

# Information Transfer Across Landscapes and the Co-evolution of Multiply-Informed Dispersal from Neighbors and Immigrants

Dispersal plays a key role in natural systems by shaping spatial population and evolutionary dynamics. Dispersal has been largely treated as a population process with little attention to individual decisions and the influence of information use on the fitness benefits of dispersal despite clear empirical evidence that dispersal behavior varies among individuals. While information on local density is common, more controversial is the notion that indirect information use can easily evolve. We used an individual-based model to ask under what conditions indirect information use in dispersal will evolve. We modeled indirect information provided by immigrant arrival into a population which should be linked to overall metapopulation density. We also modeled direct information use of density which directly impacts fitness. We show that immigrant-dependent dispersal evolves and does so even when density dependent information is available. Use of two sources of information also provides benefits at the metapopulation level by reducing extinction risk and prolonging the persistence of populations. Our results suggest that use of indirect information in dispersal can evolve under conservative conditions and thus could be widespread.

13 **INTRODUCTION**

14

15           Dispersal is a key component of many ecological and evolutionary processes ranging  
16 from population dynamics to local adaptation and has been the focus of extensive empirical and  
17 theoretical investigation (Clobert et al. 2001; Ronce 2007; Nathan et al. 2008; Clobert et al.  
18 2012). The impact of dispersal on both population dynamics, movement across the landscape,  
19 and local adaptation makes it a critical element of understanding how populations are affected by  
20 landscape fragmentation and global warming (Chaine & Clobert 2012). Dispersal has largely  
21 been treated as a population level character even though dispersal decisions are fundamentally an  
22 individual behavior that should benefit from knowledge of the landscape. Recent empirical  
23 evidence suggests that information use in making dispersal decisions and navigating the  
24 landscape plays an important role in patterns of dispersal (Bowler & Benton 2005; Clobert et al.  
25 2009; Schmidt, Dall & Van Gils 2010). Information use would cause a shift in how we view  
26 dispersal. Exchanges among populations would no longer represent a random subset of  
27 genotypes and might affect local adaptation patterns. Dispersers might not spread randomly  
28 across the landscape and some populations might receive more or fewer immigrants. In applied  
29 work, if we want to encourage dispersal, we would need to make sure that the key information  
30 sources are available or even manipulate information to get the desired level of dispersal. Yet our  
31 fundamental understanding of informed dispersal remains limited (Clobert et al. 2009).

32           The use of information in dispersal decisions has received attention through a limited  
33 range of possibilities despite potentially important effects on fitness (Ims & Hjermmann 2001;  
34 Ronce et al. 2001; Bowler & Benton 2005; Clobert et al. 2009; Schmidt et al. 2010). Classical  
35 ecological (metapopulation) and evolutionary (gene-flow) theory assumes constant dispersal

36 rates with more or less random movement and no information use (Hanski & Gaggiotti 2004). At  
37 the other extreme, ideal free settlement models assume perfect knowledge of the entire landscape  
38 which influences dispersal (Holt & Barfield 2001). Both approaches are analytically tractable,  
39 but biologically unrealistic since organisms often use some information but rarely have perfect  
40 information. Significant progress in understanding dispersal itself will require specific attention  
41 to biologically plausible mechanisms for gathering information (Schmidt et al. 2010).

42         Recent models have investigated how local population density affects dispersal (Travis,  
43 Murrell & Dytham 1999; Cadet et al. 2003; Ronce 2007; Enfjäll & Leimar 2009; Hovestadt,  
44 Kubisch & Poethke 2010; Bocedi, Heinonen & Travis 2012), but it is becoming increasingly  
45 clear that organisms use a variety of information sources (Ronce et al. 2001; Danchin et al. 2004;  
46 Bonnie & Earley 2007; Clobert et al. 2009; Schmidt et al. 2010) that might inform them about  
47 the presence or content of other populations in the landscape. For example, tourists in Paris are  
48 easily identified by the fact that they are using maps (unlike Parisians) and this suggests that  
49 there is indeed a habitable world outside of Paris. These more 'indirect' sources of information  
50 derived from the observation of conspecifics are more controversial because they less accurately  
51 predict fitness in any given patch (Schmidt et al. 2010). However, indirect information carries a  
52 distinct advantage of providing some information about other patches without requiring costly  
53 exploration of other sites. A few recent empirical examples in birds, lizards, and other organisms  
54 now suggest that indirect social information is accessible and used by individuals in making  
55 dispersal decisions (Doligez, Danchin & Clobert 2002; Cote & Clobert 2007a; Chaine et al.  
56 2010; De Meester & Bonte 2010). Yet it remains unclear how prevalent this behavior might be  
57 across species. Widespread use of indirect information would dramatically alter our

58 understanding of dispersal and would have consequences for both fundamental work in ecology  
59 and evolution as well as applied conservation.

60       Using a theoretical model, we show that simple rules for the use of indirect social  
61 information in dispersal decisions can evolve under a broad range of conditions and therefore  
62 might be quite common in nature. We investigated the evolution of information use prior to  
63 dispersal using a simple metapopulation model in which we allowed information use in dispersal  
64 to evolve. We were primarily interested in whether the use of indirect information provided by  
65 immigrants could evolve, and if so, could it evolve in competition with direct information about  
66 local density.

67

## 68 **THE MODEL**

69

70       We constructed an individual-based model of informed dispersal behavior, based on  
71 information about the local density and/or the number of immigrants, while simplifying the  
72 landscape and genetic features of the system. In each patch, discrete time structured population  
73 dynamics were modeled using a two age class life cycle with age-specific demographic  
74 parameters (Fig. 1). Our initial model used a ‘fast’ life history roughly equivalent to a small  
75 lizard or passerine life cycle (survival:  $s_0=0.2$ ,  $s_1=0.35$ ,  $s_2=0.5$ ; fecundity:  $f_1=7$ ,  $f_2=7$ ). Juveniles  
76 were given the opportunity to disperse to other patches prior to the subsequent reproductive  
77 episode if they survived their first year. All patches were equally connected and population size  
78 was limited at reproduction by the maximum patch carrying capacity which was the same for all  
79 patches ( $K=100$ ). This configuration leads to very stable populations with low levels of

80 demographic stochasticity and very small benefits of dispersal (populations are all similarly near  
81  $K$ ) essentially creating a conservative scenario for the evolution of informed dispersal.

82 The simulation was in discrete time. Individuals were described by their age, the values  
83 of their adaptive traits (see below), their patch of residence, their dispersal status, the strategy  
84 they played if they dispersed, and the probability of dispersal. At each time step, the following  
85 operations are performed in sequential order for all individuals in the metapopulation: Survival;  
86 Reproduction and mutation; Dispersal.

87 We modeled two forms of information use that could influence dispersal: 1) measures of  
88 the local density which are known to provide a benefit to dispersal behavior (Cadet et al. 2003)  
89 and 2) measures of the number of immigrants entering a patch (Cote & Clobert 2007a). Local  
90 density directly influences reproductive success whereas the number of arriving immigrants  
91 indicates that other populations are attainable and may provide some information about overall  
92 metapopulation density. The influence of local density and immigrant-borne information on  
93 dispersal behavior were modeled as:

94

$$95 \quad \text{Density-dependent:} \quad D \frac{n_i}{K_i} - 2 \quad (1)$$

96

$$97 \quad \text{Immigrant-dependent :} \quad \mathfrak{I}_i - 2 \quad (2)$$

98

99 where  $n_i$  is the number of individuals in patch  $i$ ,  $K_i = K$  is the patch carrying capacity, and  $M_i$  is  
100 the number of immigrants entering the patch. The coefficients ( $D$  and  $I$ ) influenced the intensity  
101 of these behaviors and each was free to evolve independently of the others. Immigrant-dependent  
102 dispersal only occurred if immigrants were present (i.e. if  $M_i > 0$ ). Fixed intercepts were included

103 to set a lower limit to dispersal via each form of information use at 12%. This intercept allowed  
 104 dispersal to evolve more rapidly without having an impact on the evolved dispersal rate which  
 105 was always significantly higher (see SOM, Fig. S8). We assumed haploid genetics and clonal  
 106 reproduction with mutation in ‘genes’ for the coefficients ( $D$  and  $I$ ) that affect each  
 107 informed-dispersal strategy. These behaviors were then used to determine the probability of  
 108 dispersal associated with *density* ( $d_D$ ) and *immigrant* ( $d_I$ ) information sources using the following  
 109 function:

$$f(x) = \frac{1}{1 + \exp(-x)} \quad (3)$$

112 where  $x$  is the influence of each form of information described by equations 1 and 2. This  
 113 function allowed us to convert the biologically meaningful relationships described in equations 1  
 114 and 2 to probabilities of dispersal  $d_D$  and  $d_I$  respectively.

116 Because immigrant-dependent dispersal can only occur if immigrants exist (i.e. some  
 117 dispersal already occurs), we also included a fixed parameter for baseline *uninformed* dispersal  
 118 ( $d_U = 0.1$ ) that always occurred prior to the use of either density or immigrant information  
 119 sources. Dispersers were randomly assigned to a new patch. Dispersers were subsequently  
 120 counted as immigrants that could influence the behavior of other juveniles during a given  
 121 dispersal episode in models including immigrant-dependent dispersal. Individual juveniles were  
 122 selected at random across the metapopulation to take their dispersal decisions. Indeed, those  
 123 chosen early were much less likely to have seen immigrants than those chosen to make their  
 124 dispersal decision later.

125 We constructed alternative models of information use to examine the independent effects  
126 of density (D-only) and immigrants (I-only) on dispersal as well as their joint co-evolutionary  
127 dynamics when individuals could use both forms of information simultaneously (D&I). In  
128 models including both density- and immigrant-dependent information (D&I), *all* individuals  
129 were capable of using both sources of information and the sum of the two sources of information  
130 determined the dispersal probability. This assumption matches empirical findings that individuals  
131 use multiple sources of information in decision making (Le Galliard, Ferriere & Clobert 2003;  
132 Cote & Clobert 2007b; Cote, Boudsocq & Clobert 2008; Clobert et al. 2009). In the case of  
133 simultaneous models, if  $d_D + d_I > 1$ , then the individual dispersed, otherwise it dispersed with  
134 probability  $(d_D + d_I)$ . The information source used to calculate ‘realized’ informed dispersal rates  
135 in this case was determined by a random draw using the relative dispersal probability of each  
136 information source ( $d_D$  or  $d_I$ ).

137 We determined the probability that informed dispersal evolved and the dispersal rate  
138 associated with information use using Monte Carlo simulations of 100 trajectories over  $1.5 \times 10^6$   
139 time steps for each set of parameters and each model case. Because all individuals were capable  
140 of information use from one or two sources, then all values of the evolved coefficient potentially  
141 existed in the population unless the entire metapopulation went extinct. Therefore, we  
142 determined that ‘evolution’ of an informed dispersal strategy had occurred if the evolved  
143 coefficient was greater than 0 more often than by chance across simulations since drift should  
144 lead to negative coefficients as often as positive ones. This approach gives similar results to  
145 quantify evolution if it increases above an estimate of random drift as presented in the  
146 supplemental materials (see SOM).

147 Our initial model exploration focused on the use of density and immigrant sources of  
148 information and the coevolution of both forms when together. Subsequent models (see SOM)  
149 explored the effects of variation in the costs of dispersal, life history, carrying capacity, patch  
150 number, environmental stochasticity, variation in baseline dispersal ( $d_U$ ), the order in which  
151 different sources of information are used, and the immigrant information use strategy function.

152

## 153 **RESULTS**

154

### 155 **Evolution of Information Use: single source of information**

156 We found that informed dispersal could evolve and drive dispersal behavior and  
157 metapopulation dynamics under a broad range of contexts. Consistent with other models (Travis  
158 et al. 1999; Ronce 2007), we found that density dependent dispersal evolves when it is the only  
159 source of information (Fig. 2a, 3). Here we show that the arrival of immigrants also provides  
160 useful information that can drive dispersal behavior (Fig. 2b, 3). Indeed, information-dependent  
161 dispersal coefficients (D and I) were significantly biased towards positive values in contrast to  
162 expectations from drift which should lead to an equal probability of positive and negative values  
163 (Sign test: D-only: 97/100 positive trials,  $P < 0.0001$ ; I-only: 99/100 positive trials,  $P < 0.0001$ ).

164 Both density and immigrant dependent dispersal evolved even when in competition with  
165 uninformed dispersal (fixed  $d_U = 10\%$  and when U was allowed to evolve; see SOM and Fig. S9,  
166 S10a) and lead to increased dispersal (Fig. 2a,b) despite a highly stable and homogenous  
167 landscape. Dispersal reaction norms due to information use illustrate this nicely: local density  
168 and immigrant number influence dispersal (Fig. 4a and b respectively) at equilibrium compared  
169 to a flat, fixed dispersal rate of uninformed dispersal. Density-dependent dispersal shows a

170 steady increase in dispersal as local density rises (Fig. 4a). In contrast, immigrant-dependent  
171 dispersal shows a rapid increase in dispersal with the first few immigrants and then quickly  
172 asymptotes at high levels of dispersal (Fig. 4b).

173 For informed dispersal to evolve there must be some benefit to these strategies.  
174 Individuals benefit from dispersal when they find a new population with a lower density given  
175 that fitness is density-dependent. We compared the density of the new destination patch and an  
176 individual's original patch right before reproduction to estimate the benefit of dispersal to that  
177 individual. Informed dispersal led to discovery of a less dense patch than the population of origin  
178 on average. Both density and immigrant information seemed to present very similar advantages  
179 early in the evolutionary process (Fig. S5a,b and Fig. 5a). However, the benefit of informed  
180 dispersal was extremely slight (0.5-0.02%) since the landscape was largely homogenous and  
181 most populations were very close to their carrying capacity at all times. Environmental  
182 stochasticity augmented spatial heterogeneity in patch density and led to a larger benefit during  
183 the evolution of informed dispersal (Fig. 5a; Fig. S5; see also McPeck & Holt 1992; Travis &  
184 Dytham 1999).

185

### 186 **Evolution of Information Use: multiple sources of information**

187 Coexistence of density and immigrant dependent dispersal occurred often in our model  
188 when both forms of information use were possible (48% of simulations for model D&I; Fig. 2c  
189 and 3). Information-dependent dispersal coefficients for both behaviors (D and I) were again  
190 significantly biased towards positive values overall in contrast to expectations from drift (Sign  
191 test for D&I model: D: 65/100 positive trials,  $P=0.035$ ; I: 82/100 positive trials,  $P<0.0001$ ).  
192 Reaction norms of density- and immigrant-dependent dispersal both show increases with density

193 or immigrant number respectively and rise well above background levels of uninformed dispersal  
194 (Fig. 4c,d). If we contrast these reaction norms to the reaction norms that evolve when only one  
195 form of information use is possible, we see that the slope of density dependent dispersal  
196 decreases considerably (Fig. 4a vs. c) whereas the shape of the immigrant-dependent dispersal  
197 curve changes only slightly (Fig. 4b vs. d; dispersal above 98% at 3 vs. 5 immigrants  
198 respectively). Optimal levels of density-dependent dispersal therefore shift considerably when  
199 another source of information affects dispersal. In contrast, immigrant-dependent information  
200 has large effects on dispersal with the arrival of the first few immigrants and this trigger does not  
201 change much when other sources of information are available.

202 While both forms of dispersal evolved less often when both were present (a decrease of  
203 32% and 17% for density and immigrant dependent dispersal respectively), coexistence remained  
204 high when in competition with a second source of information (D&I) relative to models where  
205 just one strategy was possible (D-only or I-only; Fig. 3). Joint evolution of both information use  
206 behaviors occurred even in competition with uninformed baseline dispersal (see SOM, Fig. S9,  
207 S10, S11).

208 Informed dispersal showed benefits at the metapopulation level when both forms of  
209 information were used together relative to using just one source of information. This benefit was  
210 most apparent when demographic stochasticity increased. Lower population carrying capacities  
211 raised the risk of extinction due to increased demographic stochasticity, and for a narrow window  
212 of carrying capacities the use of two sources of information helped reduce the risk of extinction  
213 for the metapopulation as a whole by 20-40% relative to use of just one source of information  
214 (Fig. 5d). At slightly lower carrying capacities, when metapopulation extinction always occurred,  
215 the use of two different sources of information lead to longer persistence (200-10000 time steps

216 or roughly 100-5000 generations; Fig. S3) of the metapopulation than if just one source of  
217 information was used. An increase in the frequency of environmental stochasticity lead to higher  
218 metapopulation extinction, and the risk of extinction was lower when one or more sources of  
219 information was available (D-only or I-only or D&I) compared to uninformed dispersal only  
220 (U-only) (Fig. 5c).

221

## 222 **DISCUSSION AND SYNTHESIS**

223

224 Our results show that informed dispersal evolves under a broad array of contexts and that  
225 both density and indirect immigrant-dependent information sources evolve and can coexist. The  
226 frequent evolution of informed dispersal in the very conservative setup examined here (e.g.  
227 stable metapopulation) suggests that use of a variety of information sources, including indirect  
228 measures of the metapopulation landscape, could be common in nature. Indeed, direct  
229 information use in dispersal decisions is widespread (Ims & Hjermann 2001; Matthysen 2005;  
230 Ronce 2007; Clobert et al. 2009; Schmidt et al. 2010) and the few empirical investigations of  
231 indirect information use that we are aware of have found evidence for it despite a broad  
232 taxonomic range. For example, common lizards modify their dispersal behavior in response to  
233 immigrants who appear to provide information about the density of their natal population (Cote  
234 & Clobert 2007a). Likewise, our recent work in *Tetrahymena* ciliates shows that residents alter  
235 their dispersal rate when arriving immigrants come from populations that differ in density or  
236 social structure. In both of these empirical examples, immigrants carry more information (e.g.  
237 population density) than we included in our model. This additional information should serve to

238 increase the fitness benefits of immigrant-dependent dispersal suggesting that we have probably  
239 underestimated the likelihood that it evolves.

240 For use of both information sources to evolve, there must be benefits to adjust behavior  
241 using two sources of information rather than a single source. Benefits of density-dependent  
242 dispersal are well known since movement out of high density patches should have direct fitness  
243 benefits when reproduction is density dependent (Travis et al. 1999). Our results demonstrate  
244 that even under very conservative conditions, immigrant dependent dispersal also presents a  
245 benefit and evolves. Likewise, coexistence of density- and immigrant-dependent dispersal under  
246 the stable meta-population structure that we modeled suggests that these behaviors can evolve  
247 and coexist frequently even when the benefits of each behavior are low. Coexistence also implies  
248 that neither source of information carries benefits that would cause competitive exclusion of the  
249 other information source. Using two sources of information also provided additional benefits and  
250 could play an important role in metapopulation stability, especially as increased stochasticity  
251 creates larger inequalities in population densities. While the benefits we measured in our model  
252 were small in the relatively homogenous landscape we constructed, conditions that more  
253 realistically imitate empirical landscapes should confer much larger benefits to this behavior.

254 Joint evolution of density and immigrant dependent dispersal would be prevented if  
255 information content of density and immigrant number were not sufficiently different or if one  
256 information source was superior to the other (Enfjäll & Leimar 2009; Hovestadt et al. 2010;  
257 Schmidt et al. 2010; Bocedi et al. 2012). Immigrant arrival might be related to the overall density  
258 of the metapopulation since populations that have more individuals will generate more  
259 dispersers, and therefore immigrants, even through a fixed baseline dispersal rate. This estimate  
260 of the overall metapopulation density contrasts to density-dependent measures of the local

261 population alone. Competitive exclusion might be expected since immigrant number should be  
262 more decoupled with local fitness in any single patch and thus dispersal should carry a higher  
263 variance in benefits relative to direct information on local density. Yet we frequently found  
264 coexistence of information use through both density and immigrant information. This suggests  
265 that each source of information is not fully redundant and that one source of information is not  
266 necessarily superior to the other. This equivalency of information can serve as an advantage  
267 under some contexts (e.g. when stochasticity is high; Fig. 5 and S3) and would be especially  
268 useful where the costs of information use from one source might constrain dispersal below an  
269 optimal level (Bocedi et al. 2012). Likewise, if immigrants also carry additional information  
270 about their populations (Cote & Clobert 2007a) or help orient dispersers towards certain  
271 populations, then we could expect the benefits of indirect information use to be even more  
272 advantageous.

273         The potential prevalence of informed dispersal has a number of important implications  
274 for both fundamental and applied ecology. In basic ecological research, the use of information  
275 has recently been explored in terms of density dependent dispersal, and this simple behavior  
276 greatly effects how movement influences population persistence (Ims & Hjermann 2001; Cadet  
277 et al. 2003; Matthysen 2005). Earlier models of ‘informed’ dispersal—such as ‘ideal free  
278 distribution models—generally assumed perfect knowledge of the landscape (Abrahams 1986;  
279 Gray & Kennedy 1994; Holt & Barfield 2001) which presumably was acquired through  
280 prospecting that carried low costs. Low cost prospecting might work when patches are close (e.g.  
281 foraging patches), but is less realistic when habitat patches are more distant. The use of indirect  
282 information, such as the arrival of immigrants, could provide another mechanism by which the  
283 ideal free distribution is achieved (Baguette, Clobert & Schtickzelle 2010). If immigrant arrival

284 is linked to overall metapopulation density and if immigrants carry additional information about  
285 the quality of those habitats as suggested in empirical examples (Cote & Clobert 2007a), then we  
286 might approach an ideal free distribution through use of indirect information transfer across the  
287 landscape. Deviation from ideal free models might then in part reflect the quality or reliability of  
288 that indirect information transfer (see also Abrahams 1986; Gray & Kennedy 1994; Chaine &  
289 Clobert 2012). Most likely, individuals use a number of sources of information on local  
290 conditions, direct prospecting of nearby patches, and indirect measures of the landscape such as  
291 immigrant-borne information (Clobert et al. 2009). If this form of information use is prevalent,  
292 then we must shift our view of dispersal from largely random movement among populations to  
293 much more targeted and informed movement patterns that approach ideal-free expectations.

294         Connectivity and dispersal are crucial aspects of population persistence, yet studies of  
295 dispersal and metapopulation dynamics usually ignore the important role that information  
296 transfer across the landscape might play in guiding subsequent dispersal decisions. Applied  
297 management or conservation efforts to increase connectivity or gene flow might be greatly  
298 hampered if we do not also introduce the indirect cues that influence dispersal. Indeed, the highly  
299 variable success of artificial corridors (Gilbert-Norton et al. 2010) could in part be caused by the  
300 lack of indirect information since immigrants will be rare when a new corridor is first  
301 constructed (see also Le Galliard et al. 2003). More generally, conservation efforts could be  
302 greatly aided by modifying natural dispersal through the manipulation of information that is  
303 accessible to residents rather than by costly alterations of the landscape between habitat patches  
304 (Chaine & Clobert 2012). As we show here, access to multiple sources of information may better  
305 mitigate extinction risk in highly stochastic environments compared to situations where little  
306 information exists. Broader inclusion of how information is used in dispersal should provide us

307 with new tools for conservation and fundamentally modify our approach to conservation ecology  
308 and the management of populations in peril.

309 Our findings also have important implications for dispersal theory and the incorporation  
310 of information use into this field. We found the evolution of both forms of informed dispersal  
311 despite potentially large differences in the quality of information gleaned from each source.

312 Whereas local density directly affects fitness, immigrant arrival at best gives some indication of  
313 surrounding population sizes when density dependent dispersal exists and at worst simply  
314 provides evidence that other populations exist. Coexistence of the two sources of information  
315 suggests that the quality of information may be somewhat less important than the presence of  
316 that information. In support of this notion, models of indirect information use based on  
317 immigrant presence rather than immigrant number show very similar results (Fig. S12). This  
318 result is empirically supported by the fact that dispersal in the common lizard was found to be  
319 sensitive to the presence and not to the quantity of immigrants (Cote & Clobert 2007a).

320 Similarly, recent models of density dependent information use suggest that the precision of  
321 information provides diminishing returns and high quality information is not optimal when it  
322 also incurs elevated costs associated with gathering additional precision (Bocedi et al. 2012).

323 Both of these investigations adopt very simple dispersal contexts and yet both show that  
324 information use in dispersal evolves quite readily and should be common in nature. More  
325 generally, the passive information transfer across the landscape that evolves in our models could  
326 be an important first evolutionary step that allows more active information transfer and  
327 communication to evolve both within populations and across landscapes.

328

329 **ACKNOWLEDGEMENTS**

330

331 We thank O. Ronce and B. Lyon for comments on an early draft and discussions on this topic.

# Figure 1

Life cycle of organisms in the model

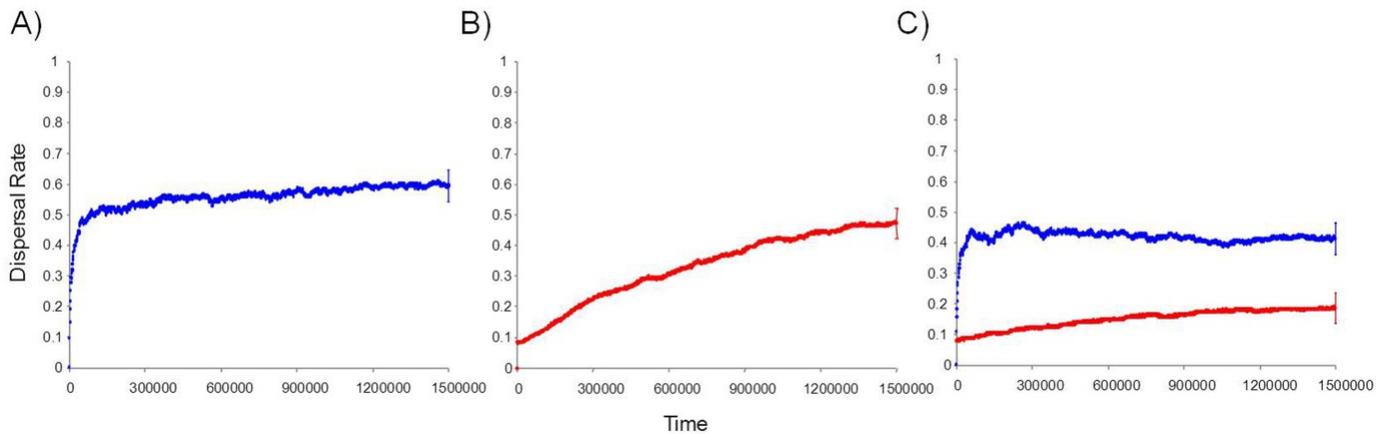

Diagram of the basic life cycle of individuals in the model. The two age classes of reproductive individuals are described by their age-specific survival ( $s$ ) and fecundity ( $f$ ).

## Figure 2

Temporal dynamics of the evolution of informed dispersal

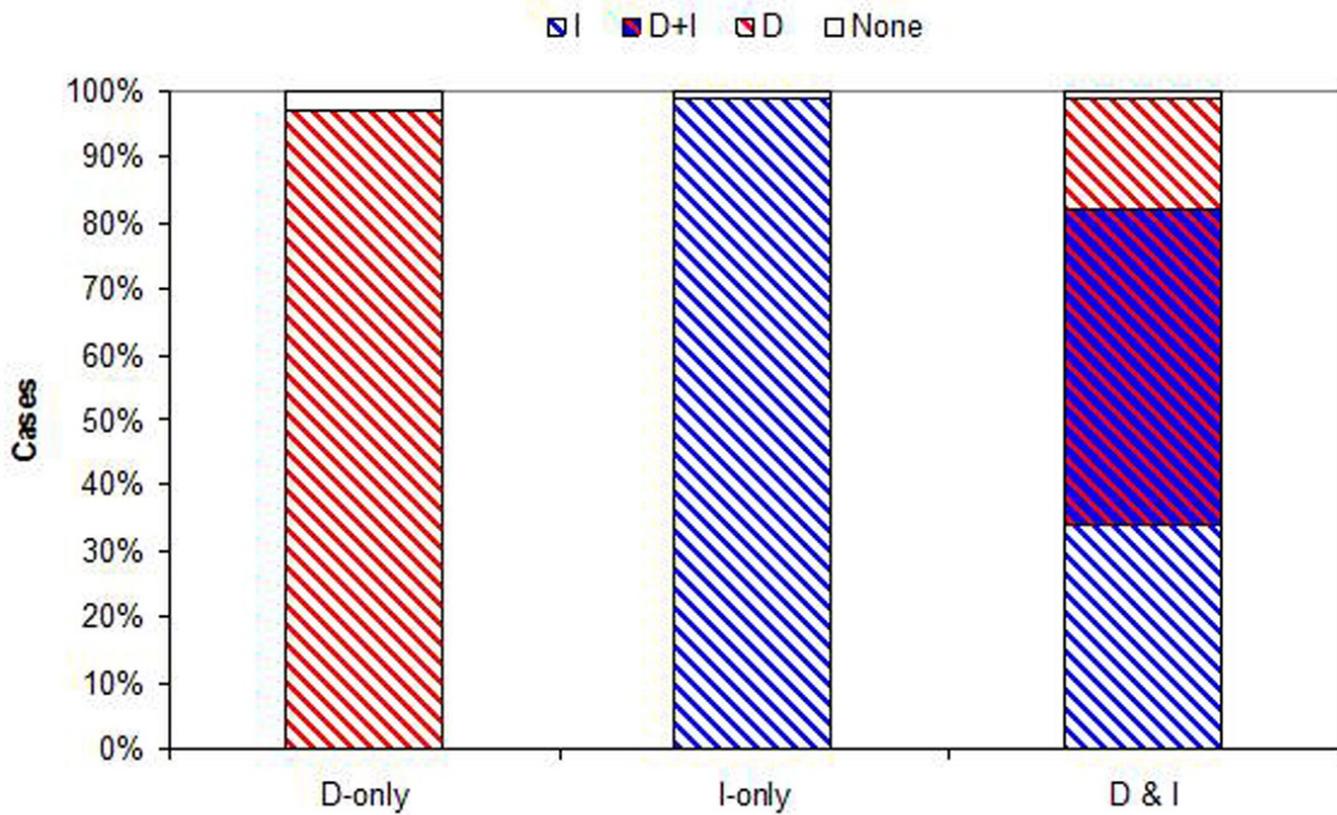

Temporal dynamics of the evolution of information based dispersal due to local density ( $d_D$  in red) and the number of arriving immigrants ( $d_I$  in blue). Trajectories reflect average dispersal rates for 100 Monte Carlo simulations. A) Dynamics of immigrant number information use alone ( $d_I$ ). B) Dynamics of density dependent information use alone ( $d_D$ ). C) Dynamics of both density dependent and immigrant dependent information when used simultaneously (D&I) with no cost of dispersal and D) when density dependent information use reduce survival to 0.99. Uninformed dispersal is fixed at 10% and does not evolve. The 95% confidence interval is shown for the last time step on each trajectory.

## Figure 3

### Evolution of information use

Probability that each form of information use evolves. Plotted are the proportion of simulations where dispersal evolved based on density dependent information (D, red), immigrant information (I, blue), both density and immigrant information (D+I, red and blue hatch), or where dispersal did not evolve (None, white) across 100 Monte Carlo simulations. D-alone and I-alone are for models with just one source of information available (plus U fixed at 10%). D&I is a model with both density and immigrant dependent dispersal present. Probability that each form of information use evolves. Plotted are the proportion of simulations where dispersal evolved based on density dependent information (D, red), immigrant information (I, blue), both density and immigrant information (D+I, red and blue hatch), or where dispersal did not evolve (None, white) across 100 Monte Carlo simulations. D-alone and I-alone are for models with just one source of information available (plus U fixed at 10%). D&I is a model with both density and immigrant dependent dispersal present. Probability that each form of information use evolves. Plotted are the proportion of simulations where dispersal evolved based on density dependent information (D, red), immigrant information (I, blue), both density and immigrant information (D+I, red and blue hatch), or where dispersal did not evolve (None, white) across 100 Monte Carlo simulations. D-alone and I-alone are for models with just one source of information available (plus U fixed at 10%). D&I is a model with both density and immigrant dependent dispersal present.

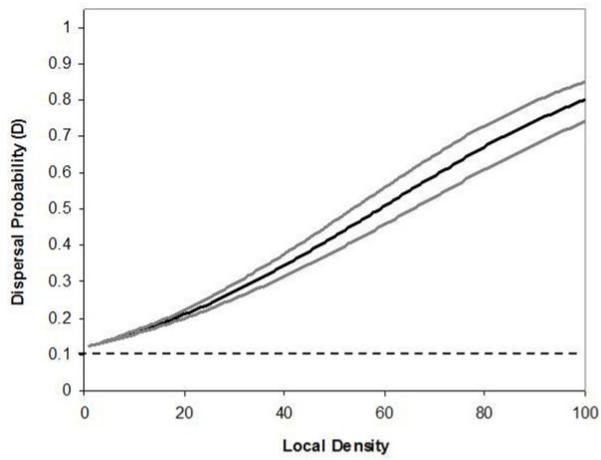

## Figure 4

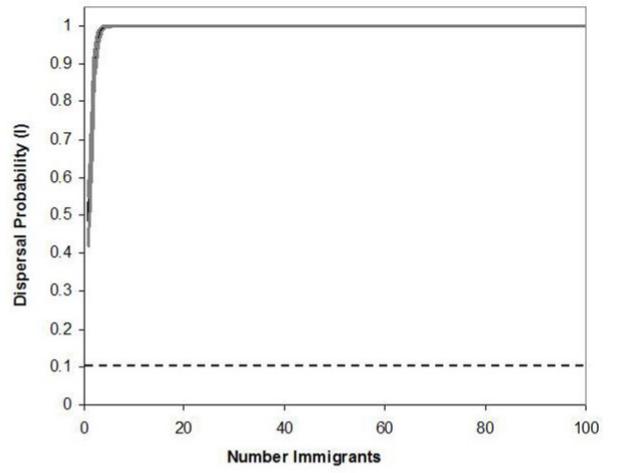

### Behavioral reaction norms of informed dispersal

Reaction Norms for informed dispersal behavior. Solid lines show the reaction norms (black) and 95% CL (grey) for each form of dispersal. Dashed lines reflect uninformed baseline dispersal. Reaction norms were created using the Informed Dispersal equations with the mean evolved coefficient after 100000 generations. Lines for the 95% CL were constructed using the variance in evolved coefficients among 100 Monte Carlo runs. Top panels are for models where only one source of information is possible and show dispersal due to A) density dependent dispersal (D-only) and B) immigrant dependent dispersal (I-only). Bottom panels are for models where only both sources of information are possible (D&I) and show dispersal due to C) density dependent dispersal and D) immigrant dependent dispersal.

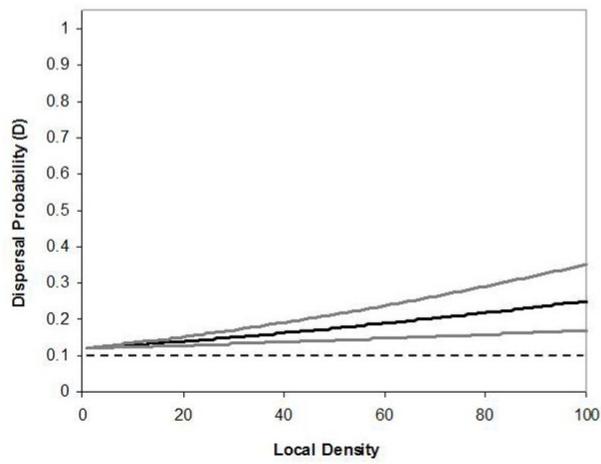

A) Density for D-alone

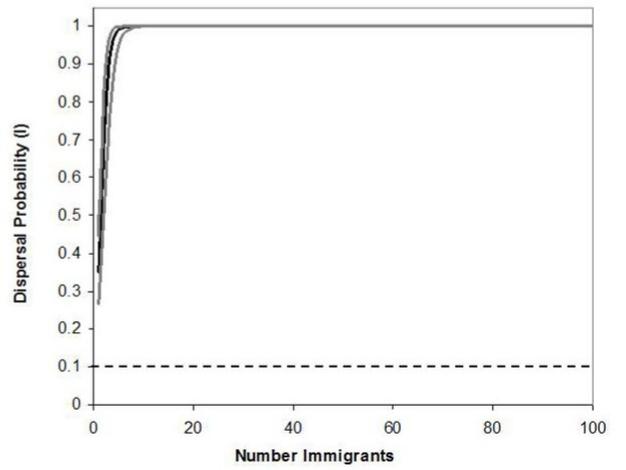

B) Immigrant for I-alone

C) Density for D&I

C) Immigrant for D&I

# Figure 5

## Benefits of informed dispersal

The relative benefit of dispersal behavior to an individual is estimated by how much better a disperser did by moving (i.e. old pop density/ new pop density, both at reproduction). Shown is the dispersal benefit over the first 100000 time steps for models with low environmental stochasticity (5% of populations hit) in models A) I-only (D-only is similar) or B) D&I. Benefits of multiply-informed dispersal (D&I) relative to using no information or a single source of information (D or I-only) is also observed at the meta-population level by reducing global extinction risk (proportion of 100 Monte Carlo simulations where the metapopulation goes extinct) as stochasticity increases due to C) random environmental stochasticity or D) small population size.
