

Modelling the impacts of an invasive species across landscapes: a hierarchical approach

We develop a hierarchical modelling approach to estimate the extent of ecological impacts of the invasive Asian paper wasp across different landscapes in New Zealand. We used: i) a baseline distribution layer (modelled via MaxEnt); ii) Asian paper wasp nest density (from >460 field plots, related to their preferences for specific land cover categories); and iii) and their foraging intensity (rates of foraging success, and the time available to forage on a seasonal basis). Using geographic information systems this information is combined and modelled across different landscapes in New Zealand. The highest densities of Asian paper wasps were in herbaceous saline vegetation, followed closely by built-up areas, and then scrub and shrubland. Nests densities of 34 per ha, and occupancy rates of 0.27 were recorded for herbaceous saline vegetation habitats. However, the extent of impacts of the Asian paper wasp remains relatively restricted because of narrow climate tolerances and spatial restriction of preferred habitats. A hierarchical approach based on geographic information systems and species distribution models, in combination with factors such as distribution, density, and predation, create a powerful tool that allows the extent of impacts of invasive species to be assessed across large spatial scales. These models will be useful for conservation managers as they provide easy visual interpretation of results, and can help prioritise where direct conservation action or control of the invader are required.

5 Introduction

Species distribution models (SDMs), which can be used to predict a species' potential occurrence across a landscape, have become a key part of ecological research and conservation planning (Guisan & Thuiller, 2005; Thuiller et al., 2008; Elith & Leathwick, 2009; Franklin, 2013). Such models can explore more than just distribution, and are increasingly being used for a range of biodiversity applications such as modelling the habitats of communities, ecological refuges, potential impacts under climate change, and biotic interactions (Araújo & Luoto, 2007; Bradley, 2013; Porto, Carnaval & da Rocha, 2013; Ross & Howell, 2013).

However, one aspect of SDMs that is less utilised is analyses of the impacts of invasive species across large spatial scales. Yet SDMs are ideal for this type of study because they capture localised impacts (at sites) and can extend these impacts across larger spatial scales using geographic information systems (GIS). Predicting impacts across landscapes is an extremely useful tool for invasive species, and may highlight the need for direct conservation action or control of the invader.

Social insects form a large part of the invasive invertebrate literature because they usually have a wide host range, feed at a range of trophic levels, can reach very high densities, often have noticeable effects on prey, and are commonly associated with human trade (Suarez, Holway & Ward 2005; Snyder & Evans 2006; Wilson, Mullen & Holway 2009; Ward et al., 2010; Roura-Pascual et al. 2011; Roy HE et al., 2011). Four species of paper wasps (*Polistes*) are invasive around the globe (Beggs et al., 2011): *P. versicolor* (Olivier) in the Galápagos; *P. dominula* in North America; and *P. humilis* (Fabricius) and *P. chinensis antennalis* Perez in New Zealand.

In New Zealand, *P. chinensis antennalis*, commonly known as the Asian paper wasp (APW), was first recorded in 1979, and has subsequently spread rapidly across much of the North Island and several locations in the South Island (Clapperton, Tilley & Pierce, 1996). Although the distribution and nesting biology of the APW is well known (Clapperton, Tilley & Pierce, 1996; Yamane, 1996; Clapperton & Dymock, 1997; Clapperton & Lo, 2000), little has been published on its ecological impacts. Densities of paper wasps can reach up to 210 nests/ha (Clapperton 1999), and although densities of 20-40 nests/ha are more common, this still translates into ~1000–2000 wasps/ha, who are responsible for many 10,000s of prey captured per season (Clapperton 1999).

Paper wasps do not naturally occur in New Zealand (along with many other groups of social insects (Ward et al, 2006)), and consequently, there are concerns that APW could have a

significant impact on native biodiversity, particularly on the larvae of butterfly and moths, which are heavily preyed upon (Clapperton 1999; Ward & Ramón-Laca 2014).

In this paper we used a hierarchical approach, built on a potential distribution layer (modelled via MaxEnt), and hierarchically added, land-cover-specific densities, and foraging intensity, to develop a comprehensive model of the spatial extent of the impacts of Asian paper wasps across New Zealand.

Materials and Methods

Distribution

Occurrence data

In total, 253 geo-referenced occurrence records of the presence of Asian Paper wasps (APW) were obtained from (a) published literature (Clapperton 1999) (n = 71); (b) Museum collections (n = 112); (c) field surveys in 2012 (n = 22); and (d) through a publicity campaign asking members of the public for sightings of the APW (n = 48; only records that were supported by photographic evidence were used, e.g. a worker wasp, or nest, both of which are very distinct). Specimens from museum collections are held in the Auckland War Memorial Museum (Auckland), the New Zealand Arthropod Collection (Auckland), Te Papa (Wellington), Entomology Research Museum (Lincoln University), and Otago Museum (Dunedin).

Environmental variables

Environmental layers used were elevation (m), growing degree days (at a 10°C base), annual rainfall (mm), solar radiation (MJm⁻²day⁻¹), maximum annual temperature (°C), and minimum annual temperature (°C). Environmental layers came from the National Institute of Water and Atmospheric Research, except for elevation which is available from Landcare Research LRIS portal (<http://lris.scinfo.org.nz/>). Each environmental layer was created at 500 m (25 ha) spatial resolution. The nesting biology of paper wasps is known to be strongly influenced by such abiotic variables (Yamane, 1996).

Model method

Distribution models were generated using MaxEnt (Version 3.3.3) to discriminate the environments associated with the presence of APW from the rest of the landscape (Phillips,

Anderson & Schapire, 2006; Elith et al., 2011). MaxEnt models were trained with a random sample of 75% of the species occurrence data, and the remaining 25% was used to test model performance (Guisan & Zimmermann 2000). We used 50 model runs on random subsamples of the occurrence data to assess uncertainty of the SDM predictions. We evaluated models using the Area Under the Curve (AUC) metric. The MaxEnt output is a logistic probability with values between 0 (low probability) and 1 (high probability).

As the occurrence dataset was not constructed using a systematic sampling approach, a geographic sampling bias may occur (Phillips et al., 2009; Syfert, Smith & Coomes, 2013). Therefore, we created a sampling bias grid in MaxEnt using a quartic kernel density layer (Figure 1) to correct for this bias as recommended (Phillips et al., 2009; Syfert, Smith & Coomes, 2013). To provide a surface that highlights both suitable and unsuitable habitats, we require a threshold value that outlines a minimum value that constitutes a suitable habitat. After reviewing the continuous raster output and the nominal threshold values from the MaxEnt models, we selected the average 10% minimum threshold for all 50 MaxEnt runs to define the minimum probability of a suitable habitat. This value was selected as it provides flexibility to account for the variation in quality of the input data.

Density

We used previous information on habitat preferences of the APW in combination with land cover satellite imagery to undertake field surveys to generate density estimates and occupancy rates of APW. In a hierarchical approach, we then combined these land cover-specific densities with the MaxEnt distribution model to generate density estimates of APW across New Zealand.

Land cover

Asian paper wasps occur across a range of native ‘open-canopy-habitats’ such as grassland, marshland and shrubland, where nests are typically found within short (<2 m high) plants (Clapperton, 1999; Clapperton & Lo, 2000). They are also common in urban areas, with nests found in residential gardens and on wooden fences. Although the habitat preferences of APW are well established, there is little information on their densities within these habitats.

In order to select habitats for field surveys to generate density estimates, we used the LCDB-3 database (LCDB NZ Land Cover Database, 2012) derived from the 2007–2008 LUCAS satellite imagery, which classifies land cover into 33 classes. Three land cover classes are highly

suitable for APW: i) built-up area (BUA); ii) herbaceous saline vegetation (HSV); and iii) scrub and shrubland (SAS).

Some land cover classes were not surveyed because they are not suitable for APW (e.g. water bodies; bare or lightly vegetated surfaces; artificial surface (such as roads)); are too disturbed to allow nests to develop (e.g. cropland; pasture); or are not preferred (e.g. forest types, alpine vegetation) (Clapperton, 1999). We considered some land cover classes (orchard vineyard & other perennial crops (OVPC); herbaceous freshwater vegetation (HFV); tall tussock grassland (TTG)) to be possibly suitable but of very low preference (due to high disturbance and unsuitable vegetation to construct a nest), and did not survey these classes but instead estimated a nominal value of three nests per ha and occupancy rate of 0.03.

Field surveys

During January to March 2012 we surveyed the three most suitable land cover classes: built-up area (BUA); herbaceous saline vegetation (HSV); scrub and shrubland (SAS). We walked slowly through plots (10 x 10 m) checking vegetation for nests of APW (Table 1). We believe we achieved a high detection rate as nests are larger and more obvious from January to March. However, as it is possible we failed to detect all nests, our densities are conservative. All plots were in the Auckland region.

Foraging Intensity

Paper wasps are generalist predators of invertebrates, and we inferred their effects on biodiversity through foraging intensity as measured by: i) their foraging success of prey capture, and ii) the time available to forage.

Foraging success rate

The foraging of APW has been studied at three sites in northern New Zealand (Clapperton, 1999). We used some of this published data to derive a foraging success rate based on: i) the return of foraging wasps (“traffic rate”; average 0.33 per minute; range 0.23–0.46); ii) the proportion of wasps that carried material back to the nest (average 0.30; range 0.25–0.38), and iii) the proportion of material that represented a prey item (as opposed to liquid food or nesting material) (average 0.75; range 0.70–0.80, excluding the value 0.12 as an outlier). Multiplying these data gives a foraging success rate of 4.5 prey captured/nest/hour (range 2.4–8.4).

Foraging time available

Available foraging time to AWP was estimated by examining “sunshine hours” across New Zealand. Paper wasps do not forage at night or in periods of rain (Clapperton, 1999). Sunshine hours accounts for periods of cloud cover and rain, which reduce foraging, but are also topographically very accurate, and take into consideration the landscape effects of slope and gullies, etc. We used hourly sunshine data (MJm^{-2} , obtained from the National Institute of Water and Atmospheric Research, 500 m spatial resolution), and summed these across days, months, and the period February to April (when paper wasps are active).

Foraging success and the total time available to forage (for the period February to April, when paper wasps are active) was multiplied together, and then hierarchically combined with land cover specific densities and the MaxEnt distribution model to develop a comprehensive model of the spatial extent of the impacts of Asian paper wasps across New Zealand.

Results

Distribution

The MaxEnt model predicted that coastal and lowland regions of the North Island are highly suitable for the APW, with potential to extend inland and inhabit considerable areas of the middle and lower North Island (Figures 2, 3). Suitable sites in the South Island are largely restricted to northern regions and the eastern lowland. However, coastal areas of the West Coast and Central Otago (where the APW have been present in Alexandra for over a decade) are also predicted to be suitable (Figures 2, 3). The average test AUC of the MaxEnt models was 0.846 (± 0.013).

These distributions correspond very well to an intolerance of cooler mountainous and wet regions. Jackknife tests of variable importance showed elevation contributed the highest gain, and was the variable containing the most information by itself (possibly because elevation is strongly correlated with temperature and rainfall). Solar radiation was the variable that decreased the gain the most when it is omitted, and contains the most information that is not present in other variables. Contribution to the MaxEnt model gain ranked solar radiation (43.5%) as the most important variable, followed by growing degree days (26.1%) and elevation (21.5%).

Density

A total of 466 plots were surveyed, where average densities of AWP nests ranged from 0 – 34 nests per ha (Table 1). The highest densities were in herbaceous saline vegetation (HSV), followed closely by built-up areas (BUA) and then scrub and shrubland (SAS) (Kruskal-Wallis, $H = 21.53$, d.f. = 2, $P < 0.001$, Table 1). No nests were found in forest plots. A high proportion of plots had no nests (Figure 4), thus the occupancy rate of APW in plots was generally low, with only 15% of plots occupied by at least one nest. However, occupancy was higher in HSV (0.27) and BUA (0.23) compared with SAS (0.09). Three nests was the maximum found in a plot ($n = 2$ plots).

Extrapolation of suitable land cover across New Zealand shows over 874,000 ha is estimated to be suitable for APW (Table 1). However, this is greatly reduced (to 92,000 ha) when rates of occupancy are included. A combination of density and occupancy data estimates the total number of APW nests in New Zealand in the region of 1.5 million per year (Table 1).

Foraging Intensity

Based on the estimated total number of nests across the entire country (1,568,118, Table 1), and the estimates of foraging success and foraging time available (Table 2), the APW is responsible for consuming an estimated 3-4 billion prey items during a single season. Total sunshine hours from different locations throughout New Zealand for the February-April period were very similar (Table 2). Consequently, there was little difference in terms of the number of prey items consumed from different locations around New Zealand (Figure 5).

Discussion

Site-based studies provide important details about the impacts of an invasive species; however, these are often very limited in spatial scale. Because of this limitation it remains unknown whether the stated impacts also occur at other sites (or habitats, etc.). This is particularly true in areas that have different abiotic conditions that could directly affect the biology of an invasive species.

Creating a hierarchical approach based on key features of an invasive species (distribution, density, foraging intensity) and that incorporates species distribution modelling (SDM) and geographic information systems (GIS) allows the extent of impacts to be examined across large spatial scales. The ability to “scale-up” impacts across large spatial scales could be extremely useful for pest management, particularly to provide a greater assessment of the

possible impacts of an invasive species in the early stages of its invasion, before it reaches equilibrium.

Despite forming a large part of the exotic fauna worldwide, the impacts of invasive invertebrates have received disproportionality less attention compared with the impacts of plants and vertebrates, especially for impacts associated with natural ecosystems (Kenis et al., 2009; Roy et al., 2011). Although the threat posed by invasive invertebrates towards natural ecosystems is well recognised, evidence is scarce and limited to a few well-known examples (Kenis et al., 2009; Brockerhoff et al. 2010). However, New Zealand is well known for understanding the impacts of invasive invertebrates, particularly ants and social wasps in natural ecosystems (Ward 2007; Beggs et al. 2011). The impacts of paper wasps are also of concern, especially because the native invertebrate fauna did not evolve alongside a diverse and abundant social insect fauna, and thus could be particularly susceptible to such predators. The potential impacts of such highly predacious and generalist arthropods have recently been highlighted (Snyder & Evans, 2006).

Although consuming an estimated 3-4 billion prey per year, the overwhelming impression of APWs across New Zealand is that the extent of their impacts is very restricted (e.g. Figure 5). A large proportion of the country is climatically unsuitable for their establishment, and because of their strong habitat preferences they are then further restricted. However, localised, or habitat-specific impacts, may be considerable. Recent research shows the APW prey on a large diversity of endemic caterpillars in the HSV habitat (Ward & Ramón-Laca, 2014). Further assessment of the impacts of APWs should be directed towards HSV habitat because it had the highest nest density and occupancy rates.

Several aspects could be further examined to improve modelling. In particular, there is some uncertainty with the potential distribution in the Central Otago region (e.g. Queenstown), where their presence has been recorded for over a decade (Harris, 2002). More locality records from Central Otago would help reduce this uncertainty. Determining density and occupancy rates from other regions around New Zealand would also be valuable. The current values are based on field plots around Auckland (upper North Island). It is possible that density and occupancy rates may be less in other regions because APWs have (and are) spreading southward and these regions are less likely to be at equilibrium for density and occupancy. Additionally, improved estimates of how abiotic factors interact with nest and foraging activity are also important to understand the rates of predation by the APW.

Conclusion

A hierarchical approach based on GIS and SDMs, in combination with factors such as distribution, density, and specific impacts on biodiversity (in this case predation) create a powerful tool that allows the extent of impacts of invasive species across large spatial scales to be assessed. These models will be useful for conservation managers as they provide easy visual interpretation of results, and can help prioritise where direct conservation action or control of the invader are needed, but can also highlight gaps in models where better information is needed.

Acknowledgements

Thanks to those who provided additional distribution data of Asian paper wasps, especially John Early, Phil Sirvid, and Richard Toft. Thanks to Catalina Amaya-Perilla and Tom Saunders for assistance with field surveys. Permission for field sampling was obtained from the Auckland Council (#SS42).
