Background. Wound healing in skeletal muscle leads to tissue regeneration or the formation of fibrotic scar tissue and is dependent on the interactions between fibroblasts, myofibroblasts, myogenic cells, and cytokines, such as TGF- β 1. Historically, recapitulations of the *in vivo* myogenic tissue regeneration environment utilized simplified *in vitro* models lacking 3D tissue structure and cellular complexity. The objective of this study was to establish a 3D co-culture model of skeletal muscle fascicles through inclusion of multiple cell types normally found in the tissue niche and mimicking wound healing paradigms.

Methods. Three culture systems were compared: cell monolayers grown on 2D dishes and 3D tissues prepared via a self-assembly method or collagen 1-based hydrogel biofabrication. The myogenic impact of TGF- β 1 and mono-/co-culture strategies containing human dermal fibroblasts, myofibroblasts, and C2C12 mouse myoblasts was assessed in 2D and 3D environments. qPCR identified gene expression changes during fibroblast to myofibroblast and myoblast differentiation between culture conditions. Changes to cell phenotype and tissue morphology were characterized via immunostaining for myosin heavy chain, procollagen, and α -smooth muscle actin. Tissue elastic moduli were measured with parallel plate compression and atomic force microscopy systems, and a slack test was employed to quantify differences in tissue architecture and integrity.

Results. TGF- β 1 treatment improved myogenesis in 3D mono- and co-cultures, but not in 2D. The 3D TGF- β 1-treated self-assembled co-culture demonstrated the highest myogenin and collagen 1 gene expression, indicating that the inclusion of myofibroblasts significantly enhanced myogenesis beyond the capacity of fibroblasts or TGF- β 1-treatment in monocultures containing only myoblasts. These constructs possessed the greatest tissue stability, integrity, and muscle fiber organization, as demonstrated by their rapid and sustained shortening velocity during slack tests, and the highest Young's modulus of 6.55kPa, approximate half the stiffness of *in situ* muscle. Both self-assembled and hydrogel-based tissues yielded the most multinucleated, elongated, and aligned muscle fiber histology. In contrast, the equivalent 2D co-culture model treated with TGF- β 1 completely lacked myotube formation through suppression of myogenin gene expression.

Discussion. These results demonstrate that our 3D co-culture model treated with TGF- β 1 more closely mimics myogenesis *in vitro* than 2D or monoculture systems. Tissue engineering can be used to improve *in vitro* models for skeletal muscle development, discovery of therapeutics for muscle regeneration, and research and development of *in vitro* meat products. Critically, this study highlights the impact of TGF- β 1 and myofibroblasts as myogenesis accelerators across multiple tissue engineering platforms.

Skeletal muscle fascicle engineering is improved by co-culture with myofibroblasts and TGF- β 1

Abstract

Background. Wound healing in skeletal muscle leads to tissue regeneration or the formation of fibrotic scar tissue and is dependent on the interactions between fibroblasts, myofibroblasts, myogenic cells, and cytokines, such as TGF- β 1. Historically, recapitulations of the *in vivo* myogenic tissue regeneration environment utilized simplified *in vitro* models lacking 3D tissue structure and cellular complexity. The objective of this study was to establish a 3D co-culture model of skeletal muscle fascicles through inclusion of multiple cell types normally found in the tissue niche and mimicking wound healing paradigms.

Methods. Three culture systems were compared: cell monolayers grown on 2D dishes and 3D tissues prepared via a self-assembly method or collagen 1-based hydrogel biofabrication. The myogenic impact of TGF- β 1 and mono-/co-culture strategies containing human dermal fibroblasts, myofibroblasts, and C2C12 mouse myoblasts was assessed in 2D and 3D environments. qPCR identified gene expression changes during fibroblast to myofibroblast and myoblast differentiation between culture conditions. Changes to cell phenotype and tissue morphology were characterized via immunostaining for myosin heavy chain, procollagen, and α -smooth muscle actin. Tissue elastic moduli were measured with parallel plate compression and atomic force microscopy systems, and a slack test was employed to quantify differences in tissue architecture and integrity.

Results. TGF- β 1 treatment improved myogenesis in 3D mono- and co-cultures, but not in 2D. The 3D TGF- β 1-treated self-assembled co-culture demonstrated the highest myogenin and collagen 1 gene expression, indicating that the inclusion of myofibroblasts significantly enhanced myogenesis beyond the capacity of fibroblasts or TGF- β 1-treatment in monocultures containing only myoblasts. These constructs possessed the greatest tissue stability, integrity, and muscle fiber organization, as demonstrated by their rapid and sustained shortening velocity during slack tests, and the highest Young's modulus of 6.55kPA, approximate half the stiffness of *in situ* muscle. Both self-assembled and hydrogel-based tissues yielded the most multinucleated, elongated, and aligned muscle fiber histology. In contrast, the equivalent 2D co-culture model treated with TGF- β 1 completely lacked myotube formation through suppression of myogenin gene expression.

Discussion. These results demonstrate that our 3D co-culture model treated with TGF- β 1 more closely mimics myogenesis *in vitro* than 2D or monoculture systems. Tissue engineering can be used to improve *in vitro* models for skeletal muscle development, discovery of therapeutics for muscle regeneration, and research and development of *in vitro* meat products. Critically, this study highlights the impact of TGF- β 1 and myofibroblasts as myogenesis accelerators across multiple tissue engineering platforms.

Introduction

Muscle regeneration occurs when muscle fibers are damaged during exercise or injury and quiescent satellite cells are activated to a proliferative myoblast phenotype (Hill, Wernig, & Goldspink, 2003). They differentiate as they begin expressing the myogenic transcription factor myogenin (MYOG) and terminally exit the cell cycle. Their fusion with an injured muscle fiber or other myoblasts forms a nascent syncytial myofiber (Charge & Rudnicki, 2004; Le Grand & Rudnicki, 2007). Fibroblasts support and stabilize muscle fiber architecture and biomechanics through basement membrane synthesis and facilitate muscle regeneration with extracellular matrix (ECM) deposition and remodeling (Murphy, Lawson, Mathew, Hutcheson, & Kardon, 2011; Sandbo & Dulin, 2011; Sanes, 2003). The interaction between myoblasts and fibroblasts, two predominant cell types involved in skeletal muscle regeneration, with surrounding ECM and trophic factors determine healing outcomes. TGF- β 1, produced by multiple cell types during wound healing, is a primary mediator of the mechanical, biochemical, and cellular behaviors observed in the response of muscle to injury (Karataki, Fili, Philippou, & Koutsilieris, 2009). TGF- β 1 signaling differentiates fibroblasts into myofibroblasts, which are important producers of collagen I (COL I), the main protein component of scar tissue, and α -smooth muscle actin (α -SMA), a highly contractile form of actin (Mendias et al., 2012). Normally these proteins are transiently expressed during muscle regeneration and contribute to tissue remodeling by temporarily providing physical substrates and biochemical cues for muscle fiber regeneration, but excessive TGF- β 1-mediated myofibroblast activation leads to ECM accumulation and tissue stiffening that decreases the ability of myoblasts to regenerate muscle (Gilbert et al., 2010; Smith, Lee, Ward, Chambers, & Lieber, 2011).

The use of culture models consisting solely of myoblasts to investigate skeletal muscle regeneration is narrow in scope and validity and prevents effective screening of therapeutics. Using co-culture systems allows the bi-directional signaling between fibroblasts and myoblasts that attenuates and stabilizes myogenesis. Additionally, while 2D *in vitro* cell culture systems have demonstrable value, they are limited by a number of factors that have unwanted influence on cell behavior. After isolation, primary cells quickly lose their *in situ* characteristics in response to a mechanically and biochemically alien environment (Janson, Rietveld, Willemze, & El Ghalbzouri, 2013). Fibroblasts and muscle stems cells are particularly sensitive to mechanical stimulation, and the rigidity of substrata can mask the cellular responses under investigation (Engler, Sen, Sweeney, & Discher, 2006; Godbout et al., 2013). It is therefore highly valuable to further optimize the *in vitro* recapitulation of the *in vivo* environment. In this regard, myogenesis should be studied within the context of tissues rather than cell culture plates. Engineered tissue that contains aligned muscle fibers embedded within connective tissue is biomimetic to muscle fascicles observed *in vivo* (Turrina, Martinez-Gonzalez, & Stecco, 2013) and is therefore our design target for modeling skeletal muscle.

Signaling of profibrotic factors such as TGF- β 1 can deregulate the regenerative capacity of muscle and drive fibrosis when in excess (Lieber & Ward, 2013; Mann et al., 2011) but regularly contribute to muscle regeneration at moderate levels. The use of TGF- β 1 may therefore be a means to organize tissue-engineered skeletal muscle development *in vitro*. In this study, we have utilized TGF- β 1 supplementation in 3D self-assembled, scaffoldless tissue constructs (Gwyther et al., 2011) and collagen 1-based hydrogels consisting of monocultures of mouse myoblasts, human fibroblasts, or TGF- β 1-differentiated myofibroblasts, and their combination in co-culture. We found that TGF- β 1 signaling in 3D improves myogenesis in myoblast monocultures, and the presence of myofibroblasts further enhances this effect. Our scaffoldless self-assembled tissues and hydrogels both similarly possessed enhanced myogenesis, indicating this technique has wide applicability across a variety of skeletal muscle tissue engineering platforms. However, 2D experiments demonstrated an inhibition of myogenesis in both mono- and co-culture conditions. Our data suggest that 2D *in vitro* models of skeletal muscle are insufficient to provide a complete understanding of the idiosyncratic mechanisms of skeletal muscle regeneration. This information

underscores the necessity for replicating the *in vivo* environment *in vitro* by using tissue engineered culture models.

Materials and Methods

Cell and tissue culture

Cultures consisting solely of human neo-natal dermal fibroblasts (passage 4 hDFs, PCS-201-010, ATCC, Manassas, VA) or mouse myoblasts (pre-passage 4 C2C12s, CRL-1772, ATCC) were plated on standard cell culture plates at 1 k/cm² in growth media (GM) consisting of DMEM (Gibco, Waltham, MA), 10% fetal bovine serum (FBS, Hyclone, Pittsburg, PA), 1% penicillin/streptomycin (P/S, Gibco). To promote differentiation of fibroblasts to myofibroblasts, some fibroblasts were incubated with 1 ng/mL TGF- β 1 (PeproTech, Rocky Hill, NJ) for 6 days between P4 and P5. C2C12s and P4 fibroblasts and myofibroblasts were trypsinized, resuspended in GM, and seeded at a 1:1 ratio either on standard cell culture plates at 20 k/cm² or in 3D self-assembled tissue constructs. To develop 3D self-assembled tissues, cell suspensions were added into custom 2% agarose ring molds with a central post at 350K cells per millimeter of post diameter (Fig 1). Hydrogels were produced from a protocol adapted from Baaijens et. al [18] where 1.5×10^6 C2C12s alone or a 1:3 ratio of fibroblasts/myofibroblasts and C2C12s were resuspended in 42% GM, 54% rat collagen type 1 (3mg/mL, Corning Life Sciences), and 2.7% NaOH (0.5M). The hydrogel mixture was poured between house-shaped Velcro anchors super glued to the bottom of a six well plate and gelled for 45 minutes before adding GM. After 24 hours, media were switched to differentiation medium (DM) composed of DMEM, 2% horse serum (Sigma-Aldrich, St. Louis, MO), and 1% P/S, with or without 1 ng/mL TGF- β 1. Media was changed every 2-3 days for 7 days, after which cells and tissues underwent qPCR, ICC or IHC, or mechanical characterization. See Figure 1 for listing of experimental groups.

Gene expression analysis

Total RNA was isolated from cultures using TriZol reagent (Life Technologies, Carlsbad, CA) according to the manufacturers recommended instructions. cDNA was reverse transcribed from 1 μ g total RNA using qScript SuperMix (Quanta Biosciences, Gaithersburg, MD) according to manufacturers instructions. qPCR was carried out using a 5 ng equivalent of cDNA in a 1X

reaction of PerfeCTa SYBR Green SuperMix (Quanta Biosciences) and 250 nM each (forward and reverse) custom oligonucleotide primers (Integrated DNA Technologies, Coralville, IA) generated by using PrimerBlast (National Center for Biotechnology Information, Bethesda, MD). Reactions were carried out on an Eppendorf RealPlex2 qPCR system, and fold changes in gene expression were calculated using the $\Delta\Delta CT$ method using species-specific GAPDH primers. Primer sequences are listed in S1 Table. Human collagen 1 and α -SMA expression levels in the 2D FibCon condition were used as the reference group for fibroblast gene expression, and mouse myogenin gene expression levels of 2D MyoCon were used as a reference for myoblasts. N = 5 for all groups.

Immunostaining

2D and 3D cultures were assessed qualitatively with immunostaining. 2D cultures were fixed with 4% formaldehyde for 20 minutes, and 3D cultures were fixed for 2 hours. 3D self-assembled tissues were then submerged in OCT media, frozen for cryosectioning, sectioned at 30 μ m thick, and applied to glass slides. Hydrogels remained unsectioned for whole-mount imaging. After fixing, 2D and 3D samples were permeabilized with 0.1% Triton X-100 in PBS for 20 minutes, and then incubated with a blocking solution consisting of 5% FBS in PBS for 20 minutes. Following blocking, samples containing myoblasts were stained with rhodamine phalloidin (R415, 1:40 dilution, Life Technologies) and/or myosin heavy chain (MF-20, 1:50, Developmental Studies Hybridoma Bank, Iowa City, IA), procollagen (M-38, 1:50, Developmental Studies Hybridoma Bank) or α -SMA (A 2547, 1:1000, Sigma-Aldrich) primary antibodies. Primary antibody staining was followed by incubation with Alexa-Fluor 488 or 564 secondaries (1:250, Life Technologies) and DAPI (1:50,000, Invitrogen, Carlsbad, CA). Imaging of 2D samples was completed with an Olympus IX81 microscope (Olympus corporation of the Americas, Center Valley, PA), 3D self-assembled tissues were imaged with an Olympus Fluoview FV1000 Confocal Microscope, and hydrogels were imaged with an Olympus Fluoview FV1000MPE multiphoton microscope. All images were processed with ImageJ (Version 1.48, National Institute of Health, Bethesda, MD). The total area of procollagen staining was measured in 2D FibCon and FibTGF β images and divided by the total number of nuclei to find the average area of procollagen staining per cell. Increased area procollagen signal was extrapolated as a change of in cell shape and increased cell spreading. Circularity of DAPI stained fibroblast

nuclei was measured to compare changes in cyto- and nucleoskeletal shape. N = 13 images for each group. 2D MyoCon and CoCon images were also processed to measure changes in myotube alignment. In each image, the myotubes formed angles with a common axes (x or y). The standard deviations of the angles from each image were measured to compare the variation in each group, with smaller averaged standard deviations for one sample image indicating higher myotube alignment. N = 8-9 images for each sample.

Slack Test

The slack test method has been adapted by our lab to indirectly measure and compare tissue integrity, ECM maturity, and muscle fiber development between engineered samples. Self-assembled tissue constructs were released from tension in culture and their shortening lengths were recorded over time. The initial lengths (μm , L_i) of rings were recorded across their longest axis while they remained on their posts. Rings were then removed from the agarose posts, suspended in PBS (37°C) on a submerged horizontal microbeam from the Microsquisher system (CellScale, Ontario, Canada), and points across their longest axis were tracked to measure shortening every 3 minutes for 27 minutes. The final length (L_f) was divided by the initial length and multiplied by 100 to determine the percent shortening. Tissues were then stored in their respective medias for 24 hours at 37°C and imaged with a stereoscope. ImageJ was used to calculate the inner circumferential area (C_1) and outer circumferential area (C_2) of each ring. C_1 was divided by C_2 and multiplied by 100 to yield the percent of tissue area shrinking in CoCon and CoTGF β samples.

Tissue elastic moduli assessments

For calculations of the elastic stiffness of self-assembled engineered tissues, two methods of mechanical characterization were used: a compression-based system to generate slopes from stress-strain curves and atomic force microscopy (AFM). Tissue constructs were sectioned into 4-5 pieces with diameters between 250-500 μm and were compressed in a PBS fluid bath (pH 7.4, 37°C) using a Microsquisher (Cellscale). Tissues were compressed to 40% of their original diameter at a rate of 1% per second using microbeams with diameters between 0.2-0.3048 mm. Force-displacement curves were generated and the slope of the linear portion of the curve was

extrapolated as the elastic modulus of the tissue. Slopes were averaged for each 3D condition with N = 8-12 section samples per group.

Tissue elastic moduli were measured by an Asylum MFP3D-Bio AFM (Asylum Research, Santa Barbara, CA) through a nano-indentation method using MFP-3D software (Version 13.04.77). Force-distance curves were determined using equations 1 and 2:

$$1) F(\delta) = \frac{4\sqrt{R}}{3} \frac{E}{1-\nu^2} \delta^{3/2}$$

$$2) F(\delta) = \frac{E}{1-\nu^2} \frac{2 \tan \alpha}{\pi} \delta^2$$

Where F is the measured force, E is the local Young's modulus, R is the cantilever's tip radius (for a spherical tip), α is the cantilever's tip angle (for a cone tip), ν is the Poisson's ratio of the sample (assumed as 0.5 for an incompressible material), and δ is the sample indentation. Pyramidal tips with a nominal tip radius 20 nm, 200 μ m in length, 20 μ m in width, and a tip semi-angle of 15° on silicon nitride triangular V-shaped cantilevers with a nominal spring constant of 0.06 N/m (DNP-10; Bruker Inc., Camarillo, CA) were employed. The recorded force-distance curves were analyzed in MATLAB and statistical analysis was done using SPSS (Ver. 17.0, IBM, Somers, NY).

Statistics

Statistical analyses were performed with two-tailed unpaired t-tests and one-way ANOVAs using GraphPad Prism (Version 4, GraphPad Software) and statistical significance was defined as $p < 0.05$. Means are reported with standard error bars in bar graphs. Skew coefficients were calculated in Excel (Version 14.6.4, Microsoft).

Results

Fibroblast to myofibroblast differentiation is observed in 2D cultures treated with TGF- β 1, regardless of myoblast presence.

2D fibroblast-only cultures displayed increased α -SMA staining in TGF- β 1-treated samples (Fig 2A, B) and increased α -SMA gene expression ($p < 0.01$, Fig 3A), indicating their differentiation to myofibroblasts. There was no significant difference in collagen 1 transcription between any

2D conditions containing fibroblasts or myofibroblasts (Fig 3B), but post-translational control of the protein differed with TGF- β 1 treatment. Fibroblasts in the control group were spindle-shaped and displayed smaller areas of procollagen signal per cell nuclei (Fig 2C, I), while TGF- β 1 treatment significantly increased the area of procollagen staining per nuclei by 32.2 % ($p < 0.0001$, Fig 2D, I) and enhanced the secretion of procollagen out of the cell (red arrow in 2D). Nuclei circularity was also increased in 2D FibTGF β samples ($p < 0.0001$, Fig 2J), indicating a widening of the nucleoskeleton accompanying increased cell spreading, compared to the more elongated nuclear shape in control conditions. Enhanced cell proliferation was also observed with TGF- β 1 treatment ($p < 0.0001$, Fig 2K), as recorded by average number of nuclei per field of view. α -SMA gene expression in 2D CoCon samples was similar to transcript levels of the fibroblast-only control group, but was significantly upregulated in 2D CoTGF β conditions ($p < 0.01$, Fig 3A).

Myogenesis is suppressed in 2D cultures with TGF- β 1 supplementation and in the presence of fibroblasts, yet fibroblasts increase myotube alignment.

Robust myotube formation was present in 2D MyoCon samples (Fig 2E), decreased with exposure to TGF- β 1 (Fig 2F) or in co-culture with fibroblasts (Fig 2G), and completely inhibited in myofibroblast co-cultures supplemented with TGF- β 1 (Fig 2H). MYOG gene expression in the 2D MyoTGF β and 2D CoCon conditions were similar to each other and both displayed significant MYOG downregulation in comparison to 2D MyoCon. 2D co-cultures exposed to TGF- β 1 showed the lowest MYOG expression of any group ($p < 0.01$, Fig 3C). Notably, despite diminishing myogenesis, fibroblasts organized myotube formation by increasing their alignment in 2D CoCon samples ($p < 0.001$, Fig 2L).

In comparison to fibroblasts grown on plastic, self-assembled tissues containing only fibroblasts have a suppressed ability to assume a myofibroblast phenotype.

In comparison to 2D fibroblast-only controls, expression of procollagen was dramatically downregulated in fibroblast-only tissues, and this was not improved by TGF- β 1 exposure ($p < 0.01$, Fig 3B). α -SMA staining was absent in 3D FibCon samples (S1 Fig, A), but was somewhat increased with TGF- β 1 treatment (S1 Fig, C). 3D FibCon and FibTGF β α -SMA gene expression was transcriptionally downregulated to an even greater degree than procollagen, yet these values

were not significantly different from each other ($p < 0.01$, Fig 3A). Fibroblast/myofibroblast-only tissues were quite fragile; they would easily rupture during handling (arrow, Fig 4D) and would sometimes collapse, losing their annular shape (Fig 4C, F). Despite their fragility, their surfaces were smooth and homogenous (Fig 4S). Interestingly, the average thickness of constructs containing myofibroblasts treated with TGF- β 1 was 33.2 % larger than respective controls ($p < 0.01$, Fig. 5F), similar to the myofibroblast hypertrophy seen in 2D FibTGF β .

TGF- β 1 supplementation improves myoblast differentiation and alignment in myoblast-only self-assembled tissues.

3D myoblast-only groups differed in their degree of myogenesis and their myotube formation patterns. 3D MyoCon contained myotubes that had some degree of organization but generally weren't aligned (Fig 6A, B), whereas myoblast samples treated with TGF- β 1 had myotubes that were aligned along their circumferential axis (white filled arrow, Fig 6E, F). Gene expression profiles indicated that 3D MyoCon samples had significantly lower myogenin expression than both the 2D MyoCon control and 3D MyoTGF β condition ($p < 0.01$, Fig 3C), but the 2D control and 3D TGF β treated condition were not significantly different from each other. α -SMA was present in both untreated (Fig 6C, D) and TGF- β 1 treated (Fig 6G, H) myoblast constructs, but quantitative differences were not assessed. Observable in the α -SMA stained sections are fissures and breaks in the tissue (white asterisks, Fig 6C, G). Additionally, the surfaces of myoblast-only tissues presented nodular syncytium of fused myoblasts lacking the anchorage necessary to elongate and form myotubes (arrow, Fig 6I-K), and this was macroscopically observable (unfilled arrows, Fig 4T). Heterogeneous tissue patterning is also seen here, with many ripples along the tissue surface, large buds (filled arrow, Fig 4T), and regions of varying density.

In self-assembled co-cultures, fibroblasts and myofibroblasts homogenize tissue surfaces, myofibroblasts improve myotube formation, and TGF- β 1 enhances myogenesis.

Addition of fibroblasts or myofibroblasts smoothened the surface of co-culture tissues (Fig 4U), similarly to fibroblast- or myofibroblast-only samples, and these constructs lacked the studding of nodular syncytium seen in myoblast-only tissues. Co-culture conditions (Fig 4M, P) appeared visually denser than their fibroblast- (Fig 4A, D) and myoblast-only (Fig 4G, J) counterparts. Similar to the hypertrophy observed in 2D and 3D myofibroblast conditions treated with TGF-

$\beta 1$, CoTGF β tissues were 27.9 % thicker than CoCon ($p < 0.01$, Fig 5F). While human fibroblast/myofibroblast α -SMA gene expression was decreased in all 3D conditions compared to the 2D FibCon group, it was significantly higher in 3D CoCon and CoTGF β compared to 3D fibroblast-only tissues ($p < 0.01$, Fig 3A), and co-culture transcription levels were not influenced by TGF- $\beta 1$ supplementation. A non-species specific α -SMA antibody was visible within myotubes, where CoCon samples showed α -SMA within punctate and short myotubes (Fig 7A), while those in CoTGF β tissues were elongated and more mature (Fig 7C), indicating that TGF- $\beta 1$ facilitated the development of bundles of myotubes aligned in parallel. Additionally, collagen 1 expression was increased in 3D co-cultures compared to 3D fibroblast/myofibroblast-only cultures ($p < 0.01$, Fig 3B), but CoCon constructs were not significantly different from the 2D FibCon condition. Interestingly, collagen 1 gene expression was highest in 3D CoTGF β samples, which was also the condition of highest MYOG expression ($p < 0.01$).

3D CoCon constructs containing fibroblasts frequently presented dense bulges with thickened regions of cells composed of differentiating myoblasts (Fig 7E, F) between thinner regions absent of MyHC staining (Fig 7H, I); this heterogeneous tissue architecture can also be seen macroscopically (arrow, Fig 4M). CoCon constructs contained myotubes that were short but numerous. Some myotubes fused from one wall of the tissue to another, so that during sectioning, cross sections of myotubes are apparent (filled arrows, Fig 7E, F). In contrast, CoTGF β samples containing myofibroblasts had myotubes that were thicker and more multinucleated (Fig 7G, J, K). These tissues also had many cross-sections of myotubes (filled arrow, Fig 7J), but additionally contained much longer circumferentially aligned myotubes than in control co-culture samples (unfilled arrow, Fig 7G). MYOG expression in 3D CoTGF β constructs was significantly higher than all other groups ($p < 0.01$, Fig 3C), while MYOG expression in 3D CoCon constructs was suppressed compared to 2D MyoCon ($p < 0.01$), and was not significantly different from 3D MyoCon. This data demonstrates that addition of fibroblasts with myoblasts in 3D co-culture does not improve myogenesis beyond what is observed in cultures consisting solely of myoblasts, and TGF- $\beta 1$ supplementation is a myogenesis-promoting factor.

Zero-force velocity is greatest in co-culture with TGF- $\beta 1$ supplementation in slack tests

Slack tests are a measurement of zero force velocity tissue shortening resulting from the recoil of stretched elastic elements and myofibrillar filament sliding in sarcomeres. Slack tests assess acto-myosin kinetics that are independent of Ca^{2+} activation, which provides biomechanical information about extracellular matrix networking, MHC isoform and muscle fiber type, and muscle organ characteristics (Claflin & Faulkner, 1985; Josephson & Edman, 1998; Reggiani, 2007). The initial maximum lengths of self-assembled tissue constructs were recorded prior to removal from their posts (white arrow, Fig 5A). Constructs were then released from tension and their lengths measured every 3 minutes (Fig 4A, D, G, J, M, P) for 27 minutes (Fig 4B, E, H, K, N, Q) and allowed to slack over 24 hours (Fig 4C, F, I, L, O, R). These time points were selected because shortening was no longer visibly distinguishable after 25 minutes of the assay, but continued at a slowed rate over 24 hours. While all groups shortened significantly from their original size ($p < 0.001$, Fig 5B), tissues containing only fibroblasts or myofibroblasts shortened the least, with 3D FibCon remaining 87.3% and FibTGF β 85.4% their original size. Fibroblast/myofibroblast tissues were the only cell-content matched tissue group that did not display significantly different final length values from each other. Myoblast tissues underwent significantly greater shortening than fibroblast/myofibroblast samples: MyoCon rings shrank to 69.4% and MyoTGF β to 62.2% their initial diameter. Co-culture tissues underwent the greatest alteration, however. CoCon underwent the most significant shortening compared to all other groups (48.7%), and CoTGF β was the second most shortened group (55.1%). Plotting tissue length changes over time shows most of the length change occurs within the first 3 minutes and slows considerably by 15 minutes (Fig 5C), with co-culture samples displaying the highest velocities. Interestingly, after 24 hours, CoTGF β tissues (Fig 4R) showed an even greater degree of sample shortening than CoCon (Fig 4O). Since reference points for tracking changes in length were not conserved overnight, their inner circumferential areas (C_1) were divided by their respective outer circumferential areas (C_2 , Fig 5A) to yield percent differences in contraction between co-culture groups. CoCon constructs had significantly larger inner cross sectional areas than the CoTGF β conditions, indicating a greater degree of tissue shrinkage in TGF- β 1 treated co-culture rings ($p < 0.05$, Fig 5E). In summary, while TGF- β 1 exposure for fibroblast-only samples did not lead to significantly more zero-force shortening in comparison to untreated controls, TGF- β 1 positively impacted shortening of myotubes within myoblast-containing

tissues, and the interactions between TGF- β 1-treated myofibroblasts and myoblasts promoted the greatest degree of shortening.

Tissue elastic moduli increase in co-culture and with TGF- β 1 exposure.

Using the parallel plate compression system, the Young's modulus for sectioned self-assembled tissues was determined to be 2.04 kPa for FibCon, 0.81 kPa for FibTGF β , 3.32 kPa for MyoCon, 3.86 kPa for MyoTGF β , 4.47 kPa for CoCon, and 6.55 kPa for CoTGF β (Fig 5H). FibCon and FibTGF β tissues were significantly softer than CoCon and CoTGF β ($p < 0.001$). While MyoCon and MyoTGF β were also significantly softer than CoTGF β ($p < 0.001$), TGF- β 1 did not significantly increase stiffness of samples containing only myoblasts. Similarly, while TGF- β 1 treatment increased the stiffness of CoTGF β , it was not a significant increase with respect to CoCon. Consequently, AFM was used to increase the sensitivity of measurements of elasticity at the tissue surface. AFM generated Young's moduli of 2.66 kPa for MyoCon, 3.64 kPa for CoCon, and 6.02 kPa for CoTGF β , with all groups being significantly different from one another ($p < 0.01$, Fig 5I).

Supplementation with TGF- β 1 and addition of myofibroblasts enhances myogenesis in collagen 1-based hydrogels.

MyoCon, MyoTGF β , CoCon, and CoTGF β hydrogels were imaged for myosin heavy chain. In the myoblast control condition lacking TGF- β 1 supplementation, some MyHC was present in unfused mononuclear cells, but observable myotube formation was absent (Fig 8A). In contrast, TGF- β 1-treated myoblast hydrogels showed robust myotube formation, with somewhat inconsistent alignment orientations (Fig 8B). Without supplementation with TGF- β 1, co-cultures with fibroblasts and myoblasts showed small and immature myotube-shaped cells (Fig 8C), in contrast to its TGF- β 1-treated counterpart containing myofibroblasts (Fig 8D). CoTGF β hydrogels yielded the thickest and longest muscle fibers of any condition and possessed the highest degree of multinucleation. These muscle fibers also demonstrated the best alignment. CoTGF β hydrogels were also more visibly contracted in their culture wells than other conditions (Fig 8E), although MyoTGF β hydrogels displayed a lesser degree of contraction. Contraction of MyoCon and CoCon hydrogels was not observed.

Discussion

These experiments investigated the impact of tissue remodeling and ECM deposition on the biomechanical tissue niche; TGF- β 1 signaling; and cell-cell signaling between fibroblasts, myofibroblasts, and myoblasts on *in vitro* simulations of myogenesis. Our data demonstrates that transitioning from 2D to 3D culture systems has a profound impact on gene and protein expression involved in mechanotransduction. Consistent with other literature, TGF- β 1 differentiated fibroblasts to myofibroblasts in 2D cultures containing only fibroblasts (Dahl, Ribeiro, & Lammerding, 2008; Dong et al., 2013; Sandbo & Dulin, 2011), but switching to a 3D culture equivalent resulted in suppression of myofibroblast markers. Additionally, myoblasts have been reported to assume a myofibroblast-like phenotype with TGF- β 1 exposure in 2D (Cencetti, Bernacchioni, Nincheri, Donati, & Bruni, 2010; Charge & Rudnicki, 2004; Filvaroff, Ebner, & Derynck, 1994; Li et al., 2004), and our TGF- β 1 treated 2D cultures showed similar decreases in myogenecity in monocultures, with the myofibroblast co-culture displaying the most downregulated myogenin expression of any group. *In vivo*, however, while muscle fiber regeneration can be inhibited by exogenous TGF- β 1 (Filvaroff et al., 1994; Mendias et al., 2012), endogenous TGF- β 1 signaling plays an important role in myogenesis. Genetically truncating the type II TGF- β receptor in myoblasts arrests their ability to differentiate *in vivo*, indicating that TGF- β 1 signaling routinely contributes to muscle development and regeneration (Karalaki et al., 2009; Myhre & Pilgrim, 2012). In agreement with these studies, we found that TGF- β 1 supplementation improved myogenesis in our 3D muscle models, a reversal of the observations in 2D cultures.

The mechanism for TGF- β 1-mediated increases in myogenic differentiation and contractility highlights a differential effect of TGF- β 1 on myofibrillogenesis in 2D and 3D systems. Myofibrillogenesis initiates sarcomere development by increasing the dense packing of contractile and cytoskeletal proteins in muscle cells. During myofibrillogenesis, myofibrils are assembled from the framework of the actin cytoskeleton and undergo maturation by successive incorporation of proteins with increasing contractility. This process is driven by transmitting mechanical tension in the actin cytoskeleton to surrounding ECM through costameres (Sanger, Wang, Fan, White, & Sanger, 2010) and results in the development and alignment of sarcomeres

(Weist et al., 2013). TGF- β receptor activation increases cytoskeletal polymerization of α -SMA stress fibers in 2D culture platforms (Filvaroff et al., 1994), but also simultaneously has an inhibiting effect on myogenesis. However, since α -SMA is a precursor protein to sarcomeric actin in myofibrillogenesis, moderate TGF- β 1 levels in 3D may accelerate myofibrillogenesis through an α -SMA-mediated upregulation mechanism that could increase the tensional forces cells exert on their environment.

In 3D, fibroblasts and myofibroblasts benefit muscle regeneration through depositing ECM, organizing myoblast differentiation and myotube fusion, and stimulating myofibrillogenesis (Sanger et al., 2010; Turrina et al., 2013). Myotube formation dynamically remodels the biomechanical environment within muscle to further attenuate fibroblast and myofibroblast activity. *In vitro* cell traction studies have shown that myotubes exert 5-8 times greater traction forces on their substrates than fibroblasts, and these forces increase as myotubes mature (Dahl et al., 2008). Contracting myotubes transmit their forces to surrounding ECM through costameres and exert tensional forces throughout the muscle organ to facilitate contraction (Costa, 2014). This mechanism of force transmission could explain the greater recoil and shortening capacity in our co-culture tissues in contrast to myoblast-only samples with a suppressed ability to disperse forces to the surrounding ECM. The relative absence of supportive ECM for myotubes in self-assembled monocultures decreases the availability for integrin connections to the tissue microenvironment and reduces tensional forces applied to surrounding structures, resulting in less elastic recoil after being released from tension. Additionally, our data showing lower elastic moduli in 3D myoblast monocultures than co-cultures is congruent with the findings of Meyer and Lieber, who found the elastic stiffness of skeletal muscle fibers to be significantly dependent on the presence of ECM. In their study, dissected muscle fibers stripped of their extracellular matrix sheaths had four-fold lower elastic moduli than fascicles that retained their ECM (Meyer & Lieber, 2011).

3D fibroblast and myofibroblast co-cultures were distinct in their morphology, force transmission capacities, and biomechanical properties. The bundling of highly multinucleated myotubes in parallel within CoTGF β constructs was more similar to *in vivo* muscle fascicle morphology than fibroblast co-cultures, and was accompanied by the greatest upregulation in

myogenin expression of all groups. Enhanced muscle fiber maturation and patterning likely increased the magnitude of zero-force shortening in CoTGF β samples due to acto-myosin kinetics. This is in accordance with a study by Larkin et. al, who found that TGF- β 1 treatment of heterogeneous fibroblast and satellite cell populations in engineered muscle constructs increased their force generation capacities during electrical stimulation (Weist et al., 2013). Our study further identifies that the activation of myofibroblasts from fibroblasts benefits myogenesis during co-culturing with myoblasts, due in part to their enhanced ECM generation. The tenacity of myofibroblasts in co-culture is demonstrated through the highest collagen 1 gene expression of all conditions, where collagen 1 reinforcement likely improved tissue integrity and stiffness from TGF- β 1 treatment. Additionally, we have shown that TGF- β 1 treatment in monocultures of myoblasts also improves muscle differentiation in 3D tissue-engineered cultures.

Conclusions

The tissue-engineered TGF- β 1-treated myoblast and myofibroblast co-culture model is a promising candidate for therapeutic treatment of volumetric muscle loss and can be used as a screening tool for pharmaceutical trials on muscle regeneration. Additionally, this model can be used to improve meat quality of *in vitro* meat, which has experienced accelerated interest in recent years (Langelaana, 2010; Post, 2012). Because of growing awareness of the livestock sector's contribution to worsening climate change, deforestation of the rain forests, reductions in biodiversity, environmental degradation (Steinfeld, 2006), and increased bacterial resistance to antibiotics (Frieden, 2013), devising a sustainable solution for biomanufactured meat production is imperative. *In vitro* meat is a significantly more sustainable solution to traditional factory farming as it uses less food, water, and land resources; produces less greenhouse gases; requires less energy for production (Tuomisto & de Mattos, 2011); and does not require antibiotic misuse. Since meat quality is dependent, in part, on sarcomere development, muscle fiber type, and connective tissue content (Joo, Kim, Hwang, & Ryu, 2013), including TGF- β 1 as a cell culture media supplement and co-culturing muscle cells with myofibroblasts can produce meat with flavor and texture increasingly similar to that derived from livestock.

Although our self-assembled CoTGF β model of skeletal muscle achieved structural similarity to muscle fascicles, utilizing this self-assembly strategy for scale up of tissue engineering is not practical. Here we have shown that the CoTGF β technique can be used in hydrogel-based systems, which possess flexibility in design parameters to incorporate vasculature (Koffler et al., 2011; Levenberg et al., 2005). Additionally, electrical stimulation of muscle fibers further matures *in vitro* skeletal muscle models by accelerating sarcomere development (Langelaan et al., 2011) and increasing contraction force (Fuoco et al., 2015; Ito et al., 2014). Accordingly, applying vascularization and electrical stimulation regimens to TGF- β 1-treated myofibroblast co-cultures holds promise for skeletal muscle tissue engineering techniques to continue to improve their recapitulation of native muscle.

Acknowledgements

The authors thank Dr. Marsha Rolle at Worcester Polytechnic Institute for graciously providing a PDMS mold from which agarose molds were based, Dr. William Chillian at Northeast Ohio Medical University for supplying C2C12 cells for experiments, and Dr. Zhenyu Jia at Northeast Ohio Medical University for his assistance with the statistics used in this study.

Technical protocol for 2D/3D culture systems and experimental conditions design

(Upper) *Technique*: 2D cell culture and 3D tissue engineering protocols involve an initial high serum culture period on standard cell culture plates to separately amplify myoblast and fibroblast populations, with a subset of ‘preconditioned’ fibroblasts being treated with TGF- β 1 to differentiate them into myofibroblasts. After 6 days the cells are passaged and either replated on cell culture plates for 2D studies or used for 3D systems. Our 3D systems included a scaffoldless self-assembly method for tissue engineering and a collagen 1 hydrogel based-technique. A low serum culture period subsequently follows, lasting 7 days, and some groups are supplemented with TGF- β 1. The black arrow denotes the location of a tissue construct around the annulus inside an agarose mold, scale bar = 2mm. (Lower) *Conditions*: Experimental design is defined by comparisons between culture systems (2D culture plates vs 3D agarose gels/collagen 1-based hydrogels), cellular content (co-culture or monoculture of myoblasts, fibroblasts, or myofibroblasts), and their biochemical treatment in culture (\pm TGF- β 1). The resulting group identification terms code for the conditions investigated in these experiments.

Zero force shortening of self-assembled tissues and their surface characteristics

Tissue shortening was assessed when removed from agarose molds after 3 minutes, 27 minutes, and 24 hours. 3D FibCon (A-C), FibTGF β (D-F), MyoCon (G-I), MyoTGF β (J-L), CoCon (M-O), and CoTGF β tissue rings (P-R), with scale bars = 1000 μ m. The filled arrow in (D) indicates a structural rupture in the tissue, and the black arrow in (M) indicates thinned myoblast-free region of sample. Higher magnification images of FibCon (S), MyoTGF β (T), and CoTGF β tissues (U) show surface texture. In (T), the filled arrow is a large nodule on a MyoTGF β sample, and unfilled arrows indicate smaller syncytium, scale bars = 300 μ m.

Figure 5(on next page)

Biomechanical properties of self-assembled tissue constructs

(A) An agarose gel mold with central post and tissue of tissue skewered onto a microbeam from the Microsquisher system. The white arrow denotes the longest axis of the tissue used to track shortening from initial length. C_1 = inner circumferential area and C_2 = outer circumferential area used to measure shrinkage by tissue area, scale bar = 1000 μ m. (B) Percent (%) of initial length of the longest axis of tissue samples 27 minutes after their removal from agarose gels. All groups shortened from their original size significantly ($p < 0.001$), and the magnitude of change was significantly different between each group ($p < 0.05$), except for (a) and (b). (C) Tissue shortening rate of samples over time. (D) Image of the Microsquisher system used to obtain young's modulus of tissue sections (white asterisk), scale bar = 600 μ m. (E) The % area of (C_1) / (C_2) in CoCon and CoTGF β tissues after 24 hours of contraction. (F) Initial thickness of tissue samples, asterisks indicate $p < 0.001$. (G) Screenshot of AFM cantilever and sample (white asterisk), scale bar = 100 μ m. (H) Young's modulus of tissues generated from Microsquisher force-displacement data. (a) is significantly softer than (e) and (f); (b) is significantly softer than (c), (d), (e), and (f); and (c) and (d) are significantly softer than (f), with $p < 0.001$. (I) Young's modulus of MyoCon, CoCon, and CoTGF β tissues calculated by AFM, asterisks indicate $p < 0.01$. Graphs display group averages with standard error bars.

Figure 6(on next page)

Histology of self-assembled myoblast monocultures

3D MyoCon (A-D, I-K) and MyoTGF β constructs (E-H) are displayed with myosin heavy chain (A, E, I), MyHC merged with DAPI (B, F, K), and DAPI alone (J). α -SMA (C, G) and α -SMA merged with DAPI (D, H). White filled arrows indicate direction of alignment and anisotropy of myotubes (E), while unfilled arrows indicate unanchored syncytium (A, I), and white asterisks identify regions of tissue breakage (C, G), scale bars = 100 μ m.

Figure 7 (on next page)

Histology of self-assembled co-cultures

3D CoCon (A, B, E, F, H, I) and CoTGF β tissues (C, D, G, J, K). α -SMA (A, C) and α -SMA merged with DAPI (B, D). Myosin heavy chain staining of CoCon constructs (E, H), f-actin staining of E (F), and DAPI staining of H (I). MyHC staining of CoTGF β tissues (G, J, K) with DAPI and f-actin staining (J, K). (J) is an inset of G. White fill arrows indicate cross sections of myotubes observed with MyHC and actin staining, while unfilled arrows show elongated myotubes fused along circumferential axis of tissue rings, scale bar = 100 μ m.

Figure 8(on next page)

Histology of mono- and co-cultures in collagen 1-based hydrogels

Myosin heavy chain staining of MyoCon (A), MyoTGF β (B), CoCon (C), and CoTGF β (D) hydrogels. Scale bar = 100 μ m. (E) are images of the hydrogels from culture wells of a 6-well plate, in descending order: MyoCon, MyoTGF β , CoCon, and CoTGF β hydrogels.
