Toll like receptors (TLRs) are an important component of innate immunity, the first line of pathogen defence, and can recognise pathogen-associated molecular patterns (PAMPs). Amphibians are currently facing population declines and even extinction due to chytridiomycosis caused by the *Batrachochytrium dendrobatidis* (Bd) fungus. TLR2 and TLR4 have been shown in other vertebrates to be involved in innate immunity against various fungi, and such genes may therefore play a functional role in amphibian-chytridiomycosis dynamics. Frogs from East Asia appear to be tolerant to the Bd fungus, so we characterized TLR2 and TLR4 from three Japanese Ranidae frog species, *Rana japonica*, *R. ornativentris* and *R. tagoi tagoi* (n = 5 per species). We found that these genes are evolutionarily conserved, with overall evidence supporting purifying selection. Despite this, we identified specific codon sites that are under positive selection. However, it remains unclear whether the Bd fungus is a selective force acting on TLRs of Japanese frogs.

13 **Abstract**

14 Toll like receptors (TLRs) are an important component of innate immunity, the first line of pathogen  
 15 defence, and can recognise pathogen-associated molecular patterns (PAMPs). Amphibians are currently  
 16 facing population declines and even extinction due to chytridiomycosis caused by the *Batrachochytrium*  
 17 *dendrobatidis* (Bd) fungus. TLR2 and TLR4 have been shown in other vertebrates to be involved in innate  
 18 immunity against various fungi, and such genes may therefore play a functional role in amphibian-  
 19 chytridiomycosis dynamics. Frogs from East Asia appear to be tolerant to the Bd fungus, so we  
 20 characterized TLR2 and TLR4 from three Japanese Ranidae frog species, *Rana japonica*, *R. ornativentris*  
 21 and *R. tagoi tagoi* (n = 5 per species). We found that these genes are evolutionarily conserved, with  
 22 overall evidence supporting purifying selection. Despite this, we identified specific codon sites that are  
 23 under positive selection. However, it remains unclear whether the Bd fungus is a selective force acting on  
 24 TLRs of Japanese frogs.

## 26 Introduction

27 Toll-like receptors (TLRs) are a type of pattern recognition receptor that recognize pathogen-associated  
 28 molecular patterns (PAMPs) such as bacterial cell walls and nucleic acids (Medzhitov, 2001). The  
 29 signalling of TLRs triggers the synthesis and release of pro-inflammatory cytokines, and thus TLRs have an  
 30 important role in innate immunity and activation of adaptive immunity. TLRs are type 1 membrane  
 31 glycoproteins comprised of extracellular and cytoplasmic domains; the extracellular domain is also  
 32 considered as a 'pathogen-recognition domain' with a variable number of leucine rich repeats (LRR),  
 33 while the cytoplasmic domain is a conserved toll/IL-1 domain (Mikami et al., 2012). The TLR repertoire  
 34 differs between vertebrate groups ranging from 10 loci in humans and great apes to 21 in urodele  
 35 amphibians (Takeda, Kaisho & Akira, 2003; Quach et al., 2013; Babik et al., 2014). Specific TLR loci are  
 36 generally considered to recognize different groups of PAMPs, for example, TLR1 and TLR6 associate with  
 37 TLR2 to recognize acylated lipopeptides, TLR4 recognize lipopolysaccharides in gram-negative bacteria, and  
 38 TLR5 recognize bacterial flagellin (Politorak et al., 1998; Voogdt et al., 2016). In addition, TLR2 and TLR4  
 39 can recognize PAMPs derived from different fungi species (reviewed by Roeder et al., 2004; Luther &  
 40 Ebel, 2006).

41 In amphibians, TLRs have been described in *Xenopus* frogs (20 loci from 14 families, Ishii et al., 2007) and  
 42 newts (21 loci from 13 families, Babik et al., 2014). TLR families characterized in both frogs and newts  
 43 include TLR01, TLR02, TLR03, TLR05, TLR07, TLR08, TLR09, TLR12, TLR13, TLR14, TLR21, and TLR22.  
 44 However, the prevalence of TLR4 across amphibian taxa is uncertain: no TLR4 orthologs were found in  
 45 newts, but putative TLR4 were identified in *Xenopus* (Ishii et al., 2007; Babik et al., 2014). In addition,  
 46 TLR4, amongst over 11 TLR genes, were isolated from transcriptome data of *Bombina maxima* frogs  
 47 (Zhao et al., 2014).

48 Most TLR genes are functionally constrained, and typically have high sequence conservation and slow  
 49 evolutionary rates to maintain a functional role of recognizing conserved PAMPs (Roach et al., 2005),

although extracellular LRR domains have higher evolutionary rates compared to intracellular domains (Mikami et al., 2012). Overall adaptive constraint was identified in TLRs of urodele amphibians, although there were a few individual codons found to be evolving under positive selection (Babik et al., 2014), as has been observed in other vertebrates (Wlasiuk & Nachman, 2010; Shang et al., 2018). The identification of TLR-disease associations in vertebrates (Tschirren et al., 2013; Noreen & Arshad, 2015) also supports that episodic selection can occur in TLR genes as a response to changes in pathogen diversity. In addition, human TLR4 displayed significantly negative Tajima's D values in nonsynonymous variants (Smirnova et al., 2001), and subsequent evidence supporting selection for rare TLR4 variants was found (Smirnova et al., 2003). Therefore, while TLRs may be under functional constraints, there is evidence across vertebrates that positive selection may act on these genes in response to local pathogens.

Chytridiomycosis is a fungal disease in amphibians caused by *Batrachochytridium dendrobatidis* (Bd). This disease has been linked to the decline of amphibian populations worldwide (Daszak, Cunningham & Hyatt, 2003; Longcore et al., 2007; Skerratt et al., 2007; Wake & Vredenburg, 2008). Despite being prevalent in Korea and Japan (Goka et al., 2009; Bataille et al., 2013), there is no evidence of Bd-related declines in East Asian frogs. Additionally, genetic evidence for high Bd genetic diversity and endemism in this region indicates that Bd is endemic to Asia (Fisher, 2009; Bataille et al., 2013), suggesting a long co-evolutionary history between the Bd pathogen and Asian amphibians.

While adaptive immune genes of Japanese frogs have been studied in the context of chytridiomycosis (Lau et al., 2016, 2017), there are limited studies involving innate immunity genes including TLRs. Since TLR2 and TLR4 have been shown to play a role in innate immune responses to various fungi (Roeder et al., 2004; Luther & Ebel, 2006), TLRs therefore may be important in Bd resistance (Richmond et al., 2009). Here we characterized two candidate TLR genes in three Bd-tolerant Japanese *Rana* species, to further understand amphibian-chytridiomycosis dynamics.

## 74 **Methods**

### 75 *Animals*

76 Adult skin tissues were collected from three common Ranidae frog species from Japan (n = 5 per species):  
 77 the Japanese brown frog (*Rana japonica*), the montane brown frog (*Rana ornativentris*), and Tago's  
 78 brown frog (*Rana tagoi tagoi*). All frogs originated from Hiroshima prefecture in Japan, and are the same  
 79 individuals used previously to characterize MHC class I and II genes (Lau et al., 2016, 2017, Table S1).  
 80 Sample collection was approved by Hiroshima University Animal Research Committee, approval number  
 81 G14-2. All animals were considered 'healthy' as they were housed in laboratory conditions for extended  
 82 periods and exhibited no clinical signs of disease prior to euthanasia. All sample collection was approved  
 83 by Hiroshima University Animal Research Committee, approval number G14-2. Animals were euthanized  
 84 through immersion in tricaine methanesulfonate (MS222, 0.5–3 g/L water), and preserved in RNAlater  
 85 (Applied Biosystems, Carlsbad, CA, USA) at -20°C prior to excision of skin sample and genomic DNA  
 86 (gDNA) extraction using DNAsui-F (Rizo Inc., Tsukuba, Japan) following manufacturer's protocol.

### 87 *Isolation of TLR genes from transcriptome data set and primer design*

88 To isolate TLR2 and TLR4 genes, we utilised the transcriptome data set previously compiled using Illumina  
 89 sequences from immune tissues of the three species (Lau et al., 2017). Briefly, we used the assembled  
 90 transcripts that were annotated with NCBI-BLAST-2.3.30 against the Swissprot protein database  
 91 (<http://www.expasy.ch/sprot>), and isolated all transcripts that had top hits from BLAST search to  
 92 published TLR genes of other vertebrates. We manually scanned the NCBI-BLAST search results and  
 93 aligned each transcript with orthologous genes from *Xenopus laevis* and *Nanorana parkeri* (Xenbase,  
 94 <http://www.xenbase.org/>, RRID:SCR\_003280, and GenBank accession numbers XM\_002933491,  
 95 XM\_018557931, XM\_018232906, XM\_018565865). Due to low coverage of sequence data, full-length

contigs were not available for TLR2 and TLR4 genes in all three species (Figures S1 and S2); in such cases, fragmented contigs were used in the alignment. The genomic structure of most vertebrate TLR genes are unique in that they have a majority of their coding sequence located within a single exon. From the alignments, we used Primer 3 (Rozen & Skaletsky, 1998) to design degenerate primers that amplified 2348 bp and 2072 bp fragments within a single exon of TLR2 (RanaTLR2\_F: 5'-TGRTTGCATACATATGGAGTTG-3', RanaTLR2\_R: 5'-GTGGTCCTCTGGCTGAAGAG-3') and TLR4 (RanaTLR4\_F: 5'-CTGGCAAGCCTTTCTGAACT-3', RanaTLR4\_R: 5'-AGCGGARCATCAACTTTACG-3'), respectively, across all three species (Table S1).

#### *TLR PCR and sequencing*

Polymerase chain reaction (PCR) amplification was conducted in Applied Biosystems® Veriti® thermal cycler in 10 µL reactions with 0.25 U TaKaRa Ex Taq® polymerase (Takara Bio Inc.), 1x Ex Taq PCR buffer, 0.2 mM each dNTP, and 0.7 µM each primer and 0.5 – 1.0 µL skin gDNA samples (n = 5 per species) with the following cycle condition: initial Taq activation at 95°C for 1 min, then 35 cycles of 30-s denaturation at 95°C, 30-s annealing at 60°C (TLR2) or 61°C (TLR4), and 80-s extension at 72°C, then a final extension of 72°C for 3 min. PCR products were ligated into T-Vector pMD20 (Takara Bio Inc) using DNA Ligation Kit 2.1 (Takara Bio Inc.) and incubated for 30 min at 16°C. For cloning, ligation reactions were transformed into JM109 competent cells (Takara Bio Inc.). We then amplified positive clones (4 – 10 per individual reaction) using M13 primers and similar PCR conditions, and purified using ExoSAP-IT® (Affymetric Inc., Santa Clara, USA). As amplicons were over 2kbp length, we utilised four to six additional sequencing primers (Table S2, Figures S3 and S4) in addition to M13 primers for sequencing with BigDye® Terminator Cycle Sequencing kit (Applied Biosystems, Foster City, USA) and ABI 3130xl automated sequencer.

#### *Sequence analyses, $d_N/d_S$ comparison with other genes, and selection tests*

We measured polymorphism and divergence of the TLR2 and TLR4 sequences using DnaSP 6.10.03 (Rozas et al., 2017), including number of segregating sites (S), number of alleles ( $N_A$ ), nucleotide diversity ( $\pi$ ),

Tajima's D (D) and normalized Fay and Wu's H (Hn). We calculated synonymous ( $d_s$ ) and nonsynonymous ( $d_N$ ) divergence and the ratio ( $d_N/d_s$ ) between the focal species using MEGA7 (Kumar, Stecher & Tamura, 2016). We then compared the  $d_N/d_s$  ratio with that of major histocompatibility complex (MHC) class I and II, which are known to be under balancing selection in these species (Lau et al., 2016, 2017). In addition, we compared with  $d_N/d_s$  ratio of all orthologous genes collated from the transcriptome data set of Lau et al (2017). This consisted of over 3000 orthologous amino acid sequences from each of the three species that were identified using Proteinortho V5.15 (Lechner et al., 2011). We then extracted nucleotide coding sequences of orthologous genes from transcriptome data sets using a custom python script, and used PhyloTreePruner (Kocot et al., 2013) to align the sequences and remove paralogues. Finally, all sequences were compiled together and maximum likelihood estimates of  $\omega$  ( $d_N/d_s$ ) were calculated using CODEML in PAML 4.9 (Yang, 2007).

To test for selection, we used McDonald-Kreitman (MK) test in DnaSP 6.10.03 to compare species-wide data with outgroup sequences from distantly related Ranidae frogs (*Odorrana amamiensis* and *O. ishikawae*, transcriptome data, source: T. Igawa). In addition, we tested for sequence-wide neutral ( $d_N = d_s$ ), purifying ( $d_N < d_s$ ) and positive ( $d_N > d_s$ ) selection using codon-based Z tests with 1000 bootstrap replicates in MEGA7. To infer specific codons as positively selected sites (PSSs) with  $\omega$  ( $d_N/d_s$ )  $> 1$ , we used omegaMap version 5.0 (Wilson & McVean, 2006) to perform Bayesian inference on independent alignments for each species and gene, following Lau et al. (2016). Neighbour-joining phylogenetic trees from amino acid alignments (p-distance) were constructed independently for TLR2 and TLR4 in MEGA7. Protein domain structures of TLR2 and TLR4 were predicted using SMART (Letunic, Doerks & Bork, 2015).

#### Expression of TLRs

We used our transcriptome data set (Lau et al., 2017) to compare expression levels of TLR2 and TLR4 between tissue types and adult frogs and tadpoles. RSEM v 1.3.0 (Li & Dewey, 2011) was used to extract trimmed mean log expression ratio, or TMM-normalized values (Robinson & Oshlack, 2010), for TLR2 and

TLR4 transcripts in each of the 12 samples (Table S1). In the cases where full-length contigs were not available from low sequence coverage (*R. ornativentris* TLR2 and TLR4, and *R. t. tagoi* TLR4), we obtained expression values for each fragmented contig.

## Results

We characterized a total of 27 TLR2 and 20 TLR4 alleles from the three study species distinctive at the amino-acid level: seven TLR2 and five TLR4 alleles in *R. japonica*, ten TLR2 and seven TLR4 alleles *R. ornativentris*, and ten TLR2 and eight TLR4 alleles in *R. tagoi tagoi* (Table 1, Figures S3 and S4, GenBank accession numbers MG999527-MG999573). All alleles clustered phylogenetically into species-specific clades (Figure 1) with similar domain structure to that of other frogs (Figure S5). Allelic diversity among species was high (Table 1, Table S3), especially TLR2 in *R. ornativentris* and *R. t. tagoi*, where all individuals were heterozygous with two unique alleles. Only a few alleles were shared between more than one individual (Table S3); this was apparent in *R. japonica* and may be due to a population bottleneck history in the source population of Etajima (Lau et al., 2016).

Selection tests over the entire alignment indicated that TLR2 and TLR4 in the three focal species are under purifying selection ( $Z\text{-value} = 2.66 - 3.83$ ,  $p < 0.01$ , Table 2) with the exception of TLR4 in *R. t. tagoi* ( $Z\text{-value} = 1.26$ ,  $p = 0.102$ ). In addition, Tajima's D, normalized Fay and Wu's H and the McDonald-Kreitman test showed no significant support for selection (Table 1). However, omegaMap analyses identified six to nine positively selected sites (PSSs) in either TLR2 or TLR4 of each of the three focal species (Posterior probability  $> 99\%$ ), of which two (22.2%) to six (75.0%) PSSs were located in predicted leucine rich repeat domains (Table 2, Figure S3 and S4). There were no PSSs common in all three species studied, but two PSSs of TLR4 (D56 and S65) were shared across two species (Table 2, Figure S4).

The low average number of non-synonymous differences per non-synonymous site ( $d_N$ ) resulted in low  $d_N/d_S$  ratio of between 0.188 to 0.398 in TLR pairwise comparisons between *Rana* species (Table 3). Such ratios were lower than MHC class I  $\alpha 1$  and  $\alpha 2$  domains and class II  $\beta 1$  domain, but comparable to that of

MHC class 1  $\alpha 3$  and MHC class II  $\beta 2$  domains as well as other transcribed genes within the species (mean  $d_N/d_S$  of over 3000 genes = 0.380, Figure 2).

Initial examination of expression level differences between tissue types within adults (blood, spleen, skin) indicated that overall expression of TLR2 and TLR4 is low but there were a few consistent trends seen across all three species. TLR2 had high expression in adult skin relative to blood, while TLR4 had the lowest expression in adult skin relative to both blood and spleen (Table 4). Expression of TLR2 and TLR4 was seemingly low in tadpoles relative to adult samples (Table 4).

## Discussion

The preliminary characterization of TLR2 and TLR4 in the three focal species here provides a platform for future population genetics studies across the species' distributions, uncovering the full TLR diversity with more targeted PCR and sequencing approaches. The presence of the TLR4 gene in amphibians was previously unclear, described as 'putative' in *Xenopus* frogs and 'predicted' in *Lithobates catesbeiana* and *Nanorana parkeri* (GenBank accessions XP\_018421367 and PIO23183), and undetected in newts. The characterization of TLR4 genes in this study supports the existence of this gene family in anurans, whereby TLR4 alleles of the three *Rana* species were similar in phylogeny and domain structure with that of other frogs.

From selection tests, we found overall evidence of purifying selection and no support for sequence-wide positive selection. This agrees with data from other vertebrates, including newts, where TLRs are regarded as conserved with their evolution predominated by purifying selection (Roach et al., 2005; Babik et al., 2014). The low  $d_N/d_S$  ratios in TLR2 and TLR4 of the *Rana* species studied here were remarkably low compared to that of external domains of MHC class I ( $\alpha 1$  and  $\alpha 2$  domains) and class II ( $\beta 1$  domain), which are considered to be under balancing selection. However, the low  $d_N/d_S$  of TLR2 and TLR4 was comparable to  $d_N/d_S$  of MHC class 1  $\alpha 3$  and MHC class II  $\beta 2$  domains which are intracellular or not

involved in peptide recognition, as well as that of over 3000 transcribed genes within the species. These findings further support that TLR2 and TLR4 are under functional constraint.

Although we found that most of the TLR2 and TLR4 sequences of the Japanese *Rana* frogs were evolutionarily constrained, we identified evidence of adaptive evolution occurring at individual codon sites in our alignment, similar to other vertebrates studied (Wlasiuk & Nachman, 2010; Shang et al., 2018). When comparing with codon sites predicted to be important for binding of non-fungal ligands (Figures S3 and S4), two PSS identified in *R. ornativentris* TLR2 (Q284 and V299) corresponded to sites in human TLR2 predicted to be involved in ligand binding of lipopeptides (N294 and L312, Jin et al., 2007). In addition, one PSS each of *R. tagoi tagoi* (T128) and *R. ornativentris* (Q253) corresponded to human TLR4 sites predicted to be involved in secondary (N268) and phosphate (K388) binding, respectively, of bacterial lipopolysaccharides (Park et al., 2009). Positive selection at identical codon sites across different species, as observed in MHC adaptive immune genes (Lau et al., 2016, 2017), could be driven by a single selective force that is pathogen-related. However, in *Rana* TLRs there were no PSSs shared across all three species studied. Nevertheless, we cannot rule out the possibility of adaptive evolution, potentially driven by pathogens such as the Bd fungus, acting on TLR of the study species in recent evolutionary history.

Preliminary examination of TLR2 and TLR4 expression levels extrapolated from transcriptome data showed overall low expression. While the expression data is derived from single individuals that were housed in disease-free environments, it appears that skin of healthy frogs that are not immune-challenged express TLR2 more so than TLR4. However, expression of immune-related genes could be modulated following immune or stress challenges, and future studies should monitor immune gene expression following experimental infection with pathogens like Bd. A previous study in *Xenopus* frogs detected ubiquitous expression of both TLR2 and TLR4 in adults and tadpoles using PCR, but expression levels were not quantified (Ishii et al., 2007). Although we found low TLR expression in tadpoles in this

study, further conclusions cannot be made due to limited sampling and overall low TLR expression across the samples. Future quantitative studies can investigate expression level changes of TLRs during development from tadpole to adults, as well as that of other innate and adaptive immune genes extrapolated from the transcriptome data set (Lau et al., 2017).

# *Conclusion*

In this study, we characterized TLR2 and TLR4 genes from three Japanese *Rana* species, considered to be tolerant to the deadly Bd fungus. We provide strong evidence of purifying selection acting across the TLR2 and TLR4, and evidence of a few specific codon sites under positive selection. Further research is necessary to determine if the positive selection we detected is due to pathogen-driven selection from the Bd pathogen. Since immunity to pathogens like the Bd fungus is usually polygenetic, our study adds to the growing body of literature related to genes that impact Bd resistance and further contributes to understanding complex amphibian-chytridiomycosis dynamics.

Polymorphism of TLR2 and TLR4

Polymorphism of TLR2 and TLR4 in *R. japonica*, *R. ornativentris* and *R. tagoi tagoi*.

1 Table 1. Polymorphism of TLR2 and TLR4 in *R. japonica*, *R. ornativentris* and *R. tagoi tagoi*.

Gene	2N	nsites	N <sub>A</sub>	S	k	$\pi$	D	Hn	MK P-value
TLR2									
<i>R. japonica</i>	10	2312	7	28	10.48	0.0045	-0.474	-0.873	0.629
<i>R. ornativentris</i>	10	2312	10	44	13.89	0.0060	-0.521	-0.242	1.000
<i>R. tagoi tagoi</i>	10	2312	10	39	13.29	0.0058	-0.292	-1.108	0.215
TLR4									
<i>R. japonica</i>	10	2072	5	41	19.20	0.0093	-0.183	-0.144	0.279
<i>R. ornativentris</i>	10	2078	7	35	14.71	0.0071	0.008	-0.510	0.266
<i>R. tagoi tagoi</i>	10	2072	8	25	8.57	0.0041	-0.584	-1.539	0.127

2 2N: number of gene copies studied; nsites: nucleotide length of sequence; N<sub>A</sub>: number of alleles; S: number of segregating sites; k: average number of nucleotide  
3 differences;  $\pi$ : nucleotide diversity; D: Tajima's D value for all sites (no values significant p < 0.01); Hn: Fay and Wu's normalized H value for all sites (no values  
4 significant p < 0.01); MK P-value: McDonald and Kreitman Fisher's exact test P-value

# Figure 1

Phylogenetic relationships of TLR2 and TLR4 alleles from three Japanese *Rana* species.

Phylogenetic relationships of (A) TLR2 and (B) TLR4 alleles identified in *R. japonica* (orange), *R. ornativentris* (grey) and *R. tagoi tagoi* (brown) and other species based on amino acid alignments (neighbour-joining method). Human TLR5 and TLR6 were used as outgroup sequences. Accession numbers for sequences are indicated. Sequences obtained from transcriptome data include: *Lithobates catesbeiana* (DRA accession number SRP051787), and *Odorrana amamiensis* and *O. ishikawae* (source: T. Igawa).

## Figure 2 (on next page)

Distribution of  $d_N/d_S$  ratios from over 3000 genes isolated from transcriptome data compared to TLR and MHC.

Distribution of  $d_N/d_S$  ratios from over 3000 genes isolated from transcriptome data of *R. japonica*, *R. ornativentris* and *R. tagoi tagoi*.  $d_N/d_S$  location of TLR2 and TLR4, as well as MHC class I and II domains are marked with arrows.
