There is growing interest in applying detailed mathematical models of the heart for ion-channel related cardiac toxicity prediction. However, a debate as to whether such complex models are required exists. Here an assessment in the predictive performance between two established large-scale biophysical cardiac models and a simple linear model  $B_{net}$  was conducted. Three ion-channel data-sets were extracted from literature. Each compound was designated a cardiac risk category using two different classification schemes based on information within CredibleMeds. The predictive performance of each model within each data-set for each classification scheme was assessed via a leave-one-out cross validation. Overall the  $B_{net}$  model performed equally as well as the leading cardiac models in two of the data-sets and outperformed both cardiac models on the latest. These results highlight the importance of benchmarking complex versus simple models but also encourage the development of simple models.

# 6 Abstract

7 There is growing interest in applying detailed mathematical models of the heart for ion-channel  
 8 related cardiac toxicity prediction. However, a debate as to whether such complex models are  
 9 required exists. Here an assessment in the predictive performance between two established large-  
 10 scale biophysical cardiac models and a simple linear model  $B_{net}$  was conducted. Three ion-  
 11 channel data-sets were extracted from literature. Each compound was designated a cardiac risk  
 12 category using two different classification schemes based on information within CredibleMeds.  
 13 The predictive performance of each model within each data-set for each classification scheme  
 14 was assessed via a leave-one-out cross validation. Overall the  $B_{net}$  model performed equally as  
 15 well as the leading cardiac models in two of the data-sets and outperformed both cardiac models  
 16 on the latest. These results highlight the importance of benchmarking complex versus simple  
 17 models but also encourage the development of simple models.

# 18 Introduction

19 There is a growing belief within the pharmaceutical industry that in order to improve predictions  
 20 of future experiments more detailed mathematical models of biology are required (Peterson &  
 21 Riggs, 2015; Knight-Schrijver et al., 2016). However by including more detail not only does the  
 22 number of parameters that need to be estimated increase but so does the degree of structural  
 23 uncertainty if the biology is not well understood i.e. the degree of confidence in the actual  
 24 structure of the equations (Beven, 2005). The objective of this study is to look at this issue within  
 25 the field of drug induced ion-channel cardiac toxicity. This area has a well-defined question  
 26 relating to prediction where a debate about the complexity of the model needed is ongoing.

27 Numerous drugs were withdrawn from the market during the 1990s and early 2000s for causing a  
 28 fatal arrhythmia, termed Torsades de Pointes (TdeP) (Yap & Camm, 2003). Current  
 29 pharmaceutical industry screening strategies on identifying these compounds at an early stage in  
 30 drug development are based on the following biological insights (Antzelevitch & Sicouri, 1994;  
 31 Witchel, 2011). Prior to observing drug induced TdeP, prolongation of the QT interval is  
 32 commonly seen within a patient. This prolongation is due to delayed repolarisation of cardiac  
 33 cells within the ventricular wall, which is due to the drugs effect on the hERG ion-channel. Thus,  
 34 the current approach in drug development involves screening a compounds effect against hERG  
 35 in a high-throughput manner. However, there are other ion-channels involved in this process  
 36 which the safety pharmacology community are now also screening compounds against (Colatsky  
 37 et al., 2016). The question of interest then to the safety pharmacology community is: does  
 38 measuring more than hERG improve prediction for TdeP, in humans?

39 In order to answer this question a clear definition of whether a compound has TdeP liabilities or  
 40 not is required (Wiśniowska & Polak, 2017). The first study to examine the association between  
 41 multiple ion-channel inhibition and TdeP risk (Mirams et al., 2011) used a database created by  
 42 AstraZeneca (Redfern et al., 2003). This database was built using literature data only and has  
 43 never been updated since its initial publication. More recent studies (Kramer et al., 2013;  
 44 Lancaster & Sobie, 2016) have used the CredibleMeds database (Woosley, RL & Romero, KA;  
 45 Woosley et al., 2017) which was formerly known as AzCERT. Their classification is based on an  
 46 extensive search of both the literature and public databases and is continuously updated in-light  
 47 of new evidence. Furthermore it is recognised by the clinical community unlike the AstraZeneca  
 48 database.

49 In terms of the modelling approach used the literature is divided in terms of the complexity  
 50 required (Mistry, 2017). The complex models used are based on biophysical models which  
 51 describe the changes in ionic currents over time within a single cardiac cell (Trayanova, 2011).  
 52 They contain 100s of parameters and 10s of differential equations. The drug input into these  
 53 models involves scaling ion-channel conductance's by the amount of block at a given drug  
 54 concentration (Brennan, Fink & Rodriguez, 2009). Two biophysical models that have gained  
 55 favour in the literature are the *gold-standard*, as described by Zhou *et al.* (Zhou *et al.*, 2015),  
 56 model by O'Hara *et al.* (O'Hara et al., 2011), herein referred to as ORD, which is being put  
 57 forward for use by regulatory agencies (Colatsky et al., 2016) and another, by TenTusscher *et al.*

(ten Tusscher & Panfilov, 2006), forms a part of the *cardiac safety simulator* (Glinka & Polak, 2015), herein referred to as TT. An alternative simpler mechanistic model being put forward analyses the net difference, *via* a linear combination, in drug block of the ion-channels of interest, termed  $B_{net}$  (Mistry, 2017). In that study  $B_{net}$  gave similar performance to a joint three biophysical model/machine learning approach which used more than 300 metrics derived from the biophysical models (Lancaster & Sobie, 2016).

In this study the predictive performance of ORD, TT and  $B_{net}$  models using a consistent and reliable definition of TdP risk from CredibleMeds across three literature data-sets (Mirams et al., 2011; Kramer et al., 2013; Crumb Jr. et al., 2016) was analysed. Two of these data-sets, Mirams et al. (Mirams et al., 2011) and Kramer et al. (Kramer et al., 2013), measured drug effect against 3 ion-channels, hERG, Cav 1.2 and Nav 1.5 peak. The third and latest data-set, from Crumb et al. (Crumb Jr. et al., 2016), considers drug effect on 7 ion-channels, hERG (IKr), KCNQ1 + KCNE1 (IKs), Kv4.3 (Ito), Kir2.1 (IK1), Cav 1.2 (ICaL), Nav1.5 peak (INa) and Nav1.5 late (INaL), the largest number studied so far.

By using a consistent definition of TdP risk across different data-sets that have different dimensionality in terms of ion-channels studied the analysis conducted will provide a detailed view on the performance of each model. Thus enabling scientists to make a more informed decision about which modelling approach is likely to be the most useful for the prediction problem considered.

## Methods

### Data

Ion-channel IC50 values, defined as concentration of drug that reduces the flow of current by 50%, were collected from three publications (Mirams et al., 2011; Kramer et al., 2013; Crumb Jr. et al., 2016). Compounds within those data-sets were placed into two classification schemes based on the information in Credible Meds (Woosley, RL & Romero, KA; Woosley et al., 2017), see Table 1. The first classification scheme termed QT/TdP focusses on both QT prolongation and TdP risk, which was used in two previous studies (Kramer et al., 2013; Lancaster & Sobie, 2016). The second classification scheme focusses on known TdP risk only. All data is provided in supplemental material.

### Model input data

The percentage block against a given ion-channel inputted into all models was calculated using the mean maximal concentration observed corrected for plasma protein binding and is referred to as the effective therapeutic concentration (EFTPC), which was provided in the original articles, using a pore block model,

$$Block = \frac{1}{1 + \frac{IC_{50}}{EFTPC}} (1)$$

## 92 Models

### 93 Single cell cardiac model simulations

94 The AP predict platform (Williams & Mirams, 2015) which is a web-based cardiac modelling  
 95 simulation platform (<https://appredict.cs.ox.ac.uk>) was used to simulate the ORD and TT models  
 96 in all cases except for one simulation study. A MATLAB version of the ORD model available on  
 97 the Rudylab website (<http://rudylab.wustl.edu>) was used when simulating the block of 7 ion-  
 98 channels since that model on AP predict does not allow blocking of INaL – a current measured in  
 99 the Crumb *et al.* data-set. The default settings within the AP predict platform were used i.e. 1Hz  
 100 pacing for 5 minutes with the APD90, time taken for the action potential to repolarise by 90%,  
 101 recorded using the last cycle. The same protocol was applied in MATLAB when exploring the 7  
 102 ion-channels within the ORD model i.e. 1Hz pacing for 5 minutes with APD90 recorded using  
 103 the last cycle. In all simulations drug block was initiated at the beginning of simulations.

### 104 $B_{net}$

105  $B_{net}$  was defined as the net difference in block between repolarisation and depolarisation ion-  
 106 channels as,

$$B_{net} = \sum_{i=1}^n R_i - \sum_{j=1}^m D_j$$

107 where  $R_i$  and  $D_j$  represent the percentage block against repolarisation and depolarisation ion-  
 108 channels respectively for a specific drug. Ionic currents responsible for repolarisation are IKr IKs  
 109 and Ito, and that for depolarisation are ICaL, INa (peak), INa (late) and IK1.

### 110 Classification evaluation

111 For each compound the percentage change in APD90 compared to control (no block) from the  
 112 biophysical model simulations was recorded as was the  $B_{net}$  value. These values were then placed  
 113 within a logistic regression analysis to assess their correlative value to either QT/TdeP or TdeP  
 114 risk. This was done via a leave one out cross validation (LOOCV). This involves training a  
 115 classifier to  $n-1$  compounds and testing on the  $n^{th}$ . Thus all compounds perform part of the test-  
 116 set. The predicted probability of risk for each test compound is then used to generate a ROC  
 117 AUC (area under the receiver operating characteristic curve) which is reported. Note that  
 118 LOOCV has been the method of choice within this field when assessing the correlation between  
 119 metrics and drug risk (Mirams et al., 2011; Kramer et al., 2013; Lancaster & Sobie, 2016).

## 120 Results

## Data

The total number of compounds and their classification according to CredibleMeds across the 3 data-sets of interest can be seen in Figure 1. Although the total number of compounds differs from one data-set to another the proportions that are KR, PR and CR/NR does not appear to.

The distribution of block against each ionic current, at the EFTPC, across all data-sets can be seen in Figure 2. The plots show that the activity of the compounds is greatest against IKr across all data-sets. After IKr, ICaL appears to be the next channel for which a substantial amount of activity is seen. A somewhat surprising result is the degree of activity against INaL but not INa in the Crumb *et al.* data-set. The amount of activity against INaL in that data-set mirrors that of ICaL activity.

## Classification Evaluation

The results of the leave-one-out cross validation for each data-set using various models for the two classification schemes can be seen in Tables 2 and 3. For the Mirams *et al.* data-set it's noticeable that ORD performs no better than using just block against hERG for either classification scheme. Furthermore for the QT/TdEP classification ORD is no better than random chance. Both TT and  $B_{net}$  show a similar improvement over using just hERG block for both classification schemes.

Moving onto the Kramer *et al.* data-set the performance of all models improves dramatically over the Mirams *et al.* data-set. Here all 3 models show superior performance over just hERG block regardless of the classification scheme used. Note that again the performance of ORD is not as high as  $B_{net}$  or TT. In addition the difference between  $B_{net}$  and TT is negligible.

Within the latest data-set by Crumb *et al.* the performance of all models, when using only 3 ion-channels, drops to a level similar to that seen within the Mirams *et al.* data-set. The key difference between the results between those two data-sets is that ORD now shows similar performance to TT regardless of the classification scheme used. Furthermore neither biophysical model performs overly better than using hERG block.  $B_{net}$  however appears to give reasonable performance again and appears to show an improvement over using hERG block for both classification schemes. Finally when moving onto using all the ion-channel data from the Crumb *et al.* data-set the difference in performance between the models is quite striking.  $B_{net}$ 's performance improves with the addition of more information whereas there is little improvement in either biophysical model.

In summary the results show that the performance of the models is data-set dependent. However, within each data-set the  $B_{net}$  model performs just as well if not better than leading biophysical models.

## Discussion

There appears to be a strong belief within the field of ion-channel cardiac drug toxicity that large scale single cell (Mirams *et al.*, 2011) and even whole heart models (Okada *et al.*, 2015) are

required to answer a well-defined question: does measuring more than hERG improve prediction for TdP, in humans? The evidence base, that suggests that large-scale biophysical models perform better than simpler models for this question, simply does not exist. Previous studies have shown that the performance of the large-scale cardiac models can be mirrored by simpler models (Mistry, Davies & Di Veroli, 2015; Mistry, 2017).

This study builds on those previous studies (Mistry, Davies & Di Veroli, 2015; Mistry, 2017) of comparing the performance of complex biophysical models versus simpler models in the following way. First a consistent definition of TdP risk based on the CredibleMeds database was used across all data-sets (Woosley, RL & Romero, KA; Woosley et al., 2017). Second in addition to data-sets that considered drug activity against only 3 ion-channels (Mirams et al., 2011; Kramer et al., 2013) a third data-set (Crumb Jr. et al., 2016) which measured drug affinity against 7 ion-channels was also assessed.

The three models evaluated in this study were: 1) the *gold-standard* (Zhou et al., 2015) single cell model by O'Hara et al. (O'Hara et al., 2011); 2) the single cell model by TenTusscher et al. (ten Tusscher & Panfilov, 2006) which is used within the *cardiac safety simulator* (Glinka & Polak, 2015); 3) a linear mechanistic model evaluating the net difference in block between ion-channels involved in repolarising and depolarising the action potential,  $B_{net}$  (Mistry, 2017). Each model was assessed via a leave-one-out cross validation using two different classification schemes based on the CredibleMeds database. The first scheme focussed on the joint QT prolongation and TdP risk whereas the second scheme focussed on TdP risk only. In addition to using outputs from the aforementioned models within the classification exercise the amount of block against hERG channel was used as a naïve benchmark.

Overall the analysis conducted showed that the performance of  $B_{net}$  was superior to the more complex cardiac models regardless of the classification scheme used.  $B_{net}$  was also the only model that consistently showed the benefit of measuring more than hERG. Finally  $B_{net}$  was the only model whose performance improved when moving from using information against 3 ion-channels to 7. These results may appear surprising but are not uncommon in prediction problems in other fields (Makridakis & Hibon, 2000; Green & Armstrong, 2015). The key reason why complex models are not necessarily more predictive than simpler models is due to model error i.e. error in the structure of the model itself (Beven, 2005). The concept of model error has only recently been assessed (Beattie et al., 2017) within the cardiac modelling field and so more needs to be done. Thus the effect of model error on predictivity is largely unknown, although in other fields it tends to dominate prediction uncertainty (Orrell et al., 2001; Refsgaard et al., 2006).

This study is not without its caveats. The first is that the data-sets used may be too small to understand how large a discrepancy there truly is between the different models. However it is hoped that by continuing to assess new data-sets as they become available that the community will eventually have a comprehensive compound list. Second, the latest data-set by Crumb et al. (Crumb Jr. et al., 2016) although measured the affinity of drugs against 7 ion-channels the compounds only really showed activity against 3. Thus, whether the results seen here will hold for a set of compounds with activity against a large number of ion-channels still remains

unknown. Similar to the previous caveat this can only be assessed as more data is generated. The final caveat relates to the  $B_{net}$  model itself. The model currently doesn't consider the kinetics of blocking which has been highlighted as an important factor (Di Veroli et al., 2014). However these studies have been on a small numbers of compounds and so a true assessment of the importance of kinetics cannot be determined from those studies alone. If sufficient evidence regarding the importance of drug kinetics does eventually become available adjustments to the  $B_{net}$  model could be made.

## Conclusion

In summary the study conducted here highlights the importance of benchmarking complex models against simpler ones. Furthermore it highlights that simple mechanistic models can not only give similar performance to large-scale mechanistic models but can out-perform them. Finally it is hoped this study highlights that there is more than one solution to a problem and that although the question and quality of data dictates the modelling approach it should not dictate the size of the model.

301 **Table 2:** ROC AUC values from the leave one out cross validation for assessing the joint  
302 QT/TdeP risk across all data-sets for all models considered.

303 **Table 3:** ROC AUC values from the leave one out cross validation ROC AUC for assessing TdeP  
304 risk only across all data-sets for all models considered.

**Figure 1**(on next page)

Stacked bar-chart shows the proportion of compounds in each data-set that are KR, PR or CR/NR based on information within the CredibleMeds database.

# CredMeds

- CR/NR
- KR
- PR

No. Compounds

Mirams et al. (2011)

Study

## Figure 2 (on next page)

Boxplots show the distribution of block for each ionic current across all 3 data-sets.

Ion-channel

**Table 1**(on next page)

Description of the two classification schemes constructed from the CredibleMeds database.

<b>CredibleMeds</b>	<b>Description</b>	<b>QT/TdeP</b>	<b>TdeP</b>
Known Risk (KR)	Known TdeP Risk	+ive	+ive
Possible Risk (PR)	Known QT Risk	+ive	-ive
Conditional Risk (CR)	Conditional TdeP Risk (e.g. drug-drug interaction)	-ive	-ive
No Risk (NR)	Not listed on CredibleMeds	-ive	-ive

1

## Table 2 (on next page)

ROC AUC values from the leave one out cross validation for assessing the joint QT/TdeP risk across all data-sets for all models considered.

Data-Set	Leave One Out Cross Validation ROC AUC			
	$B_{net}$	3 ion-channels ORD: $\Delta APD90$	TT: $\Delta APD90$	hERG % Block IKr
Mirams (2011)	0.71	0.53	0.68	0.51
Kramer (2013)	0.96	0.86	0.94	0.67
Crumb (2016)	0.71	0.65	0.65	0.61
Crumb (2016)	0.82	7 ion-channels 0.67	0.60*	

\*based on 6 ion-channels – INaL not modelled by TenTusscher et al. (TT);  $\Delta APD90$ : percentage change in APD90

# **Table 3**(on next page)

ROC AUC values from the leave one out cross validation ROC AUC for assessing TdeP risk only across all data-sets for all models considered.

Data-Set	Leave One Out Cross Validation ROC AUC			
	$B_{net}$	3 ion-channels ORD: $\Delta APD90$	TT: $\Delta APD90$	hERG % Block IKr
Mirams (2011)	0.78	0.66	0.75	0.62
Kramer (2013)	0.86	0.80	0.84	0.68
Crumb (2016)	0.68	0.61	0.62	0.57
Crumb (2016)	0.77	7 ion-channels 0.63	0.59*	

\*based on 6 ion-channels – INaL not modelled by TenTusscher et al. (TT);  $\Delta APD90$ : percentage change in APD90
