) clades. We noted that the populations  
285 of the Northern B, Nan and *Polypedates* sp. clades are in sympatry, while their distributions are  
286 allopatric to the southern clade (*P. leucomystax*) due to the separation by the Isthmus of Kra.  
287 Climatic conditions may be a major contributor to limited migration of the current populations of  
288 both clades, but climatic oscillation in the Pliocene and Pleistocene is a highly possible scenario  
289 that drove speciation resulting in diversification of the *P. leucomystax* complex in Southeast Asia  
290 and China, which includes the divergence of the southern and northern clades in Thailand.

## 291 ACKNOWLEDGEMENTS

292 Many thanks to Mr. Roy Morien of the Naresuan University Language Centre for his editing  
293 assistance and advice on English usage.

# Figure 1

Phylogeographic relationships and a minimum spinning network of all haplotypes of the *Polypedates leucomystax* complex among populations in Thailand.

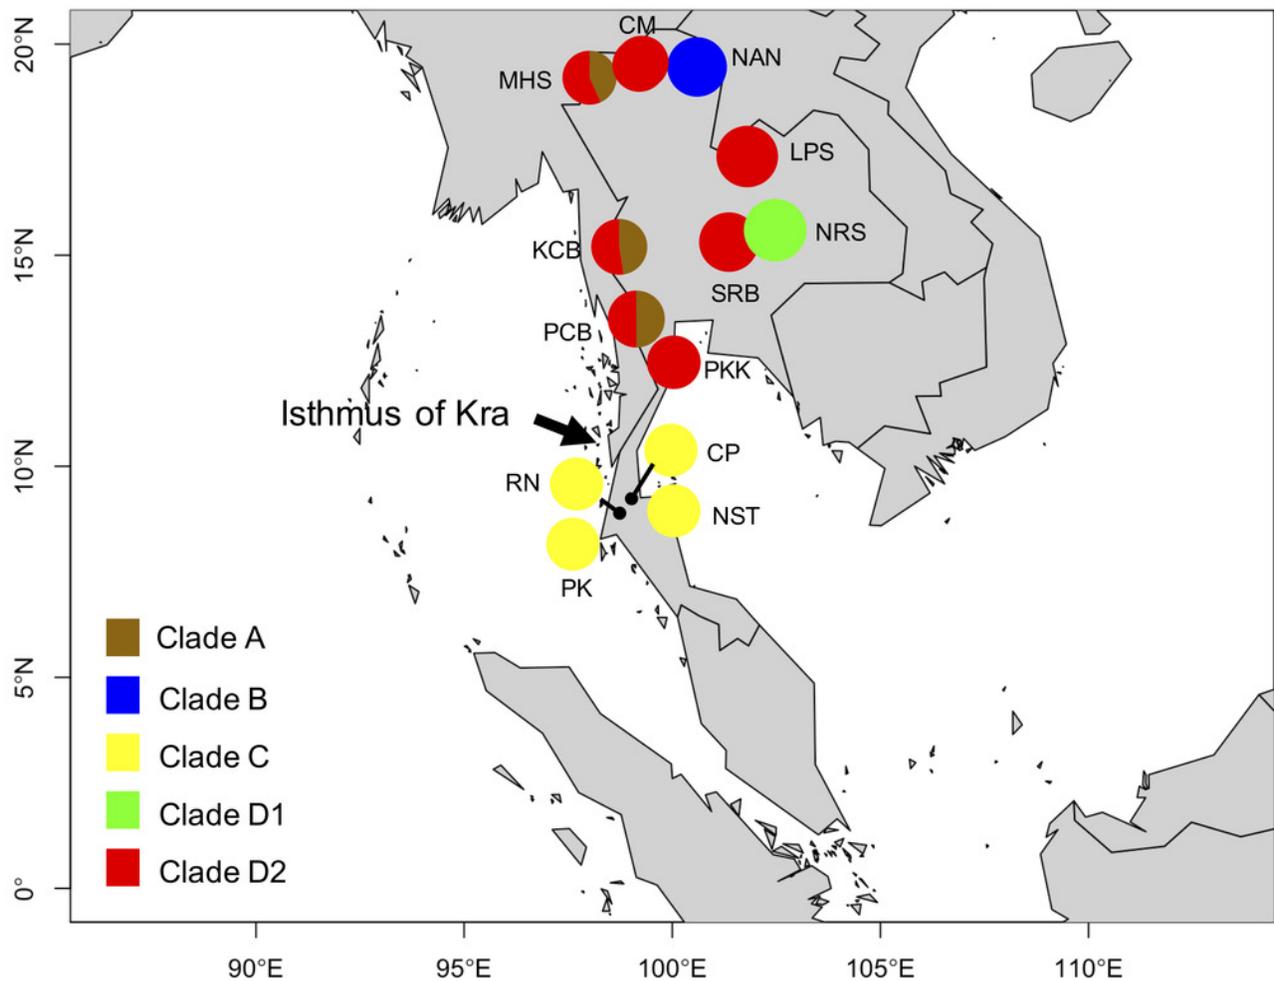

It consists of clade A as *Polypedates* sp., clade B as *P. cf. impresus*, clade C as *P. cf. leucomystax*, and clade D as *P. cf. megacephalus*, as well as outgroups (KR087858, KP996762 = *P. braueri*) inferred from Bayesian analysis of mitochondrial COI gene sequences. Bayesian posterior probability values are expressed above internodes. The asterisks above branches represent bootstrap support for Bayesian posterior probabilities and maximum likelihood (>95%). Scale bar represents 0.5 nucleotide substitutions per site. IOK represents the Isthmus of Kra.

## Figure 2

Clade distribution of the *Polypedates leucomystax* complex throughout Thailand.

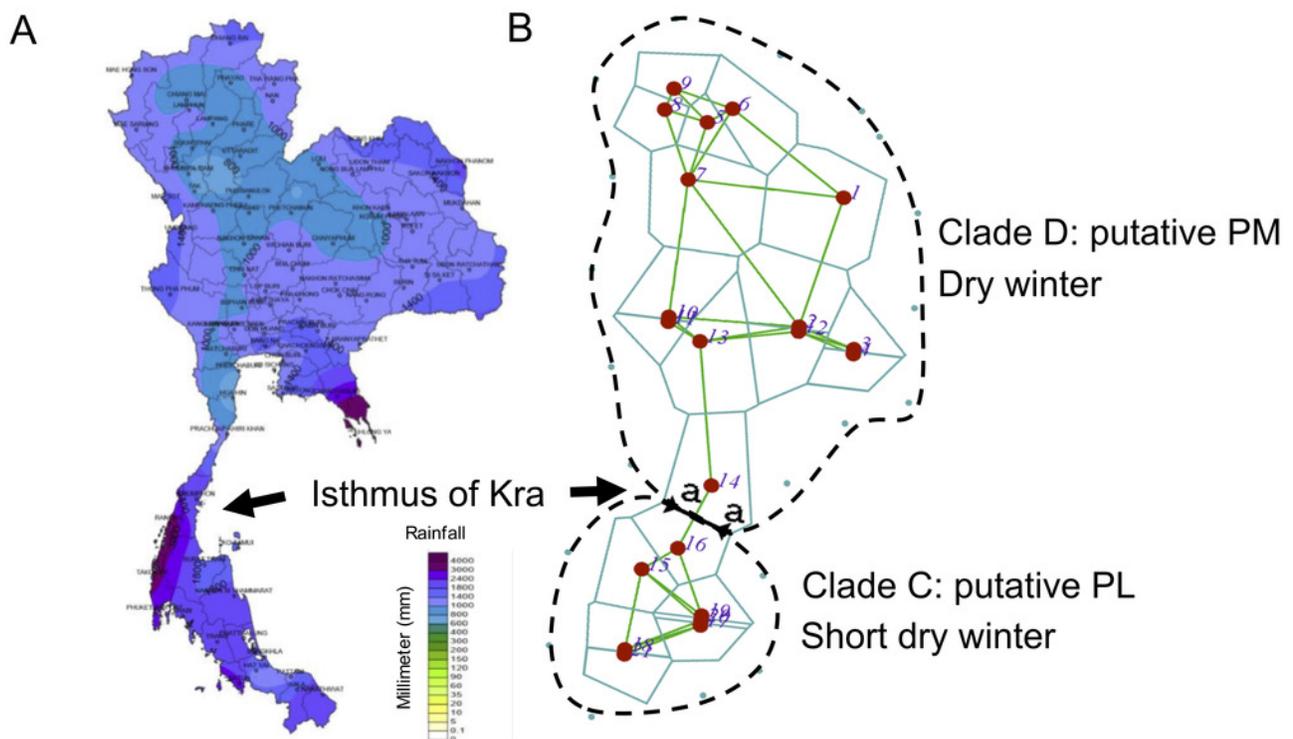

The abbreviations for each locality are given in Table 1. Different colors represent the different clades.

## Figure 3

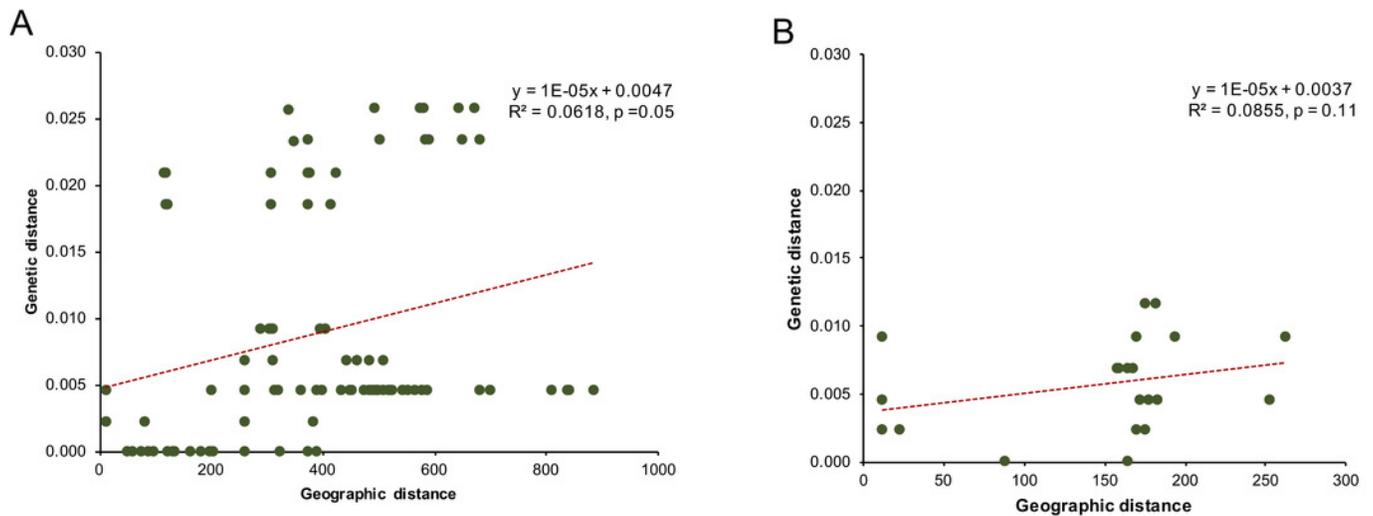

The relationship between climatic condition and genetic differentiation across the Northern B clade (putative *Polypedates megacephalus*) and the Southern clade (putative *Polypedates leucomystax*).

(A) annual rainfall (in mm) in Thailand for 2015 (Image credit: Thai Meteorological Department); and (B) a significant barrier to partition the distribution of the Northern B (putative *P. megacephalus*) and Southern (putative *P. leucomystax*) clades, by Barrier version 2.2.

## Figure 4

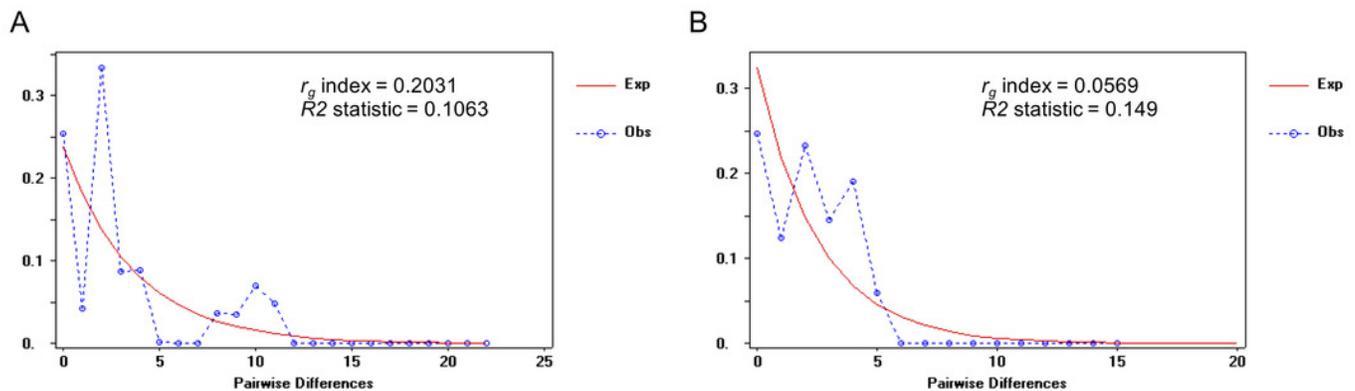

The correlation of genetic distance and linear geographic distance (km) for (A) the Northern B clade (putative *Polypedates megacephalus*) and (B) the Southern clade (putative *Polypedates leucomystax*).

## Figure 5

Mismatch distribution of the mitochondrial COI gene in (A) the Northern B clade (putative *Polypedates megacephalus*) and (B) the Southern clade (putative *Polypedates leucomystax*).

The raggedness ( $r_g$ ) index is calculated to evaluate the population expansion of each species. Ramos-Onsins and Rozas's  $R_2$  statistic represents the population growth.
