A new therocephalian taxon (*Gorynychus masyutinae* gen. et sp. nov.) is described based on a nearly complete skull and partial postcranium from the Permian Kotelnich locality of Russia. *Gorynychus* displays an unusual mixture of primitive (“pristerosaurian”) and derived (eutherocephalian) characters. Primitive features of *Gorynychus* include extensive dentition on the palatal boss and transverse process of the pterygoid, paired vomers, and a prominent dentary angle; derived features include the absence of the postfrontal. *Gorynychus* can be distinguished from all other therocephalians by its autapomorphic dental morphology, with roughly denticulated incisors and postcanines. Phylogenetic analysis recovers *Gorynychus* as a non-lycosuchid, non-scylacosaurid therocephalian situated as sister-taxon to Eutherocephalia. The identification of *Gorynychus* as the largest predator from Kotelnich indicates that therocephalians acted as apex predators in middle-late Permian transition ecosystems in Russia, corroborating a pattern observed in South African faunas. However, other aspects of the Kotelnich fauna, and Permian Russian tetrapod faunas in general, differ markedly from those of South Africa and suggest that Karoo faunas are not necessarily representative of global patterns.

10

11 **Abstract.** A new therocephalian taxon (*Gorynychus masyutinae* gen. et sp. nov.) is described
12 based on a nearly complete skull and partial postcranium from the Permian Kotelnich locality of
13 Russia. *Gorynychus* displays an unusual mixture of primitive (“pristerosaurian”) and derived
14 (eutherocephalian) characters. Primitive features of *Gorynychus* include extensive dentition on
15 the palatal boss and transverse process of the pterygoid, paired vomers, and a prominent
16 dentary angle; derived features include the absence of the postfrontal. *Gorynychus* can be
17 distinguished from all other therocephalians by its autapomorphic dental morphology, with
18 roughly denticulated incisors and postcanines. Phylogenetic analysis recovers *Gorynychus* as a
19 non-lycosuchid, non-scylacosaurid therocephalian situated as sister-taxon to Eutherocephalia.
20 The identification of *Gorynychus* as the largest predator from Kotelnich indicates that
21 therocephalians acted as apex predators in middle-late Permian transition ecosystems in
22 Russia, corroborating a pattern observed in South African faunas. However, other aspects of
23 the Kotelnich fauna, and Permian Russian tetrapod faunas in general, differ markedly from
24 those of South Africa and suggest that Karoo faunas are not necessarily representative of global
25 patterns.

26 INTRODUCTION

27 Therocephalians had perhaps the most unusual evolutionary trajectory of the major clades of
28 non-mammalian therapsids. Whereas other non-mammalian therapsid groups remained
29 relatively static in terms of niche occupation through time, therocephalians ‘reinvented’
30 themselves several times in their history, each time following mass extinctions. The earliest
31 known therocephalians (Lycosuchidae and Scylacosauridae, historically united in the
32 paraphyletic group “Pristerosauria” [Boonstra, 1953]), which are best represented in middle
33 Permian sediments of the Karoo Basin of South Africa, were large-bodied (skull length up to 40
34 cm) predators (Boonstra, 1969; van den Heever, 1980, 1994). Following the extinction of
35 dinocephalians (including the gigantic, carnivorous anteosaurs) at the end of the Capitanian,
36 therocephalians briefly served as the apex predators of the Karoo during the middle–late
37 Permian transition represented by the *Pristerognathus* Assemblage Zone (AZ) (Kammerer,
38 2011; Abdala et al., 2014; Day et al., 2015). However, by the end of the *Pristerognathus* AZ
39 lycosuchids and scylacosaurids were extinct, and the saber-toothed gorgonopsians had taken
40 over as the dominant large-bodied therapsid predators (Smith et al., 2012; Kammerer et al.,
41 2015). The surviving late Permian therocephalians all belong to the subclade Eutherocephalia,
42 which were predominantly small-bodied animals (skull length ≤ 10 cm), many of which were
43 likely insectivores (Mendrez, 1975; Kemp, 1986; Huttenlocker, 2009). A few eutherocephalians
44 re-evolved large size and inferred macropredatory habits by the end of the Permian (e.g., the
45 whaitsiid *Theriongnathus* and the akidnognathid *Moschorhinus*), but these taxa died out as a
46 result of the end-Permian mass extinction (*Moschorhinus* survived the main extinction pulse, but
47 disappears from the record shortly thereafter, making it an example of a ‘dead clade walking’;
48 Jablonski, 2002; Huttenlocker & Botha-Brink, 2013; Huttenlocker, 2014). Remarkably, despite
49 major losses in the end-Permian mass extinction, therocephalians managed to reinvent
50 themselves yet again, with a moderately successful third act as small-bodied herbivores (the

51 Bauriamorpha) in the Early–Middle Triassic (Sigogneau-Russell & Sun, 1981; Abdala et al.,
52 2014) before the clade was finally lost for good.

53 Basal theriocephalians (lycosuchids and scylacosaurids) are the most common tetrapod
54 predators in middle and earliest late Permian deposits in South Africa, with hundreds of known
55 specimens (Smith et al., 2012) and 55 named species (although this number is clearly oversplit;
56 van den Heever, 1987). By contrast, very few basal theriocephalian fossils have been found in
57 comparably-aged Laurasian rocks, despite extensive records of anomodonts, dinocephalians,
58 and parareptiles from the middle Permian of China and Russia (Li, 2001; Ivakhnenko, 2003). No
59 theriocephalians have ever been found in middle Permian Chinese rocks. Historically, only a
60 single species of theriocephalian (*Porosteognathus efremovi*, a possible scylacosaurid from the
61 Isheevo locality, Apastovskii District, Tatarstan) was known from the middle Permian of Russia
62 (Vjuschkov 1955; Ivakhnenko 2011). Furthermore, *Porosteognathus* seems to be a minor
63 component of the Isheevo assemblage, which is dominated by dinocephalians and venyukovioid
64 anomodonts (many known from complete skulls and skeletons, whereas *Porosteognathus* is
65 known only from isolated skull bones).

66 The earliest Russian assemblage preserving a substantial number of theriocephalians is
67 the Kotelnich locality in Kirov Region. Although known since the 1930s as a source of
68 spectacularly-complete pareiasaurs (Hartmann-Weinberg, 1937), theriocephalians were not
69 described from Kotelnich until the 1990s (Tatarinov, 1995a, 1995b, 1997, 1999a, 1999b). Now,
70 however, they are the most species-rich tetrapod clade known from the site, with eight named
71 species (*Chlynovia serridentatus*, *Karenites ornamentatus*, *Kotelcephalon viatkensis*, *Muchia*
72 *microdenta*, *Perplexisaurus foveatus*, *Scalopodon tenuisfrons*, *Scalopodontes kotelnichi*, and
73 *Viatkosuchus sumini*), although these may be somewhat oversplit (Ivakhnenko, 2011). The age
74 of the Kotelnich assemblage is somewhat uncertain, with both middle and late Permian ages
75 having been proposed (Tatarinov, 2000; Benton et al., 2012). Currently, an early late Permian
76 age is considered most likely, possibly equivalent with the South African *Tropidostoma* AZ

77 based on anomodont comparisons (Kurkin, 2011). Benton et al. (2012) instead suggested
78 equivalency between the Kotelnich assemblage and the *Priesterognathus* AZ. However, the
79 described therocephalian fauna of Kotelnich is composed entirely of eutheriocephalians (which
80 other than *Viatkosuchus* are very small, i.e., <10 cm skull length), not the large scylacosaurids
81 or lycosuchids characteristic of the *Priesterognathus* AZ in South Africa.

82 Here we describe a new taxon representing the first large, basal (i.e., non-
83 eutheriocephalian) therocephalian from the Kotelnich locality. This species is represented by two
84 specimens and is the largest known predatory therapsid from Kotelnich, indicating
85 therocephalian occupation of apex predator niches in the Northern as well as Southern
86 Hemisphere during the transition between middle and late Permian tetrapod faunas.

102

103 **GEOLOGICAL CONTEXT**

104 The Kotelnich locality is a rich, tetrapod-bearing fossil assemblage in the Kirov Region of
105 European Russia. The first fossils found at this locality were two pareiasaur skeletons collected
106 by the hydrogeologist S. G. Kashtanov in 1933 (Kashtanov, 1934). Subsequent expeditions by
107 A. P. Hartmann-Weinberg (in 1935) and Kashtanov (in 1936) recovered additional pareiasaur
108 material (today all considered referable to *Deltavjatia rossica*; Benton et al., 2012; Tsuji, 2013).
109 Further expeditions by staff of the Paleontological Institute in Moscow occurred between the
110 1940s–1960s, collecting mostly *Deltavjatia* specimens (see, e.g., Efremov & Vjuschkov, 1955).
111 Fossil collection at Kotelnich was renewed in the 1990s and has continued to the present day,
112 most recently through the efforts of the Vyatka Paleontological Museum in Kirov. These more
113 recent (1990s–present) excavations have revealed a substantially more diverse fauna than was
114 previously known, adding an array of anomodont, gorgonopsian, and therocephalian therapsids
115 as well as non-pareiasaurian parareptiles to the list of Kotelnich tetrapods (although *Deltavjatia*
116 remains the numerically dominant taxon; Benton et al., 2012).

117 Several fossiliferous layers are present at Kotelnich; the lowest red beds represent a
118 lacustrine or floodplain system which famously preserves numerous complete, fully articulated
119 skeletons of the mid-sized pareiasaur *Deltavjatia rossica*. This level (the Vanyushonki Member
120 of Coffa [1999]) has also produced the majority of synapsid finds, including spectacular
121 examples such as the complete, articulated specimen of the small gorgonopsian *Viatkogorgon*
122 *ivakhnenkoi* (Tatarinov, 1999a) and a block containing 15 skeletons of the arboreal anomodont
123 *Suminia getmanovi* (Fröbisch and Reisz, 2011). Although most Kotelnich tetrapods are found in
124 the red-brown mudstones at the base of the succession, plants, fish, and highly fragmentary
125 tetrapod remains (primarily isolated teeth) are also present in lenses of later deposition at the
126 top of the section (Benton et al., 2012).

127 The specimens of the new therocephalian described herein were all found in the lower
128 red beds (Vanyushonki Member). The holotype was discovered in 2008 by I. Shumov, 10.15

129 meters below the marker bed and 413 meters upstream from the village of Nizhnaya Vodskaya.
130 These specimens were mechanically prepared by O. Masyutina and are housed in the
131 collections of the Vyatka Paleontological Museum in Kirov.

138 ***Gorynychus*** gen. nov.

139

140 **LSID:** urn:lsid:zoobank.org:act:CD10EB7C-57C0-45BA-8467-75309411E0DD

141 **Type species:** *Gorynychus masyutinae* sp. nov.

142 **Etymology:** Named for the legendary Russian dragon Zmey Gorynych (Змей

143 Горыныч), in reference to the fearsome appearance of this taxon and its status as the largest

144 known predator in the Kotelnich assemblage. Also a play on the English word ‘gory’ (meaning

145 bloody) and the Ancient Greek ὄνυχος (Latinized ‘onychus’, meaning claw), in reference to this

146 taxon’s inferred behavior being ‘red in tooth and claw.’

147 **Diagnosis:** As for type and only species.

148

149 ***Gorynychus masyutinae*** sp. nov.

150 (Figs. 1–11)

151

152 **LSID:** urn:lsid:zoobank.org:act:105CB020-2584-4AD1-BF98-2B555EE69644

153 **Holotype:** KPM 346–349 (Figs. 1–9), a single individual (skull and cervical vertebrae in

154 articulation, pectoral and rib elements disarticulated but directly associated with skull) broken

155 into four pieces: KPM 346, a nearly complete skull (with damaged intertemporal region, occiput,
156 and left temporal arcade) and lower jaws with the anterior 4 1/2 cervicals in articulation; KPM
157 347, postcranial elements including remaining half of fifth cervical (precise break, originally
158 articulated with anterior portion) and worn sixth and seventh cervicals, ribs, partial clavicle, and
159 left scapulocoracoid impression; KPM 348, isolated but associated incisor with intact crown; and
160 KPM 349, isolated but associated incisor with damaged crown.

161 **Referred material:** KPM 291 (Figs. 10, 11A–C), a block of fragmentary, disarticulated
162 elements including the anterior portion of a partial right dentary, an isolated incisor, a jugal, at
163 least four vertebrae, several ribs, a fibula, and various indeterminate bone fragments. KPM
164 448/1 (Fig. 11D), an isolated incisor with damaged root.

165 **Etymology:** Named in honor of Olga Masyutina for her skillful preparation of the
166 holotype of this taxon, as well as numerous other important specimens from the Kotelnich
167 locality.

168 **Diagnosis:** Therocephalian distinguished from all other members of the group by its
169 autapomorphic dental morphology: all marginal teeth serrated, with serrations forming distinct
170 denticles that are especially prominent on the incisors and postcanines. Postcanines ‘spade’-
171 shaped and reduced in number (three in the maxilla) relative to most therocephalians. Further
172 distinguished from the other known Russian basal therocephalian *Porosteognathus efremovi* by
173 a shorter tooth row on the pterygoid transverse process situated on a more discrete, raised boss
174 and an anterolaterally-curved and expanded pterygoid palatal boss with fewer (8–9) teeth
175 (transversely broad with ~14 teeth in *Porosteognathus*).

176

177 DESCRIPTION

178 The holotype is generally well preserved (Fig. 1), with good bone quality showing surface
179 ornamentation and sutural boundaries on most of the snout and palate (Figs. 2–7). However,
180 the skull is somewhat crushed, the left temporal arch is broken off, and the intertemporal region

181 is badly eroded. The anterior five cervicals are reasonably well preserved (although the atlas is
182 not exposed as prepared), but the subsequent members of the series are badly worn (Fig. 8).
183 Other postcranial elements are broken and worn, and the scapulocoracoid is preserved mainly
184 as an impression (Fig. 9). The more extensive of the two referred specimens is a single block of
185 disarticulated, fragmentary elements (Fig. 10), although most of these elements show good
186 bone preservation (Fig. 11A–C). One of these elements, an isolated incisor with intact crown,
187 can confidently be referred to *Gorynychus masyutinae* based on the presence of very large,
188 curved denticles on its mediobasal edges. The dentary fragment also has a tall, robust
189 symphysis identical to that of the holotype; although it is possible this could represent a
190 gorgonopsian, the only gorgonopsians known from this locality are much smaller and actually
191 have weakly-developed dentary symphyses. Given the absence of any other material that is not
192 consistent with identification as *Gorynychus* and the lack of overlapping elements, this set of
193 fossils is interpreted to be the remains of a single *Gorynychus* individual. An additional isolated
194 tooth (KPM 448/1; Fig. 11D) exhibits the same denticulation and general morphology as those
195 of KPM 348 and KPM 291 (Figs. 2C, 11C) and can also be referred to *Gorynychus masyutinae*.

196

197 *Cranium*

198 The cranium of KPM 346 is 173 mm in standard basal length (from anteroventral edge of
199 premaxilla to posteroventral edge of occipital condyle) and 208 mm in total dorsal length (from
200 tip of snout to edge of temporal fenestra).

201 The palatal portion of the premaxilla is not exposed in the holotype because of occlusion
202 of the lower jaw. The only information available concerning the ventral surface of the premaxilla
203 comes from the edges of the incisor alveoli. Based on this, *Gorynychus* appears to have had an
204 upper incisor count of five. Although no incisors are preserved in place, two isolated teeth (KPM
205 348 and 349) preserved in association with the skull have root proportions identical to the empty
206 alveoli and are here interpreted as the upper incisors. Only one of these teeth (KPM 348)

207 preserves an intact crown (Fig. 2C). The crown of KPM 348 is elongate, triangular, and weakly
208 recurved with prominent mesiodistal serrations forming distinct denticles. The morphology of
209 these denticles is unique among therocephalians: they are extremely prominent, extend from
210 the tip of the crown right to the root, and each individual denticle is curved in the apical direction.
211 This only comparable morphology among therocephalians occurs in the postcanines of this
212 same specimen. The cutting edges of KPM 348 are heavily worn, but this wear is asymmetrical.
213 As shown in Figure 2C, one side of the tooth (it is uncertain whether this is the mesial or distal
214 side) has more of its margin worn down than the other. The same style of asymmetrical wear,
215 but with the sides reversed, is present on KPM 448/1 (Fig. 11D). The isolated incisor of KPM
216 291, by contrast, is relatively unworn (Fig. 11C). It is uncertain whether this is simply due to
217 recent eruption before the death of the animal or from occupying a different position in the tooth
218 row (its crown is shorter and slightly more curved than in KPM 348 or KPM 448/1, which could
219 be because it represents a more posterior tooth position or a lower incisor).

220 The facial surface of the premaxilla is overlain by the maxilla posteriorly, near the point
221 between the alveoli for I4 and I5 (Figs. 2, 4, 5). The bone surface of the premaxilla is rugose,
222 with a series of well-developed foramina located 3–4 mm above the alveolar margin. Anteriorly,
223 three foramina are situated in a distinct channel that originates vertically beneath the internarial
224 bar then curves posterolaterally (Fig. 2B). The first and third foramina in this channel are small
225 (<1 mm diameter), but the second is large (1 mm diameter) and situated deep inside the
226 groove. Posterior to this channel, several additional foramina are present on the lateral face of
227 the premaxilla. The internarial bar is angled somewhat anteriorly, such that it overhangs the
228 alveolar portion of the premaxilla in lateral view (Fig. 4). The ascending ramus of the premaxilla
229 frames the anterodorsal border of the external naris and terminates near the posterodorsal
230 narial border.

231 The septomaxilla consists of a broad ventral plate making up the base of the external
232 naris, a constricted intranarial portion, and a facial process extending between the maxilla and

233 nasal (Figs. 2, 4, 5). The ventral plate of the septomaxilla is situated immediately dorsal to the
234 premaxillary-maxillary suture. Immediately ventral to this plate is a large, ovoid foramen (1.5 mm
235 diameter) that spans the premaxillary-maxillary suture. A weak groove extends anterior to this
236 foramen for the length of the ventral plate of the septomaxilla. The constricted intranarial portion
237 of the septomaxilla separates the main portion of the external naris from the maxillo-
238 septomaxillary foramen. It has a pointed, anteromedially-directed anterior process as is typical
239 of therocephalians, but not an expanded transverse lamina as in gorgonopsians.
240 Posterodorsally, the septomaxilla makes a broad, irregular contribution to the facial portion of
241 the snout. This facial process notably does not make up the entire posterior margin of the
242 external naris—the nasal occupies the posterodorsal narial corner (Fig. 2B).

243 The maxilla is a tall, gently curved bone making up the main lateral surface of the snout
244 (Figs. 4, 5). The facial surface of the maxilla is intensely sculptured with shallow, crater-like
245 structures and small foramina, similar to that of some other basal therocephalians (see, e.g.,
246 Abdala et al., 2008). A labial emargination is absent, unlike in *Lycosuchus*. The posterior
247 terminus of the maxilla is a process under the jugal that reaches the midpoint of the orbit. The
248 tip of this process is notably expanded and rugose, but the majority of this process is notable for
249 lacking the dermal sculpturing so prominent on the rest of the maxilla and bearing a weak lateral
250 groove. The maxilla houses four teeth: the enlarged, blade-like canine and three small
251 postcanines. The canine is recurved and has well-developed serrations fore and aft, as is usual
252 in basal therocephalians (van den Heever, 1994; Abdala et al., 2014). Only a single canine is
253 erupted on each side; unlike the usual condition in lycosuchids and a frequent condition in
254 scylacosaurids, there are not simultaneously-occupied anterior and posterior canine alveoli. The
255 tip of a replacement canine is erupting anterior to the right canine, however. The postcanine
256 morphology of *Gorynychus* is unique among therocephalians—these teeth are labiolingually
257 compressed and ‘leaf’ or ‘spade’-shaped, with proportionally large denticles (serrations) along
258 both mesial and distal edges (Fig. 6). Although these denticles are not as large or exaggeratedly

259 curved as those on the incisors, they still show distinct curvature (unlike the finer, straight
260 serrations on the canine). As for the premaxilla, the palatal surface of the maxilla is for the most
261 part not visible in this specimen.

262 The nasal is a long, flat bone (Figs. 2–5). It also bears dermal sculpturing, albeit
263 developed to a lesser degree than in the facial portion of the maxilla. Dermal sculpturing to
264 some degree is present on all the bones of the snout, including (albeit very weakly) on the facial
265 portion of the jugal. The naso-frontal suture is slightly bowed posteriorly and terminates near the
266 anterior margin of the orbit.

267 The prefrontal is a roughly trapezoidal bone making up part of the snout and the
268 anterodorsal margin of the orbit (Figs. 3–5). Its contribution to the orbital rim is unusually
269 pronounced and rugose. This is also true for the lacrimal, jugal, and frontal, such that that the
270 circumorbital rim is very prominent everywhere but on the postorbital bar. Anteriorly, the
271 prefrontal terminates in a short process extending between the maxilla and nasal. The prefrontal
272 makes up a large portion (roughly half) of the anterior face of the orbital wall, and appears to
273 exclude the frontal from contacting the lacrimal.

274 The lacrimal is a large facial bone, nearly equivalent in height to the prefrontal albeit not
275 as anteroposteriorly long (Figs. 4, 5). A similarly-sized lacrimal is also present in *Lycosuchus*,
276 and although this bone is less dorsoventrally expanded in scylacosaurids it is of similar
277 anteroposterior dimensions in that group as well (van den Heever, 1994). A large (1.5 mm
278 diameter) lacrimal foramen is present on its contribution to the anterior orbital wall; this foramen
279 does not exit onto the lateral surface. A second, smaller lacrimal foramen may be present
280 ventral to the first, but this is uncertain because of damage.

281 The jugal makes up the majority of the zygomatic arch (Fig. 4). Its facial portion is an
282 attenuate process terminating below the lacrimal, posterior to the anterior lacrimal margin. This
283 facial portion is remarkably small for an early theriodont. In gorgonopsians, the jugal typically
284 terminates in a broad, plate-like contribution to the snout equalling (or exceeding) the lacrimal in

285 anterior extent (see, e.g., Kammerer, 2015; Kammerer et al., 2015). In *Lycosuchus* and other
286 early therocephalians, the facial portion of the jugal terminates well posterior to the anterior
287 edge of the lacrimal, but still forms a tall plate on the snout and occupies almost the entire
288 ventral margin of the orbit (van den Heever, 1994). The jugal is constricted beneath the
289 posterior margin of the orbit, before expanding to form a major part of the postorbital bar. In the
290 postorbital bar, an ascending process of the jugal extends dorsally behind the postorbital.
291 Posterior to the postorbital bar the jugal makes a tall contribution to the subtemporal bar,
292 narrowing posteriorly and curving downwards. In the posterior half of the subtemporal bar, the
293 jugal is bifurcated by an anterior process of the squamosal. The ventral portion of the jugal
294 extends nearly to the back of the skull, and has a weakly bulbous terminus. In addition to being
295 preserved in the holotype, an isolated jugal is present on the referred block (Fig. 10), identifiable
296 by the characteristic subtemporal curvature and well-developed process contributing to the
297 postorbital bar.

298 The squamosal is preserved mainly in its zygomatic ramus (Fig. 4), as the occiput and
299 intertemporal region are poorly preserved in this specimen (Fig. 1). It has a deep and fairly
300 restricted squamosal sulcus, giving it a 'forked' appearance in lateral view. Medially, it forms the
301 posterior portion of the lateral margin of the temporal fenestra (anteriorly, this margin is formed
302 by the jugal).

303 The frontal is a mostly-flat bone making up the interorbital skull roof (Fig. 3). The medial
304 portion of the frontal is damaged in this specimen, but its contribution to the orbit is well
305 preserved and shows that it was only weakly ornamented dorsally, until the very edge of the
306 orbit (in which it is expanded and rugose, like most of the circumorbital rim). The suture between
307 the frontal and postorbital is poorly preserved and difficult to interpret, but it appears that the
308 frontal makes only a narrow contribution to the dorsal orbital wall (Fig. 4), as in *Lycosuchus* (van
309 den Heever, 1994).

310 A distinct postfrontal is absent in *Gorynychus*; this element may be fused with the
311 postorbital. The postorbital makes up a broad portion of the skull roof at the posterodorsal
312 margin of the orbit and continues as a posterior ramus making up the medial face of the
313 temporal fenestra (Figs. 3, 4). The latter ramus is badly damaged in this specimen, like most of
314 the posterior skull roof, and its posterior terminus and surface texture is indeterminable. The
315 intertemporal bar is narrow, as its typical of therocephalians. However, this region is too
316 damaged to determine its exact proportions or presence/absence of the pineal foramen or
317 sagittal crest. The occiput is even more badly damaged, being worn off entirely dorsal to the
318 occipital condyle (Fig. 5).

319 The vomer is not exposed anteriorly, but its posterior interchoanal portion is a tall,
320 narrow blade, like that of scylacosaurids and unlike the broad, vaulted morphology of
321 *Lycosuchus* (Fig. 7). The vomer is paired—a distinct mid-vomerine suture is visible in the
322 interchoanal portion. Posteriorly, the vomer forms a broad, triangular contribution to the palate,
323 extending between the palatines to contact the anterior margin of the pterygoids posteriorly. An
324 elongate palatal depression or fossa is present medially, originating near the anterior edge of
325 the plate-like palatal portion of the vomer and extending posteriorly until it reaches the
326 transverse processes of the pterygoids. Although the depth of this structure is likely
327 exaggerated by lateral compression in this specimen, its presence is natural.

328 The palatine is the largest bone of the palate (Fig. 7). It is a topologically complex
329 element composed of a laminar anterior process that forms much of the lateral margin of the
330 choana and a broad main portion with a prominent central ridge bounded by medial and lateral
331 depressions. This central ridge extends anterolaterally to posteromedially and is confluent
332 posteriorly with a ridge on the pterygoid, terminating with the palatal boss. A suborbital fenestra,
333 characteristic of therocephalians, is present at its posterolateral margin, bounded posteriorly by
334 the pterygoid. Presumably it is also bounded laterally by the ectopterygoid, but this element is
335 indistinct if present, probably due to poor preservation of the lateral margins of the palate.

336 As is typical of early therapsids, the pterygoid consists of three distinct processes:
337 palatal, transverse, and quadrate (Fig. 7). The palatal portion of the pterygoid has an
338 anteromedial-to-posteromedially-angled, strongly interdigitated suture with the palatine.
339 Anteriorly it forms a short portion of the prominent palatal ridges (central ridge of palatine)
340 before expanding into the dentigerous palatal bosses posteriorly. Dentigerous palatal bosses
341 are ancestral for therapsids; although they are present in scylacosaurids and even various
342 eutheriocephalians (van den Heever, 1994; Huttenlocker & Smith, 2017), they are absent in
343 lycosuchids (*Lycosuchus* and *Simorhinella*) (Abdala et al., 2014). The palatal boss is 'teardrop'-
344 shaped, with a narrow posterior tip and broad, rounded anterior. It is curved anterolaterally. The
345 boss bears two tooth rows. On the left palatal boss (the more completely preserved of the two),
346 the posterior tooth row follows the curve of the boss and is made up of five teeth. The anterior
347 tooth row is transversely oriented and is made up of four teeth, for a total of nine (six are
348 present on the right boss, but as mentioned this boss is damaged and this is probably not the
349 complete complement of teeth). The transverse process of the pterygoid extends ventrolaterally:
350 it has a broad base medially, constricts in ventral view towards its midpoint, and then expands
351 into a rounded lateral tip where it braces the mandible. The anterior face of the transverse
352 process bears a broad, shallow depression. Unlike most therocephalians, but similar to
353 lycosuchids, the transverse process is dentigerous in *Gorynychus*. Unlike *Lycosuchus* and
354 *Simorhinella*, however, where the tooth row is relatively long (five teeth) and the teeth erupt
355 directly from the main ramus of the transverse process, in *Gorynychus* there are only 2–3 teeth
356 situated on discrete, ovoid bosses raised above the medial bases of the transverse processes.
357 On the right transverse process there are only two teeth, a large lateral and small medial one;
358 on the left there are three teeth of equal size, similar to the small one on the right. No
359 interpterygoid vacuity is present; although there is a weak depression between the transverse
360 processes medially, it is entirely bounded by bone dorsally. The quadrate process of the
361 pterygoid is situated dorsal to the transverse process. It extends posterolaterally from a position

362 near the medial base of the transverse process towards the quadrate, weakly curving along its
363 length. The anterolateral margin of the quadrate process forms a tall, narrow ridge;
364 posteromedially it forms a broad, concave plate bounding the lateral edge of the parasphenoid
365 rostrum.

366 The parasphenoid-basisphenoid complex forms a narrow median rostrum originating
367 behind the transverse processes of the pterygoids and extending posteriorly to the basal tubera
368 (Fig. 7). Although tall and blade-like posteriorly, the anterior two-thirds of this complex are
369 divided by a narrow median groove. The posterior terminus of the rostrum is abrupt, with a
370 sharp drop to the base of the basal tubera (typical of early therocephalians) instead of a gradual
371 decrease in height. Dorsally, the parasphenoid forms a narrow median lamina above the
372 pterygoid, forming part of the mid-orbital plate (Fig. 5). Dorsal to this anteriorly is a tall, laminar
373 bone interpreted as the orbitosphenoid, which extends dorsally to contact the frontal-postorbital
374 wall of the orbit. Dorsal to it posteriorly is the epipterygoid, which has an anteroposteriorly broad
375 footplate ventrally that sits atop the pterygoid. The ascending process of the epipterygoid
376 narrows dorsally before expanding again at its contact with the ventral face of the parietal. The
377 basal tubera are broadly separated by a median depression (Fig. 7). They are relatively slender
378 and angled medially at their posterior end. The left stapes is preserved in place, extending from
379 the basal tuber to near the quadrate. The stapes is dorsoventrally narrow but anteroposteriorly
380 broad, although narrowing along its length laterally (similar to *Lycosuchus*). No foramen or
381 dorsal process is visible, but these could be obscured by matrix. The basioccipital forms a plate
382 posterior to the basal tubera and terminates in the occipital condyle, which is similar to that of
383 other therocephalians.

384 The dentary is a massive, robust bone with a tall, well-developed, unfused symphysis
385 more similar to that of gorgonopsians than other early therocephalians (Figs. 2, 4, 5, 11A). The
386 anterior face of the symphysis is densely foraminated. The roots of at least three incisors are
387 exposed due to damage to the right dentary (Fig. 4), but it is probable that more were present,

388 given that these three do not occupy the entirety of the symphyseal length. The crowns of the
389 lower incisors are not exposed. The lower canine is not exposed in the holotype but is well-
390 preserved in the disarticulated dentary fragment in KPM 291 (Figs. 10, 11A). The lower canine
391 is a tall, recurved tooth with well-developed fore and aft serrations. It is proportionally large,
392 taking up much of the alveolar margin of the symphysis. Based on this position, it would have
393 been situated anterior to the upper canine when in occlusion with the cranium. The lower
394 postcanines are mostly obscured in both known specimens of *Gorynychus*, only a single small
395 lower postcanine is exposed on the right mandibular ramus anterior to the upper PC1 in the
396 holotype. This postcanine is smaller than any of the upper postcanines (2 mm apicobasal
397 length, versus 4 mm in the uppers) but is otherwise similar in morphology, being 'spade'-shaped
398 with well-developed denticulation. The dentary is constricted behind the symphysis, then
399 expands posteriorly, with a well-developed angular process (Fig. 4). The dorsal and ventral
400 margins have raised edges, and a distinct lateral fossa is present between them, extending
401 anteriorly almost to the level of the symphysis. Although superficially similar to the masseteric
402 fossa of cynodonts, this fossa is likely non-homologous; there is no evidence that the superficial
403 masseter was present in therocephalians. The raised ventral margin of the dentary terminates
404 posteriorly in a broad, flattened rugose region serving as the attachment site for adductor
405 musculature. The coronoid process extends freely above the postdentary bones and has a
406 broad posterodorsal terminus, as in the other basal therocephalians (van den Heever, 1994).
407 Unlike *Lycosuchus*, however, in which the posterior edge of the coronoid process is broadly
408 rounded, in *Gorynychus* this edge is nearly straight (slightly concave).

409 The postdentary bones are damaged on both sides of the skull: the surangular and
410 articular are more complete on the right side but the reflected lamina of the angular is broken off
411 ventrally; the surangular and posterior portion of the angular are broken off on the left side but
412 the reflected lamina is more complete (Figs. 4, 5). In general, the postdentary elements are very
413 similar to those of lycosuchids and scylacosaurids. The reflected lamina is large and occupies

414 the entire lateral surface of the angular (typical of early therapsids, but distinct from
415 gorgonopsians in which it is usually widely separated from the articular). The surface structure
416 of the reflected lamina is typical of early therocephalians: an anterodorsal depression becoming
417 a single broad ridge posteroventrally that then ramifies into ventral and posterior ridges. The
418 surangular is exposed laterally as a narrow, curved element atop the angular, contacting the
419 articular posteroventrally. A short angle is present at the posterior base of the coronoid process
420 of the dentary where it overlies the surangular, and the dentary is weakly raised laterally anterior
421 to this point, accommodating the internal anterior process of the surangular. The splenial is a
422 tall, 'ribbon'-like bone occupying the medial face of the anterior portion of the jaw ramus (Fig. 7).
423 It lacks any lateral exposure, being restricted to the internal surface of the jaw. It covers almost
424 all of the medial surface of the dentary anteriorly, but decreased in height posteriorly before
425 terminating at the level of the transverse process of the pterygoid. Dorsal to the splenial is a
426 narrow, laminar bone: the prearticular. This element broadens posteriorly and becomes more
427 raised and rod-like posterior to the dentary, terminating in an indistinct contact with the articular.
428 Dorsal to the prearticular at roughly the mid-length of the jaw ramus is a short, narrow, laminar
429 element interpreted as being the coronoid. The articular is poorly preserved on both sides in this
430 specimen, but a bulbous, cup-like terminus articulating with the (equally poorly preserved)
431 quadrate can be discerned in medial view on the left side (Figs. 4, 7). Although mostly worn off,
432 the base of a large retroarticular process is present.

433

434 *Postcranium*

435 Little of the postcranium is preserved in the holotype of *Gorynychus masyutinae*. The majority of
436 the cervical series is preserved in articulation with the skull and some ribs and pectoral
437 elements are preserved posterior to this (Fig. 1). The atlas-axis complex is somewhat damaged
438 and obscured by the skull and surrounding matrix and C5-7 are broken and badly worn, but C3
439 and 4 are well-preserved and exposed on both sides (Fig. 8). The cervical vertebrae are

440 amphicoelous (except, presumably, the atlas) and are separated ventrally by small, wedge-
441 shaped intercentra. The transverse processes are short and blunt. At least one cervical rib is
442 preserved on the right side of the specimen in association with (but disarticulated from) vertebra
443 C3. This rib has a broadly falcate head and mediolaterally narrow main body. Well-developed,
444 stout prezygapophyses (12 mm anteroposterior length) extending anterior to the centra are
445 present in C3 and 4, contacting the associated postzygapophyses of the anterior vertebrae
446 ventrally (and slightly laterally, as the prezygapophysis bulges out somewhat at its anterodorsal
447 edge). No anapophyses are present. The neural spines of C3 (17 mm tall) and 4 are constricted
448 immediately above their point of origin but expand dorsally into broad, rounded tips
449 (anteroposteriorly 11 mm long in C3). The axial neural spine is definitely anteroposteriorly
450 broader than that of the subsequent vertebrae (Fig. 8), but its exact dimensions (including
451 height relative to subsequent neural spines) are uncertain due to crushing. An isolated vertebra
452 interpreted as the axis in the referred specimen KPM 291 preserves a tall, broad neural spine
453 (Fig. 10), suggesting that the axial spine was substantially taller and longer than subsequent
454 neural spines, as is typical for theriodonts (Jenkins, 1971). The other vertebrae preserved in
455 KPM 291 have relatively lower, longer centra and shorter neural spines (Fig. 11B) than those of
456 C3 and 4 in the holotype. They likely represent dorsals or even anterior caudals, although most
457 are too poorly preserved to identify with any confidence.

458 The non-vertebral postcranial elements in the holotype are mostly damaged (Fig. 9) The
459 remains of at least eight ribs are present, but little of their morphology is exposed other than
460 simple, curved shafts. A robust, curved elongate bone exposed in worn cross-section probably
461 represents the clavicle, but nothing more about its morphology can be said. The left
462 scapulocoracoid is preserved almost entirely as impression (there is a small chunk of actual
463 bone from the anterior margin of the procoracoid). This impression shows that the coracoid-
464 procoracoid base of the structure was very anteroposteriorly long. The scapula is broad
465 ventrally but narrows markedly dorsally, where it curves anteriorly at tip. A prominent ridge on

466 the scapula originates at the posterior margin of this element before curving anteriorly along the
467 length of the scapular spine. An elongate bone preserved as part of KPM 291 (Fig. 10) is here
468 identified as a fibula. This element lacks the curvature seen in the cervical-thoracic ribs on this
469 block and in KPM 347, and is too long to be a lumbar rib. Additionally, it is expanded at both
470 ends, unlike a rib. The morphology of this element is similar to the fibula of other
471 therocephalians, in which it is usually a narrow, simple bone (Fourie & Rubidge, 2009).

472

473 **PHYLOGENETIC ANALYSIS**

474 *Gorynychus masyutinae* was coded into a recent analysis of therocephalian interrelationships,
475 that of Huttenlocker & Smith (2017). This analysis (available as Supplemental Information)
476 includes 136 discrete-state characters and 58 taxa, including two newly added to the analysis:
477 *Gorynychus masyutinae*, coded based on personal examination of all known specimens, and
478 *Shiguaignathus wangi*, coded based on the figures in Liu & Abdala (2017). Analysis was
479 undertaken using heuristic searching in PAUP* (Swofford, 2002) v.4.0a (build 159), treating
480 *Biarmosuchus tener* as the outgroup. All characters were treated as unordered following
481 Huttenlocker & Smith (2017). Bootstrap analysis was done using “fast” stepwise addition for
482 1000 replicates.

483 1260 most parsimonious trees of length 383 were recovered (consistency index=0.420,
484 retention index=0.785). The strict consensus tree recovers *Gorynychus masyutinae* as the
485 sister-taxon of Eutherocephalia (i.e., Akidnognathidae+Whaitsioidea+Baurioidea) (Fig. 12). A
486 position outside of Eutherocephalia is supported by the presence of a paired vomer, serrations
487 on all marginal teeth, and teeth on the transverse process of the pterygoid in *Gorynychus* (all of
488 which are typically absent in eutherocephalians) and the absence of a well-developed
489 mandibular fenestra penetrating the jaw in lateral view. The absence of the postfrontal in
490 *Gorynychus* is a character shared with eutherocephalians to the exclusion of lycosuchids and
491 scylacosaurids (although this element is still variably present in some hofmeyriids). The addition

492 of *Gorynychus* adds substantial instability to the analysis of Huttenlocker & Smith (2017),
493 notably with the complete collapse of Whaitsioidea (although a core Hofmeyriidae composed of
494 *Hofmeyria*, *Ictidostoma*, and *Mirotenthes* is retained). Another Kotelnich taxon, *Perplexisaurus*,
495 also falls outside of Eutherocephalia in the current analysis, occupying the node between
496 Scylacosauridae and (*Gorynychus*+Eutherocephalia). In previous analyses, *Perplexisaurus* was
497 a highly unstable taxon generally occupying a position somewhere near the base of
498 Eutherocephalia (Huttenlocker & Sidor, 2016; Huttenlocker & Smith, 2017), so its continued
499 lability is not especially surprising.

500 The breakdown of one of the major eutherocephalian clades (Waitsioidea) as the sole
501 result of adding *Gorynychus* to the dataset indicates remarkably poor support for a group that,
502 on a strictly gestalt basis, seems to be very well-characterized. This problem can likely be
503 blamed on extensive homoplasy in Eutherocephalia, the mosaic of features present in
504 *Gorynychus*, as well as the need for additional sources of phylogenetic data. Existing
505 phylogenetic data sets for Therocephalia are heavily skewed towards craniodental characters;
506 for example, only 19/136 characters in Huttenlocker & Smith's (2017) analysis are postcranial.
507 Although cranial-focused analyses are typical for Therapsida (an artifact, in part, of preferential
508 collection of skulls by Karoo paleontologists during most of the 20th century), recent analyses of
509 synapsid relationships (e.g., Benson, 2012) have highlighted the importance of bringing more
510 robust sets of postcranial data to bear on phylogenetic problems in this clade. Before such data
511 can be incorporated into therocephalian analyses, however, more basic descriptive work on
512 therocephalian postcrania is needed. Although skeletons are now known for a wide array of
513 taxa, anatomical descriptions are currently available for only a select few (e.g., Kemp, 1986;
514 Fourie & Rubidge, 2009; Botha-Brink & Modesto, 2011; Fourie, 2013).

515

516 **DISCUSSION**

517 At roughly 20 cm in skull length, *Gorynychus* is the largest predatory component of the
518 Kotelnich tetrapod assemblage. Co-occurring gorgonopsians are substantially smaller, with skull
519 lengths less than 10 cm. The only other Kotelnich predators approaching *Gorynychus* in size
520 are the eutherocephalian *Viatkosuchus* (co-occurring with *Gorynychus* in the Vanyushonki
521 Member) and the burnetiamorph *Proburnetia* (known only from the holotypic mould from the
522 younger Sokol'ya Gora site) (Ivakhnenko, 2011; Benton et al., 2012). This situations parallels
523 that of middle–earliest late Permian faunas in South Africa (the *Tapinocephalus* and
524 *Priesterognathus* AZs), wherein the only gorgonopsians are small animals and therocephalians
525 are the larger-bodied predators (Kammerer, 2014). The Kotelnich predatory fauna is particularly
526 comparable to that of the *Priesterognathus* AZ; in the middle Permian *Tapinocephalus* AZ,
527 although large-bodied therocephalians were abundant, the apex predators were gigantic
528 anteosaurian dinocephalians. The extinction of anteosaurs at the end of the Capitanian left a
529 depauperate fauna with therocephalians momentarily atop the food chain (Day et al., 2015). It
530 was only following the later extinction of these basal therocephalians that gorgonopsians began
531 to diversify and cemented their position as the dominant large-bodied therapsid predators
532 (Kammerer et al., 2015).

533 Although the presence of a therocephalian apex predator and relatively small
534 gorgonopsians in Kotelnich indicates that the earliest South African records may accurately
535 reflect ancestral body size in these clades (rather than regional peculiarities), in other regards
536 the Kotelnich fauna differs markedly from that of the Karoo. The dominant herbivorous taxon in
537 the Kotelnich fauna, and most abundant tetrapod of any kind, is the pareiasaur *Deltavjatia*
538 (Tsuji, 2013). This pattern is in stark contrast to that of South Africa, where dicynodont
539 therapsids are numerically dominant in all middle–late Permian faunas (Smith et al., 2012).
540 Furthermore, this does not seem to be an isolated oddity, as the best-sampled later Permian
541 Russian tetrapod fauna (North Dvina, a.k.a. Sokolki) also has pareiasaurs (*Scutosaurus*) as the

542 dominant component (although there the top predator is the giant gorgonopsian *Inostrancevia*;
543 this inferred predator-prey pair represents the 'oligobiomorph community' of Ivakhnenko [2008]).

544 The therocephalian fauna in Kotelnich is also unusual even by comparison to the
545 *Pristerognathus* AZ. Although eutherocephalian fossils have been found in the *Pristerognathus*
546 AZ, they are rarer than scylacosaurids/lycosuchids and are relatively poorly known
547 (Huttenlocker & Smith, 2017). By contrast, eutherocephalians are the most abundant and
548 species-rich theriodonts at Kotelnich. As such, the Kotelnich fauna seems to capture a phase in
549 therocephalian evolution not well-represented in the South African record: the initial
550 diversification of Eutherocephalia. The recovery of *Gorynychus* as a taxon just outside of
551 Eutherocephalia, rather than a lycosuchid or scylacosaurid, adds another wrinkle to this
552 interpretation. The few eutherocephalians known from the *Pristerognathus* AZ belong to well-
553 known groups (the whaitsioid family Hofmeyriidae and baurioid family Ictidosuchidae) deeply
554 nested within Eutherocephalia and appear in the record seemingly without precedent. In
555 Kotelnich, however, there is a combination of taxa at the base of Eutherocephalia (*Gorynychus*,
556 possibly *Perplexisaurus*) and potential early representatives of known eutherocephalian families
557 (e.g., *Viatkosuchus*). This indicates substantial therocephalian diversification occurring in
558 Laurasia at the time, and suggest that eutherocephalians originated outside of the Karoo and
559 only later migrated to the basin.

560

561 **CONCLUSIONS**

562 Based on a complete skull and partial skeleton and two additional, fragmentary specimens, a
563 new therocephalian taxon, *Gorynychus masyutinae*, is described from the (probably) earliest
564 late Permian Kotelnich locality of Russia. *Gorynychus* is the largest known predatory tetrapod in
565 the Kotelnich assemblage, and demonstrates that therocephalians acted as top predators in
566 Russian as well as South African assemblages during the transition between typical middle and
567 late Permian terrestrial communities. Although falling outside of Eutherocephalia, *Gorynychus* is

568 more closely related to eutheriocephalians than to the large-bodied therocephalian predators of
569 southern Africa (and possibly earlier Permian assemblages in Russia, if *Porosteognathus* from
570 the middle Permian Isheevo fauna truly is a scylacosaurid). The Kotelnich therocephalian fauna
571 shows greater diversity of eutheriocephalians than probable coeval faunas in South Africa, and
572 suggests that initial diversification in this clade probably was not occurring in the Karoo Basin.

573

574 **ACKNOWLEDGEMENTS**

575 We thank director A. Toporov, curator T. Berestova, and the other staff members at the Vyatka
576 Paleontological Museum for all of their help. We thank Fernando Abdala and Jun Liu for their
577 helpful reviews of the original manuscript.

757 FIGURE CAPTIONS

758

759 **Figure 1. Holotype of *Gorynychus masyutinae*.** The two blocks (KPM 346 and 347) making
760 up the majority of the holotype shown in articulation. Holotype also includes two incisor teeth
761 (KPM 348 and 349) disarticulated from the skull but found in association (see Figs. 2C and
762 10D). Scale bar equals 5 cm. Photograph by Christian F. Kammerer. [planned for page width]

763

764 **Figure 2. Anterior snout and dentition of *Gorynychus masyutinae*.** (A) Photograph and (B)
765 interpretive drawing of the skull (KPM 346) in anterior view. (C) Disarticulated incisor (KPM 348)
766 associated with skull in presumed anterior or anterolateral view. Abbreviations: apc, anterior
767 premaxillary channel; mx, maxilla; na, nasal; nr, naris; pmx, premaxilla; smx, septomaxilla. Gray
768 coloration indicates matrix. Scale bars equal 1 cm. Photographs and drawing by Christian F.
769 Kammerer. [planned for page width]

770

771 **Figure 3. Holotype of *Gorynychus masyutinae* in dorsal view.** (A) Photograph and (B)
772 interpretive drawing of skull (KPM 346). Abbreviations: d, dentary; fr, frontal; j, jugal; la, lacrimal;
773 mx, maxilla; na, nasal; pmx, premaxilla; po, postorbital; prf, prefrontal; qpt, quadrate ramus of
774 pterygoid; smx, septomaxilla; sq, squamosal. Gray coloration indicates matrix, patterning
775 indicates eroded or broken bone surface. Scale bar equals 1 cm. Photograph and drawing by
776 Christian F. Kammerer. [planned for page width]

777

778 **Figure 4. Holotype of *Gorynychus masyutinae* in right lateral view.** (A) Photograph and (B)
779 interpretive drawing of skull (KPM 346). Abbreviations: ar, articular; C, upper canine; co,
780 coronoid process of dentary; d, dentary; fr, frontal; i, lower incisor; j, jugal; la, lacrimal; mx,
781 maxilla; na, nasal; pmx, premaxilla; prf, prefrontal; PC, upper postcanine; po, postorbital; q-qj,
782 quadrate-quadratojugal complex; rla, reflected lamina of angular; sa, surangular; smx,

783 septomaxilla; sq, squamosal; ss, squamosal sulcus. Gray coloration indicates matrix, patterning
784 indicates eroded or broken bone surface. Scale bar equals 1 cm. Photograph and drawing by
785 Christian F. Kammerer. [planned for page width]

786

787 **Figure 5. Holotype of *Gorynychus masyutinae* in left lateral view.** (A) Photograph and (B)
788 interpretive drawing of skull (KPM 346). Abbreviations: C, upper canine; co, coronoid process of
789 dentary; d, dentary; ept, epipterygoid; fr, frontal; j, jugal; la, lacrimal; mx, maxilla; na, nasal; os,
790 orbitosphenoid; pa, parietal; pmx, premaxilla; prf, prefrontal; PC, upper postcanine; po,
791 postorbital; qpt, quadrate ramus of pterygoid; rla, reflected lamina of angular; sa, surangular;
792 smx, septomaxilla. Gray coloration indicates matrix, patterning indicates eroded or broken bone
793 surface. Scale bar equals 1 cm. Photograph and drawing by Christian F. Kammerer. [planned
794 for page width]
