The flood pulse is the main factor structuring and differentiating the ecological communities of Amazonian unflooded (*terra firme*) and seasonally-flooded (*várzea*) forests as they require unique adaptations to survive the prolonged annual floods. Therefore, *várzea* and *terra firme* forests hammer out a spatio-temporal mosaic of resource availability, which may result in landscape scale seasonal movements of terrestrial vertebrates between adjacent forest types. Yet the lateral movements of terrestrial vertebrates between hydrologically distinct neighbouring forest types exhibiting staggered resource availability remains poorly understood, despite the important implications of this spatial dynamic for the ecology and conservation of forest wildlife. We examined the hypothesis of seasonal movements between two adjacent forest types at two contiguous sustainable-use forest reserves in Western Brazilian Amazonia, investigating the effects of water level, landscape and anthropogenic disturbance on the overall species richness, composition, and abundance of nine major vertebrate trophic guilds. Species richness differed in neighboring *terra firme* forests between the high-and low-water phases of the flood pulse and *terra firme* forests were more species rich than *várzea* forests. There were clear differences in species composition between both forest types and seasons. Generalized Linear Models showed that water level was the main factor explaining aggregate abundance of all species and three trophic guilds. Anthropogenic disturbance and geographic setting of camera trap stations, including distance to the nearest urban center, the number of residents of the nearest community, elevation and the surrounding area of *várzea* of each camera trap station, had a variety of effects on the terrestrial vertebrate assemblage. Overall vertebrate biomass increased with distance from the nearest urban center. Our results indicate that the persistence of viable populations of large terrestrial vertebrates adjacent to major Amazonian rivers requires large, well-connected forest landscapes encompassing different forest types to ensure large-scale

lateral movements by forest wildlife.

11 Abstract

12 The flood pulse is the main factor structuring and differentiating the ecological communities of
13 Amazonian unflooded (*terra firme*) and seasonally-flooded (*várzea*) forests as they require unique
14 adaptations to survive the prolonged annual floods. Therefore, *várzea* and *terra firme* forests
15 hammer out a spatio-temporal mosaic of resource availability, which may result in landscape scale
16 seasonal movements of terrestrial vertebrates between adjacent forest types. Yet the lateral
17 movements of terrestrial vertebrates between hydrologically distinct neighbouring forest types
18 exhibiting staggered resource availability remains poorly understood, despite the important
19 implications of this spatial dynamic for the ecology and conservation of forest wildlife. We
20 examined the hypothesis of seasonal movements between two adjacent forest types at two
21 contiguous sustainable-use forest reserves in Western Brazilian Amazonia, investigating the
22 effects of water level, landscape and anthropogenic disturbance on the overall species richness,
23 composition, and abundance of nine major vertebrate trophic guilds. Species richness differed in
24 neighboring *terra firme* forests between the high-and low-water phases of the flood pulse and *terra*
25 *firme* forests were more species rich than *várzea* forests. There were clear differences in species
26 composition between both forest types and seasons. Generalized Linear Models showed that water
27 level was the main factor explaining aggregate abundance of all species and three trophic guilds.
28 Anthropogenic disturbance and geographic setting of camera trap stations, including distance to
29 the nearest urban center, the number of residents of the nearest community, elevation and the
30 surrounding area of *várzea* of each camera trap station, had a variety of effects on the terrestrial
31 vertebrate assemblage. Overall vertebrate biomass increased with distance from the nearest urban
32 center. Our results indicate that the persistence of viable populations of large terrestrial vertebrates
33 adjacent to major Amazonian rivers requires large, well-connected forest landscapes
34 encompassing different forest types to ensure large-scale lateral movements by forest wildlife.

35

36 Introduction

37 Wetland habitats are both challenging to conserve and globally important for biodiversity
38 conservation and human wellbeing (Keddy et al., 2009). Seasonal and perennial wetlands are
39 globally important and exceptionally productive habitats that support both high densities and a
40 high diversity of wild species (Halls, 1997; Junk et al., 2006). They also directly underpin the
41 livelihoods of millions of people and provide ecosystem services including productive fisheries,
42 water purification, hydrological regulation, nutrient cycling and naturally-fertilized agricultural
43 land (Costanza et al., 1997; François et al., 2005). The associated seasonal movements of
44 wetland fauna are especially challenging to conserve because their spatially complex life
45 histories require resources provided by several distinct habitats and entail diverse anthropogenic
46 threats at multiple sites (Martin et al., 2007; Wilcove & Wikelski, 2008).

47 Hunted migratory species — including salmonids, bats, passerines, waterfowl and grassland
48 ungulates — often contend with severe demographic depletion due to unsustainable offtake
49 (Madsen & Fox, 1995; Dudgeon et al., 2006; Bolger et al., 2007; McCulloch, Tucker & Baillie,
50 2008; Epstein et al., 2009). Overharvesting may be exacerbated by a “tragedy of the commons”
51 whereby human harvesters have little incentive to conserve their common-pool resource stock
52 in the absence of communal resource management institutions or governance norms (Ostrom,
53 2008). Species which form large aggregations during migrations are especially attractive targets
54 to human hunters, who can maximize the return on their foraging investment by slaughtering
55 many individuals in a short period (Peres, 1996).

56 A vast proportion of the Amazon Basin is formed by natural landscape mosaics of wetlands
57 embedded within a matrix of upland (hereafter, *terra firme*) forests on generally nutrient-poor
58 soils well above the maximum water-level of adjacent floodplains (Tuomisto et al., 1995).
59 Amazonian floodplains comprise a variety of habitats including swamp forests, hydromorphic
60 savannas, coastal wetlands, tidal forests, and seasonally-flooded forests. These Amazonian
61 wetlands are classified according to their climatic, edaphic and floristic characteristics (Junk &
62 Piedade, 2010; Junk et al., 2011). Based on these criteria, two large groups of wetlands have
63 been broadly distinguished: those with either (i) relatively stable or (ii) oscillating water levels
64 (Junk et al., 2011).

65 Most Amazonian wetlands with oscillating water levels are subjected to a predictable, long-
66 lasting monomodal flood pulse which alternates between the high- and low-water periods
67 according to the Flood Pulse Concept (Prance, 1979; Junk, Bayley & Sparks, 1989). Depending
68 on the geomorphology and geochemical profile of each watershed, these areas can be inundated
69 by white-, black- or clear-water rivers (Sioli, 1984). White-water rivers such as the Solimões,
70 Madeira, Japurá and Juruá have their origins in the Andes or Andean piedmonts, are nutrient-
71 rich, and have neutral pH. These rivers deposit their alluvial sediments along wide swaths of
72 floodplain forests of high primary productivity, which are locally known as *várzeas* (Wittmann
73 et al., 2006; Junk et al., 2011). In contrast, Amazonian black-water rivers such as the Negro,
74 Tefé and Jutai rivers discharge transparent-blackish waters with low suspended sediment loads
75 and acidic pH. Forests inundated by black-water rivers are locally known as *igapós* and are
76 typically supported by low-fertility soils and their trees exhibit 50% lower diameter increment
77 compared to *várzea* forests (Junk & Piedade, 2010; Junk et al., 2011).

78 The flood pulse is the main factor structuring and differentiating the ecological communities of
79 *várzea* and *igapó* forests from adjacent *terra firme* forests (Peres, 1997; Haugaasen & Peres,
80 2005a, Haugaasen & Peres, 2005b; Beja et al., 2009) as they require unique adaptations to
81 survive the prolonged annual floodwaters. *Terra firme* forests are more species-rich, including
82 more forest habitat specialists than *várzeas* and *igapó*, while the average population biomass
83 density is higher in seasonally-flooded forests along white-water rivers (Peres, 1997). This
84 predictable long-lasting and monomodal flood pulse triggers and synchronizes critical
85 ecological events including the availability of plant reproductive parts (Nebel et al. 2001,
86 Schöngart et al. 2002, Haugaasen & Peres 2005a, Hawes & Peres 2016), dietary shifts in
87 primates, ungulates and fishes (Bodmer 1990, Peres 1994, 1999, Saint-Paul et al. 2000), human
88 extractive activities of non-timber forest products, and the exploitation of both terrestrial and
89 aquatic prey (Newton, Endo & Peres 2011; Endo, Peres & Haugaasen 2016). As they are
90 structurally and compositionally different, Amazonian *várzeas*, *igapós* and *terra firme* forests
91 engender a spatio-temporal mosaic of resource availability which may result in landscape-scale
92 seasonal movements of terrestrial vertebrates between these often neighbouring forest types
93 (Bodmer 1990, Peres 1999, Haugaasen & Peres 2007). *Terra firme*, *várzea* and *igapó* forests
94 exhibit complementary fruit production peaks, whereby the fruiting peak in *terra firme* forests
95 occurs during the onset of the wet season, whereas fruit maturation in *várzeas* and *igapós* begin

96 during the late high-water season (Schöngart et al., 2002; Haugaasen & Peres, 2005a, 2007;
97 Hawes & Peres, 2016).

98 This asynchrony in fruit production attracts frugivorous fish and arboreal frugivores to
99 floodplain forests during the high-water period (Saint-Paul *et al.* 2000; Beja *et al.* 2009),
100 whereas ungulates, carnivores, terrestrial insectivores and ant-following birds are attracted to
101 *várzeas* and *igapós* immediately after the water level recedes. These lateral movements are due
102 to the high abundance of fruit and seed deposited on the forest floor and higher insect abundance
103 during this period (Bodmer 1990, Peres 1994, Adis & Junk 2002, Haugaasen & Peres 2007,
104 Mendes Pontes & Chivers 2007, Beja et al. 2009).

105 Our study seeks to investigate the seasonal dynamics of terrestrial vertebrates in Amazonian
106 seasonally-flooded and unflooded forests by quantifying their relative abundance during both
107 the high- and low-water phases of the flood pulse. We predict that the species richness,
108 abundance and biomass of terrestrial vertebrates in *terra firme* forests adjacent to seasonally-
109 flooded *várzea* forests during the flood pulse will be higher than during the low-water phase.
110 This abundance contrast would indicate that the terrestrial fauna most likely leave *terra firme*
111 forest and move into *várzea* forests during the low-water phase to take advantage of higher
112 resource availability. Conversely, there should be transient overcrowding of the terrestrial
113 vertebrate fauna in adjacent *terra firme* forests driven by lateral movements away from the rising
114 floodwaters during the high-water phase.

115 To test this hypothesis we conducted camera-trapping surveys in both *terra firme* and *várzea*
116 forests along a major white-water tributary of the Amazon river during the high- and low-water
117 phases of the flood pulse. We examined differences in vertebrate abundance, species richness,
118 and changes in species composition between these two forest types and seasons and the
119 associated effects of geographic or landscape setting of camera traps in relation to anthropogenic
120 disturbance. We provide crucial empirical evidence supporting the notion that Amazonian *terra*
121 *firme* and *várzea* forests should be juxtaposed within fully functional floodplain protected areas,
122 thereby enhancing both the spatial configuration of reserve design and landscape management
123 of highly heterogeneous forest macromosaics in Amazonia for both biodiversity persistence and
124 the subsistence of local extractive communities.

125 **Materials & Methods**

126 Study Area

127 This study was carried out in two contiguous sustainable-use forest reserves within the State of
128 Amazonas, Brazil: the Médio Juruá Extractive Reserve (RESEX) spanning 253,227 ha, and the
129 Uacari Sustainable Development Reserve (RDS) spanning 632,949 ha. Both reserves border the
130 white-water Juruá River, the second largest white-water tributary of the Amazonas/Solimões
131 River. These protected areas contain large expanses of *terra firme* forests (80% of both reserves)
132 as well as an approximately 18.40 ± 5.71 km wide band of seasonally-flooded *várzea* forest
133 (17.9%) encompassing the main river channel (Hawes et al., 2012) (Fig. 1). The Juruá region
134 experiences an Af climate type (constantly humid) according to Köppen criteria, with a mean
135 annual temperature of 27.1°C, a mean rainfall of 3,679 mm/year, and peak water levels of 8 - 12
136 m during a prolonged flood pulse, which is alternated by a dry phase in *várzea* between July and
137 early November (Peres, 1997). The regional elevation range is 65 – 170 m above sea level. All
138 forest sites surveyed consist of largely undisturbed primary forest, although commercially
139 valuable timber species have experienced small-scale selective logging along the Juruá River
140 from 1970 to 1995, especially in *várzea* forests.

141 The RESEX Médio Juruá and RDS Uacari were created in 1997 and 2005, respectively, and are
142 currently inhabited by some 4,000 legal residents, distributed across 74 local communities.
143 These communities are located on both sides of the Juruá River, adjacent to either the main river
144 channel or tributaries and oxbow lakes. Residents of these reserves are variously engaged in
145 agricultural and extractive activities for both subsistence and cash income (Newton, Endo &
146 Peres, 2011; Campos-Silva & Peres, 2016).

147 Research permissions and full approval for this purely observational research were provided by
148 Centro Estadual de Unidades de Conservação do Amazonas (CEUC/SDS/AM – 020/2013) and
149 by Instituto Chico Mendes de Conservação da Biodiversidade (ICMBio – 38357-1).

150 Camera trapping

151 Data on the relative abundance of terrestrial vertebrates were collected at 279 camera-trapping
152 stations (CTS) deployed at distances of $3,100 \pm 367$ m ($\bar{x} \pm SD$) apart, along a ~514-km nonlinear
153 section of the Juruá River (Fig. 1). We used Bushnell Trophy Cam 119436c, Reconyx Hyperfire

154 HC500 and Bushnell 8MP Trophy Cam HD camera traps. These were programmed to record
155 three and five consecutive photographs and 10-sec videos, respectively, at each trigger event
156 without intervals. A CTS consisted of one camera trap deployed 40-60 cm above ground, and
157 operated over a functional period of 38.7 ± 13.9 days ($\approx 928.8 \pm 333.6$ hours). The sensor
158 sensitivity was set to high, and all CTS were unbaited and deployed away from trails.

159 Camera-trapping stations were deployed in two complementary sample designs (Table 1; Fig.
160 1): From April 2013 to June 2014, 193 CTS were deployed at intervals of 50m, 350m, 1000m,
161 3000m and 6000m Euclidean distance along transects, arrayed in contiguous *terra firme* primary
162 forest, radiating away from local communities. This design facilitated surveys of terrestrial
163 vertebrate abundance at varying distances from the *várzea* interface and at varying intervals
164 during the receding flood pulse. In the second design, repeated over two inundation (March-
165 April 2013 and 2015) and two low-water phases (September-October 2013 and 2014), CTS were
166 deployed in both *várzea* forests and adjacent *terra firme* sites. In this arrangement, *terra firme*
167 CTS were deployed during both high- and low-water phases whereas *várzea* CTS were surveyed
168 only during the low-water phase, as *várzea* habitat is only available to the terrestrial fauna during
169 this time of year.

170 Data management and estimates of the number of independent detections were undertaken using
171 *camtrapR* version 0.99.8 (Niedballa et al., 2016). Images of conspecifics >30 min apart were
172 defined as independent detection events. Species nomenclature followed the IUCN Red List
173 (IUCN 2013). Primates, non-terrestrial birds and rodents and marsupials smaller than 1 kg were
174 excluded from our analyses, but all other avian and mammalian taxa were considered. Congener
175 brocket deer (*Mazama* spp.), armadillos (*Dasypus* spp.), and small tinamous (*Crypturellus* spp.)
176 were each treated as single species functional group due to difficulties in differentiating them in
177 nocturnal (black and white) images.

178 All species considered here were grouped into nine trophic guilds (frugivore-insectivores,
179 granivore-frugivores, frugivores, carnivores, frugivore-carnivores, insectivore-frugivores,
180 insectivores, browsers and frugivore-browsers) based on Benchimol & Peres (2015). An
181 assemblage-wide metric of aggregate biomass was calculated by multiplying the species-
182 specific camera-trap detection rate (number of detections/100 trap-nights) by the mean adult
183 body mass per species, which could then be summed across all species detected at each CTS.

184 For group-living species, we multiplied individual body mass values by the mean observed
185 group size obtained from line-transect surveys conducted in the same study landscape
186 (Abrahams, Peres & Costa, 2017).

187 For each CTS, we extracted landscape and human disturbance covariates using ArcGIS (version
188 10.3) (Table 2). We calculated the mean water level of the Juruá River during the exposure
189 period of each CTS using daily water-level readings, recorded over 38 years (from 1st January
190 1973 to 31st December 2010; $N \approx 14,600$ measurements) at a nearby locality (Gavião
191 Meteorological Station in Carauari-AM). As a continuous variable, mean water-level during
192 CTS sampling intervals was a far more powerful descriptor of seasonality period than either
193 categorical season (e.g. low-water vs high-water season) or time of the year (e.g. Julian day) per
194 se.

195 Data analysis

196 All analyses were conducted in R version 3.3.2 (R Core Development Team 2016). We first used
197 both Student's paired t-tests and ordinary t-tests to examine differences in species richness and
198 abundance of *terra firme* forests between the high- and low-water phases, and between *terra firme*
199 sites during the low-water phase and *várzea* forests, respectively. We estimated species richness
200 per CTS, accounting for any differences in the number of trap nights, using a rarefaction method
201 and first-order Jackknife estimator available in the *specaccum* function of the “vegan” package of
202 R. We choose this estimator because it gives the most reliable results in tropical forest camera-trap
203 studies (Tobler et al., 2008). For the abundance analyses, we considered the camera-trapping rate
204 (number of independent detections per 100 trap-nights) as our response variable. These analyses
205 were performed using CTS data from our second sample design.

206 To assess the effects of forest type and season on terrestrial vertebrate assemblage structure, we
207 used Principal Coordinates Analysis (PCoA) using a Bray–Curtis similarity distance matrix.
208 Prior to these analyses, to reduce the weight of abundant species in the ordination space,
209 terrestrial vertebrate abundance was standardized by dividing the number of detections of each
210 species by the total number of detections at each CTS. Differences in species composition
211 between forest types, and seasons were tested using Permutational Multivariate ANOVA
212 (PERMANOVA) (Anderson, 2001) performed using the Bray-Curtis similarity matrix. To test
213 for seasonal effects on species composition at *terra firme* CTS, we performed a Procrustes

214 rotation analysis of the ordination matrices derived from CTS that were surveyed during both
215 the high- and low-water phases of the flood pulse. In the PCoA and PERMANOVA analyses,
216 we employed all CTS, whereas the Procrustes rotation was performed using only the data from
217 the second sample design.

218 We tested the hypothesis of seasonal faunal movement between forest types and investigated
219 the effects of landscape context and anthropogenic disturbance employing Generalized Linear
220 Models (GLMs). We used a Poisson distribution for count data using CTS from both sample
221 designs, but a Negative Binomial distribution was chosen when overdispersion was detected
222 (Hilbe 2007). For the metric of biomass we used a Gaussian error structure. The number of
223 camera-trapping nights per CTS was specified as an *offset* variable in all models to account for
224 difference in sampling effort (i.e. number active nights) between CT deployments.

225 We controlled for high levels of variable inter-dependence by performing a Pearson's correlation
226 matrix, retaining non-correlated variables ($r < 0.70$). We retained 11 variables describing the local
227 habitat, season, landscape context, and level of human disturbance of CTS sites (vz1k, vzdist, elev,
228 waterlevel, riverdist, defor1k, defor5k, defordist, ctydist, popcomm1 and commdist1; see
229 description of these variables in Table 2). For those variables representing the same class of human
230 disturbance (e.g. deforestation area), the appropriate buffer size was determined by running all
231 models using different buffer thresholds, and then using the threshold resulting in the strongest
232 effect on our response variables. We mitigated for collinearity between the predictors using the
233 Variance Inflation Factor ($VIF < 3$), excluding the variables above this threshold. We used
234 Akaike's Information Criteria (AICc) to select the models that best fit the data, employing a
235 stepwise method starting with the full model and discarding predictors until we reached a model
236 with the lowest AICc value.

237 **Results**

238 On the basis of 10,447 trap-nights, we recorded 4,059 independent detections of 25 terrestrial
239 vertebrate species, including 21 mammals representing 12 families and eight orders and four
240 large-bodied bird species (Table 3). We found clear differences in *terra firme* forest sites in both
241 species richness and abundance between high- and low-water phases (richness: paired $t = 2.552$,
242 $df = 21$, $p = 0.018$; abundance: paired $t = 2.950$, $df = 21$, $p = 0.007$, Fig. 2A, C). During the low-
243 water season, overall abundance was higher in *terra firme* than in *várzea* sites ($t = 2.709$, $df =$

244 48, $p = 0.009$, Fig. 2 B). Similarly, species richness was higher in *terra firme* sites (18.42 ± 3.11
245 species) than in adjacent *várzea* sites (14.31 ± 3.00 species; $t = 4.748$, $df = 48$, $p < 0.001$, Fig. 2
246 D).

247 At *terra firme* sites, the black agouti (*D. fuliginosa*) was the most common species followed by
248 the brocket deer (*Mazama spp*), pale-winged trumpeter (*P. leucoptera*), razor-billed curassows
249 (*M. tuberosum*) and collared peccaries (*P. tajacu*). The detection rates of these species were
250 higher during the high-water season than during the low-water season, whereas pacas (*C. paca*),
251 jaguars (*P. onca*), giant anteaters (*M. tridactyla*), giant armadillos (*P. maximus*) and tapirs (*T.*
252 *terrestris*) were more frequently detected during the high-water phase (Fig. 3A). During the low-
253 water season, brocket deer, black agoutis, pacas, pale-winged trumpeter, razor-billed curassows
254 and collared peccaries were more abundant in *terra firme* than in adjacent *várzea* forests, while
255 tapirs, ocelots (*L. pardalis*), pumas (*Puma concolor*) and small tinamous (*Crypturellus spp*)
256 presented higher detection rates in *várzea* (Fig. 3B).

257 PCoA ordination revealed differences between sample clusters formed by all *terra firme* sites
258 between the high- and low-water phases of the flood pulse, and between *várzea* forests and *terra*
259 *firme* sites during the low-water phase (Fig. 4A), which was further confirmed by permutation
260 tests (PERMANOVA; $F = 3.964$, $p = 0.002$; $F = 10.401$, $p = 0.001$, respectively). *Terra firme*
261 sites occupied the largest area in community space during the high-water phase, with both *terra*
262 *firme* and *várzea* forest sites during the low-water phase occupying subsets of the larger group,
263 and *várzea* sites occupying the smallest area. Additionally, the Procrustes rotation performed
264 with the *terra firme* CTS from sample design two indicated significant differences in ordination
265 space in the multivariate structure of community composition between the high- and low-water
266 phases ($R = 0.74$, $p = 0.007$, Fig. 4B).

267 Generalized linear models (GLMs) revealed that water level was a significant positive predictor
268 of both overall species abundance and the detection rates for three trophic guilds: frugivore-
269 insectivores, granivore-frugivores and carnivores (Fig. 5 A, D, F, G). The size of the nearest
270 local extractive community was associated with higher detection rates for browsers (Fig. 5 J).
271 Likewise, elevation was a positive predictor of detection rates of insectivore-frugivores (Fig. 5
272 I). The best model for frugivores retained only elevation as a significant negative predictor (Fig.
273 5 E). The area of *várzea* within a 1000-m buffer around each CTS best explained insectivore

274 detection rates (Fig. 5 L), while distance to the nearest urban center had the opposite effect on
275 our metric of overall vertebrate biomass (Fig. 5 B). The best GLM model explaining overall
276 species richness and the detection rates of frugivore-carnivore and frugivore-browsers failed to
277 retain any significant predictors (Fig. 5 C, H, K).

278 Discussion

279 Species richness and seasonal movements between forest types

280 Our camera-trapping study provides tantalizing evidence that water level governs the
281 distribution of large terrestrial vertebrates in Amazonian pristine forest mosaics. These species
282 appear to exhibit lateral seasonal movements to take advantage of periodic resource availability
283 in extremely productive floodplain forests. In our study area, the swath of floodplain forest is
284 approximately 20 km wide, thereby providing a vast area of highly productive habitat for
285 terrestrial species during the low-water phase.

286 In general, *terra firme* forest sites were more species-rich than *várzea* forest sites, a pattern that
287 conforms with results from previous studies comparing assemblages of all mammals, primates,
288 bats, birds and small mammals in Amazonian seasonally-flooded and unflooded forests (Peres
289 1999, 1997, Haugaasen & Peres 2005b; c; Beja *et al.* 2009; Pereira *et al.* 2009, Bobrowiec *et al.*
290 2014). Salvador, Clavero & Leite Pitman (2011) reported that floodplain forests in the Peruvian
291 Amazon are more species-rich than *terra firme* forests during the dry season. They also report
292 that the number of species in floodplain forest during the wet season remains the same
293 throughout the year, while in *terra firme*, a sharp increase in species richness coincided with the
294 onset of the wet season. These shifts in the number of species between the two forest types are
295 consistent with our seasonal movement hypothesis, as the bulk of terrestrial vertebrate species
296 likely exit *terra firme* terrains to feed on the seasonally abundant *várzea* forest resources.

297 Water level represents a physical barrier for most vertebrate species attempting to access *várzea*
298 forests during the high-water phase. This was confirmed by the positive relationship between
299 water level and aggregate community-wide abundance, and the number of detection events of
300 frugivore-insectivores, granivore-frugivores and carnivores. Bobrowiec *et al.* (2014) noted that
301 the flood pulse constituted a physical barrier even for Phyllostomid bats, whose species
302 composition differed between *terra firme* and *várzea* forests during the high-water period, but
303 this effect did not persist year-round. We found clear differences in species composition between

304 *terra firme* and *várzea* forests during the low-water phase and within our *terra firme* samples
305 between the high- and low-water phases of the annual cycle. These results imply that forest
306 fauna can exhibit ephemeral occupancy of *várzea* sites during the dry season and that the rising
307 flood waters force several species to seek suitable habitats in upland forests. These seasonal
308 lateral movements drive differences in species richness and composition between both seasons
309 and forest types.

310 Food availability and its distribution within forest habitats, is the most important variable
311 explaining the occupancy and abundance of mammals in different forest types (Mendes Pontes,
312 2004; Haugaasen & Peres, 2007). In *terra firme* forests, fruit production occurs during the early
313 wet season whereas in *várzea* forests, fruit production starts during the late wet season (Hawes
314 & Peres, 2016). A substantial proportion of the large terrestrial fauna may therefore move
315 between *várzea* and *terra firme* forests to exploit seasonally available resources. For instance,
316 frugivore species in our models exhibited a negative abundance relationship with terrain
317 elevation. This predictor can be used to distinguish both forest types, as our *terra firme* CTS
318 were on average situated on terrains 14 m higher than our *várzea* CTS (t-value = 9.458, df =
319 277, p-value < 0.001). As water levels recede, the terrestrial fauna rapidly colonize *várzea*
320 forests to forage on the seasonal production of residual fruit- and seed-fall (total production
321 minus dispersal and consumption by arboreal frugivores), which can be twice as high as in
322 adjacent *terra firme* forests during this period (Bodmer, 1990). Ungulate species such as collared
323 peccaries and brocket deer exhibit a marked dietary shift following the flood pulse, consuming
324 more fruits in seasonally-flooded forests during the low-water period compared to the high water
325 period (Bodmer 1990).

326 Water level is an important determinant of species detection rates in highly heterogeneous forest
327 landscapes subjected to marked seasonal floods (Negrões et al., 2011; De Lázari et al., 2013).
328 Haugaasen & Peres (2007) reported three different strategies of landscape movements across
329 forest types, which were reflected in our results: wide-ranging species, year-round residents and
330 interface species. Large-bodied granivore-frugivores such as the large-group-living white-
331 lipped peccaries is a wide-ranging “landscape” species that, on a seasonal basis, occupies large
332 home ranges in different forest types and shift their diets and habitat use in response to both
333 seasonal flooding and resulting resource fluctuations (Bodmer, 1990; Fragoso, 1998;

334 Keuroghlian, Eaton & Desbiez, 2009). Large-bodied myrmecophages and insectivore-
335 frugivores such as giant anteaters and armadillos exhibited low detection rates in *várzea* forests,
336 likely because they are year-round residents in *terra firme* forests. They seldom move between
337 forest types because the permanently wet *várzea* soils preclude their fossorial foraging behavior.
338 We never observed giant armadillo (*P. maximus*) holes in *várzea* forests, but commonly
339 observed them in *terra firme* forests, and this is consistent with previous studies in the Araguaia
340 River (Negrões *et al.* 2011) and Peruvian floodplain forests (Salvador, Clavero & Leite Pitman
341 2011).

342 Detection rates of carnivores increased with the water level, a pattern that can be explained by
343 their swimming and climbing abilities, which allow them to both move between temporary
344 forest islands and utilize the tree canopy as floodwaters rose. Jaguars (*P. onca*) in *várzea* forests
345 in the lower Japurá River are known to spend the entire high-water season high up in the trees
346 (E.E. Ramalho, pers. comm.) and subsist upon arboreal and semi-aquatic species such as howler
347 monkeys (*Alouatta seniculus* (Linnaeus, 1766)), sloths (*Bradypus variegatus*, Schinz, 1825) and
348 spectacled and black caimans (*Caiman crocodilus* (Linnaeus, 1758), and *Melanosuchus niger*
349 (Spix, 1825)) (Ramalho 2006).

350 Conservation implications

351 Our research supports the existing body of evidence that the Médio Juruá region, and many other
352 regions of the lowland neotropics, should be viewed as an essentially interconnected multi-
353 habitat socio-ecological system. The massive long-lasting seasonal flood pulse (Junk, Bayley &
354 Sparks, 1989) and the associated phenological (Hawes & Peres, 2016), hydrological, ecological
355 (Hawes *et al.*, 2012) and livelihood impacts this engenders (Endo, Peres & Haugaasen, 2016)
356 require conservation planning at the scale of the entire landscape, with major drainage basins
357 representing complementary management units.

358 Amazonian freshwater ecosystems such as seasonally white-water flooded forests are vulnerable
359 to anthropogenic disturbance. *Várzea* and *terra firme* forests function as ecologically integrated
360 and hydrologically interconnected habitats that are seasonally utilized by a suite of mobile
361 species, with terrestrial fauna often relying upon the temporally staggered resources of both
362 habitats. As such, they are threatened by both aquatic and terrestrial anthropogenic activities at

363 the local and regional scales. The immense fluvial transport network of the lowland Amazon
364 makes even remote forests accessible to hunters (Peres & Lake, 2003), making their faunal
365 resources non-excludable, whilst simultaneously difficult to monitor. These institutional
366 governance challenges over vast tracts of forest partly explain why terrestrial hunting
367 management has thus far proved elusive. Amazonian terrestrial fauna may be comparatively
368 robust to anthropogenic threats as they seasonally move short distances, usually do not form
369 large aggregations, and often occupy large areas of structurally intact forest. White lipped
370 peccaries, which range over vast areas and form herds of hundreds of individuals, are a notable
371 exception. Not only are they a highly preferred hunted species, vulnerable to overhunting even
372 under low-offtake scenarios (Abrahams, Peres & Costa, 2017), but they play an important
373 ecological role as natural agents of disturbance in plant community dynamics (Silman, Terborgh
374 & Kiltie, 2003) and re-distributing nutrients and fertilizing upland forests.

375 The existing protected area network and management policies were created principally to protect
376 terrestrial ecosystems and are therefore not adequate to mitigate the aforementioned impacts.
377 Protected areas also suffer from design, implementation and monitoring deficiencies and their
378 delimitations does not adequately represent or protect the full suite of biotic diversity (Peres &
379 Terborgh, 1995, Albernaz *et al.* 2012, Castello *et al.* 2013). Although a protected area coverage
380 of ~25% gives the impression of extensive conservation management of floodplains, less than
381 1% of the aggregate area of Amazonian floodplains in Brazil is strictly protected (Albernaz *et*
382 *al.* 2012). Sustainable development and extractive reserves represent the majority of all
383 protected areas worldwide. Their conservation effectiveness can be compromised by high
384 human population density, the uncertain economic viability of exploiting non-timber resources
385 and a shortfall in available animal protein resulting from depleted game vertebrate populations
386 (Peres, 2011; Terborgh & Peres, 2017), but see Abrahams, Peres & Costa (2017) and Campos-
387 Silva & Peres (2016) for best-case scenarios of terrestrial subsistence hunting and local fisheries
388 management.

389 We have shown that a substantial part of the large vertebrate fauna modulates their use of
390 different forests types within a highly heterogeneous forest landscape according to the marked
391 seasonality of *várzea* floodplain forests. *Várzea* forests adjacent to major rivers are preferentially
392 settled by Amazonian extractivists seeking reliable access to transport routes, fertile soils and

393 animal protein (Endo, Peres & Haugaasen, 2016). In Amazonian extractive reserves, the forest
394 type within which villages are situated can modulate their livelihood strategies. Communities
395 with greater access to *terra firme* forests are inherently more agricultural, while communities
396 with greater access to seasonally-flooded forests rely more heavily on the seasonal extraction of
397 non-timber resources such as palm fruits (*Euterpe spp.*, Martius 1824 and *Astrocaryum*
398 *aculeatum*, Meyer), rubber (*Heavea spp.*, Aublet) and oil seeds (*Carapa guianensis*, Aublet and
399 *Astrocaryum murumuru*, Mart.) (Newton, Endo & Peres 2011).

400 Our research occupies the confluence between the issues of landscape-scale conservation
401 planning, ecological connectivity, nutrient transport and uptake, and community-based natural
402 resource management. The Médio Juruá region exemplifies these issues as it encompasses
403 extensive seasonal wetlands and a suite of hunted, seasonally-mobile species. Adequate
404 conservation strategies in this region must account for the full life-history needs of mobile
405 harvested species, ecologically interconnected habitats and the diverse livelihood portfolios of
406 local communities (Lindenmayer et al., 2008). Different Amazonian forest types exhibiting
407 staggered resource pulses must be included within the same or neighboring sustainable-use
408 protected areas. This will provide sufficiently large areas to both support large-scale ecological
409 processes (e.g. species migrations, lateral movements, persistence of apex predators) and
410 anthropogenic extractive activities in the long run (e.g. estimated sustainable harvest area for
411 tapir populations >2,000 km²) (Peres & Terborgh, 1995; Peres, 2001, 2005; Haugaasen & Peres,
412 2007). This concept can be applicable to conservation planning of other regions consisting of
413 natural forests mosaics experiencing seasonal floods such as the hyper-fragmented region of the
414 Araguaia River or at the Pantanal floodplains (Negrões et al., 2011; De Lázari et al., 2013). In
415 these different scenarios, private reserves must be situated adjacent to protected areas to ensure
416 terrestrial fauna protection during the prolonged inundation season.

417 Study limitations

418 In our study, we were unable to estimate the species richness in *várzea* forests during the high-
419 water phase of the flood pulse, because our camera trapping method focused only on terrestrial
420 species, which are more sensitive to the flood pulse than arboreal and semi-aquatic species.
421 *Várzea* forests along this section of the Juruá River are typically subjected to an annual flood
422 pulse amplitude of 8 to 12 m, which lasts for up to six months. Any camera traps deployed in

423 várzea forests during the high-water period would need to be placed almost half way up into the
424 forest canopy.

425 We acknowledge that these landscape-scale seasonal movements between forest types can only
426 be conclusively verified by either radio or GPS telemetry studies targeting multiple species. The
427 prohibitive costs of such an undertaking limit its community-wide feasibility. Our evidence is
428 based on patterns of local population abundance, species richness and biomass, particularly
429 along the *várzea - terra firme* interface, where temporary overcrowding is expected to occur for
430 species abandoning the wide belt of *várzea* forest during the rise of floodwaters.

431 **Conclusions**

432 The annual floodwaters along several major white-water rivers in the Amazon is the main factor
433 structuring and differentiating *várzea* floodplains from adjacent *terra firme* forests as unique
434 adaptations are required to tolerate the prolonged flood pulse. This remarkable natural
435 phenomenon drives several key ecological processes, including staggered plant phenology, high
436 plant productivity, and supports major local livelihood activities such as subsistence fishing and
437 hunting. This landscape scale seasonal dynamics between these major adjacent forest types was
438 investigated in terms of species richness, species composition and population abundance for as
439 many as 23 vertebrate species. We have shown that many upland forest terrestrial vertebrate
440 species make seasonal use of *várzea* forests to take advantage of the abundant trophic resource
441 in this forest type following the receding waters. We acknowledge that detailed movement data
442 using GPS telemetry can further clarify the magnitude and seasonal importance of *várzea* habitat
443 use by *terra firme* vertebrates. However, we highlight that this unique seasonal dynamic is a
444 critical issue in Amazonian forest reserve design and biodiversity monitoring, particularly
445 within large sustainable use reserves encompassing complex natural landscape mosaics, where
446 unimpeded lateral movements should continue to support both local extractive economies and
447 healthy wildlife populations.

448 **Acknowledgements**

449 We are deeply grateful to the local communities of the Juruá region for their hospitality and
450 friendship during fieldwork and to Gilberto Olavo from the Centro Estadual de Unidades de
451 Conservação do Amazonas (CEUC/SDS/AM); and Rosi Batista and Manoel Cunha from the

452 Instituto Chico Mendes de Conservação da Biodiversidade (ICMBio) for permitting our research
453 work. We thank A. C. Mendes-Oliveira, F. Michalski, F. Palomares, and N. Negrões-Soares for
454 their comments on previous versions of the manuscript. This publication is part of the Projeto
455 Médio Juruá series on Resource Management in Amazonian Reserves.

Figure 1

Map of the study area in the central Rio Juruá region of western Brazilian Amazonia, Amazonas, Brazil.

Map inset shows the geographic location of the study region (black square). The boundaries of the RESEX Médio Juruá and RDS Uacari are outlined in black. Background colors represent elevation, with blue and brownish orange shades indicating low and high elevation, respectively. Solid red circles represent camera trap stations (CTS) deployed radiating inland into *terra firme* forest (sample design 1). Green and aqua circles represent CTS deployed at *terra firme* forest sites near forest habitat boundaries along the *várzea* interface and far into *várzea* forest, respectively (sample design 2).

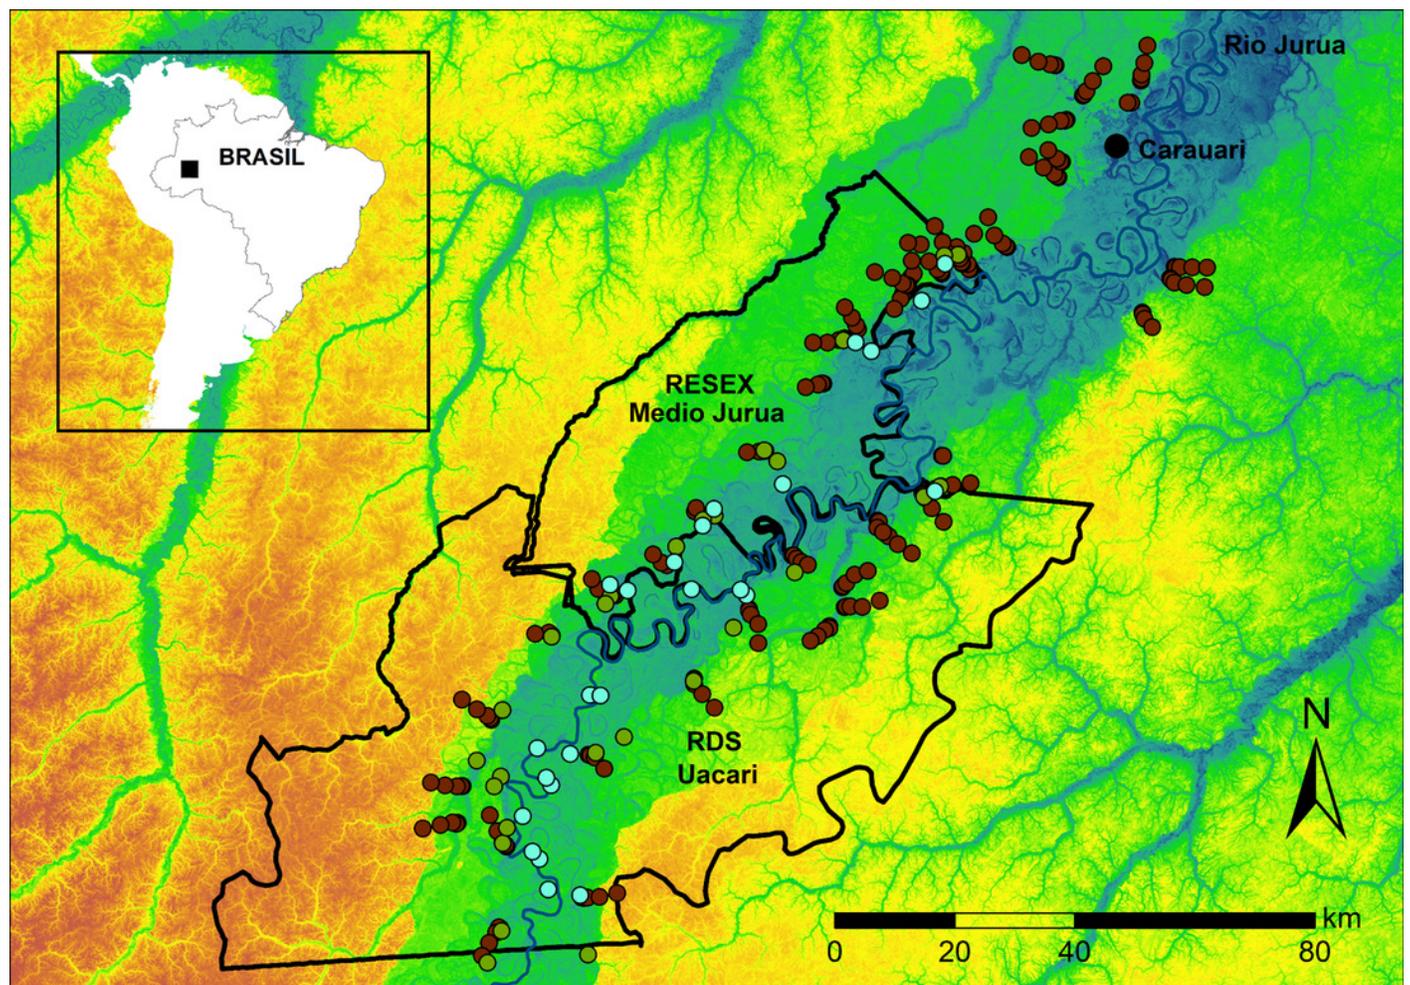

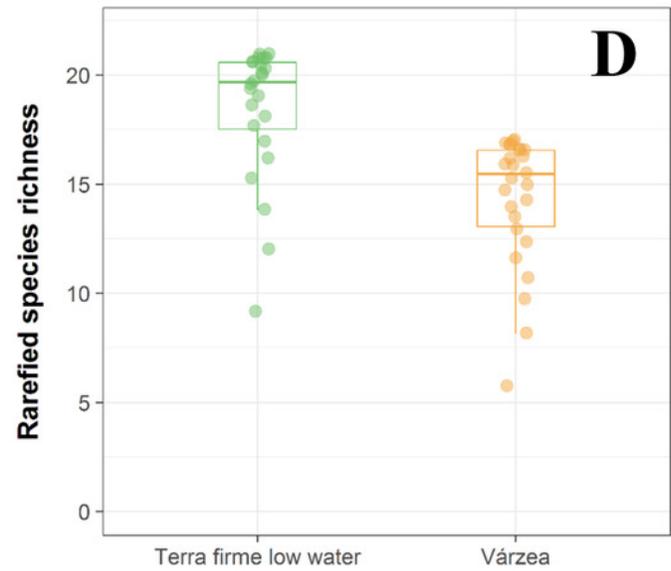

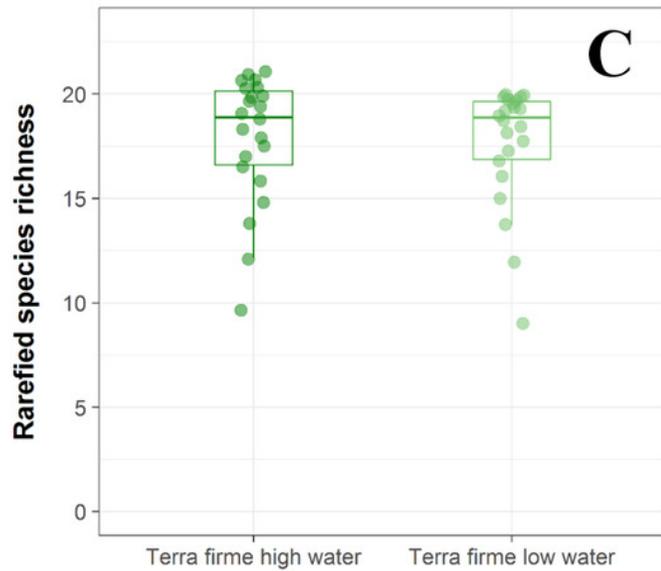

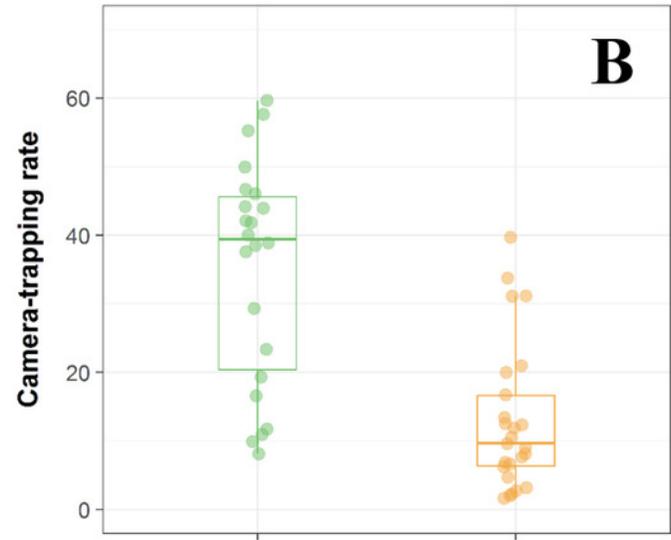

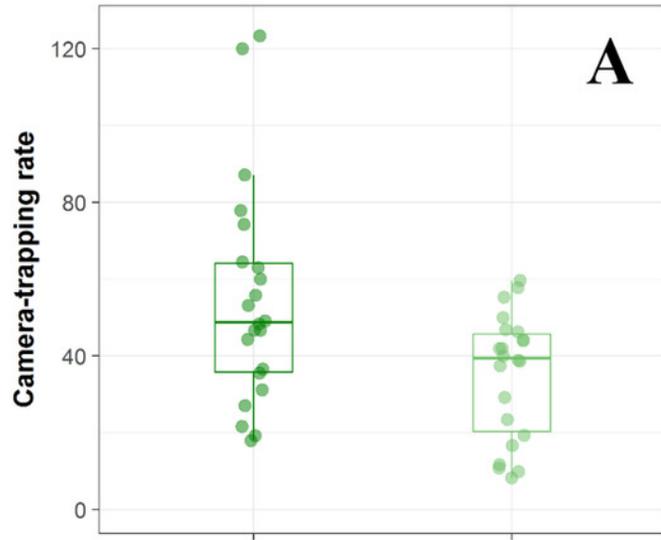

Figure 2

Comparison between *terra firme* and *várzea* forests during both the high- and low-water phases of the flood pulse considering both the total abundance and species richness of terrestrial forest vertebrates.

Boxplots comparing abundance and rarefied species richness between *terra firme* forests during both high- (dark green) and low-water (light green) phases of the flood pulse (A and C) and between *várzea* (orange) and *terra firme* forests (light green) during the low-water phase (B and D).

Season

Forest type

Figure 3

Camera trapping rate of terrestrial vertebrates recorded in *terra firme* and *várzea* forests.

(A) Camera trapping rates in *terra firme* forests during both high- (dark green bars) and low-water phase of the flood pulse (light green bars). (B) Camera trapping rates in both *terra firme* and in *várzea* forests during the low-water phase of the flood pulse. Light green and orange bars represent *terra firme* and *várzea* forests, respectively. Species are represented by the first four letters of each genus and first four letters of each species and ordered from least to most abundant top to bottom. Asterisks indicate significant differences according to paired (A) and unpaired t-tests (B); * $p \leq 0.05$, ** $p \leq 0.01$, *** $p \leq 0.001$.

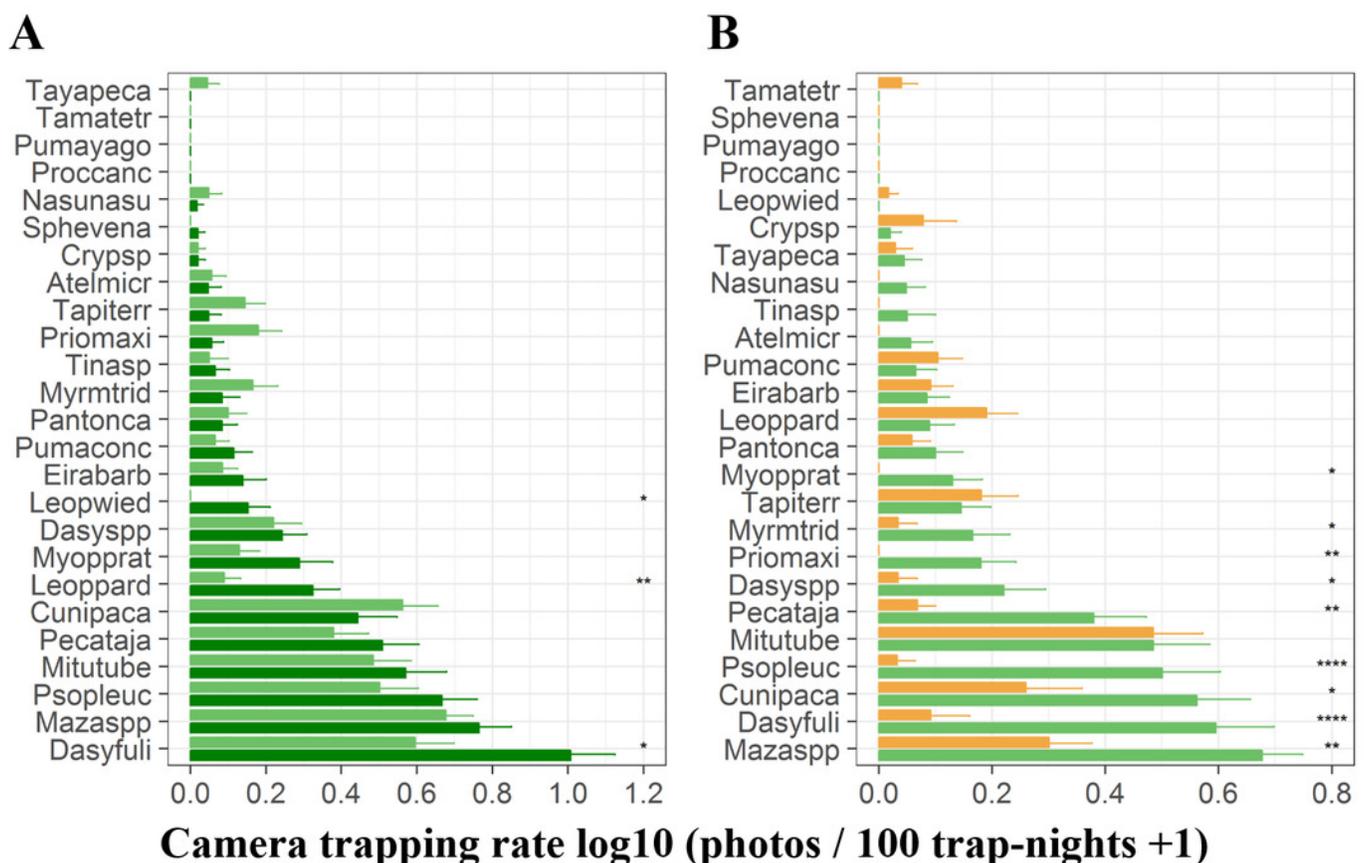

Figure 4

Terrestrial vertebrate species composition in Amazonian seasonally-flooded and unflooded forests during both high- and low-water phases of the flood pulse.

(A) Principal Coordinates Analysis (PCoA) ordination of the terrestrial vertebrate assemblage structure detected by camera traps in Amazonian *terra firme* forests during both high- and low-water phases of the flood pulse (green and light-green circles, respectively) and in *várzea* forests (orange circles). (B) Procrustes rotation plot of *terra firme* sites sampled during both high- and low-water phase of the flood pulse. Arrows (vectors) indicate the species migration in community space from the high- to the low-water season.

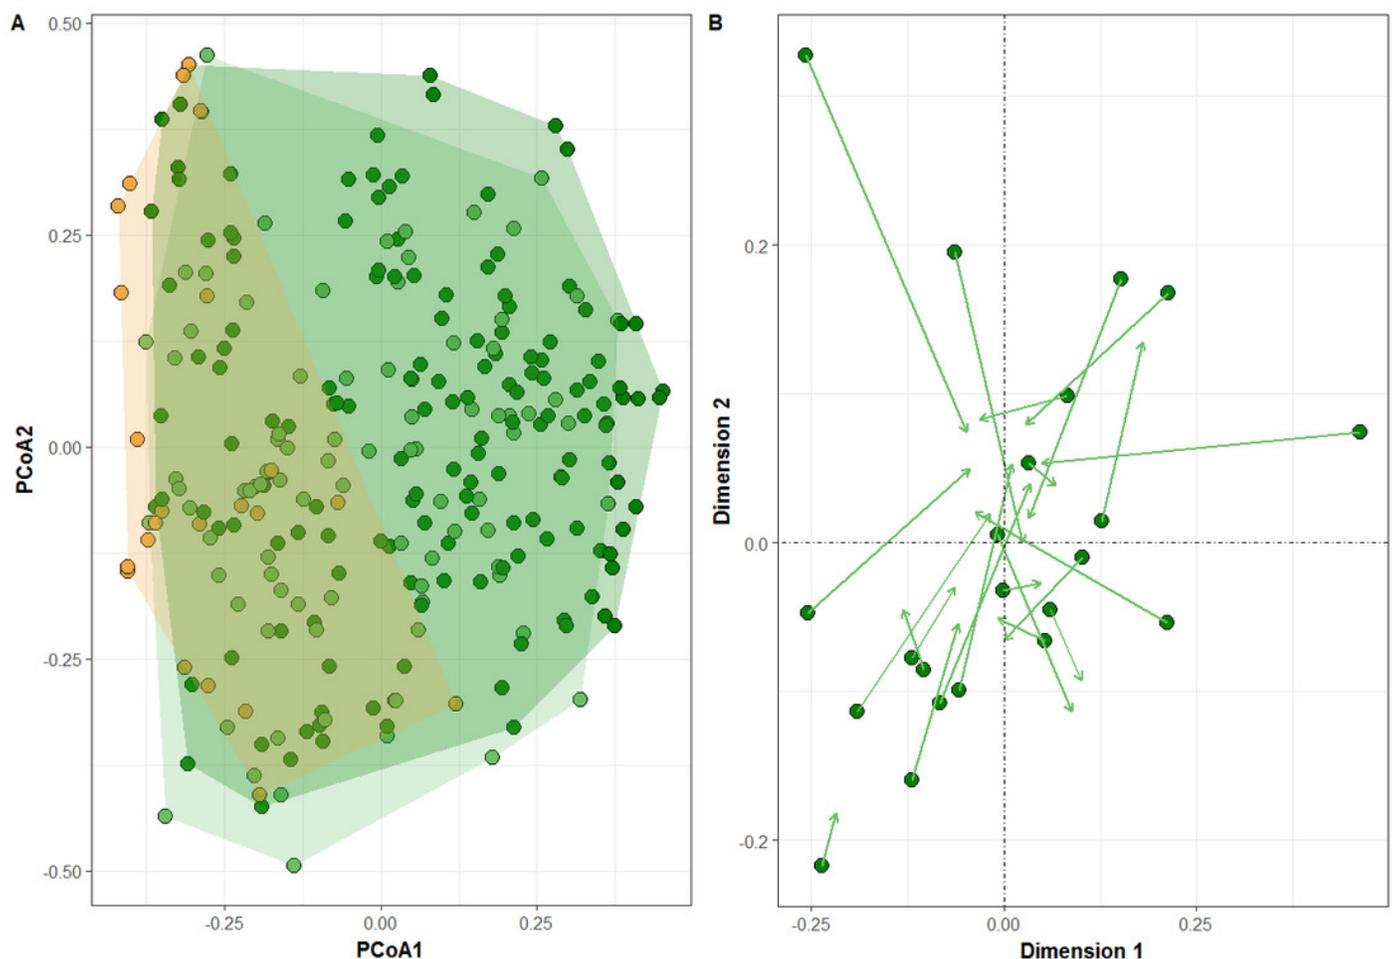

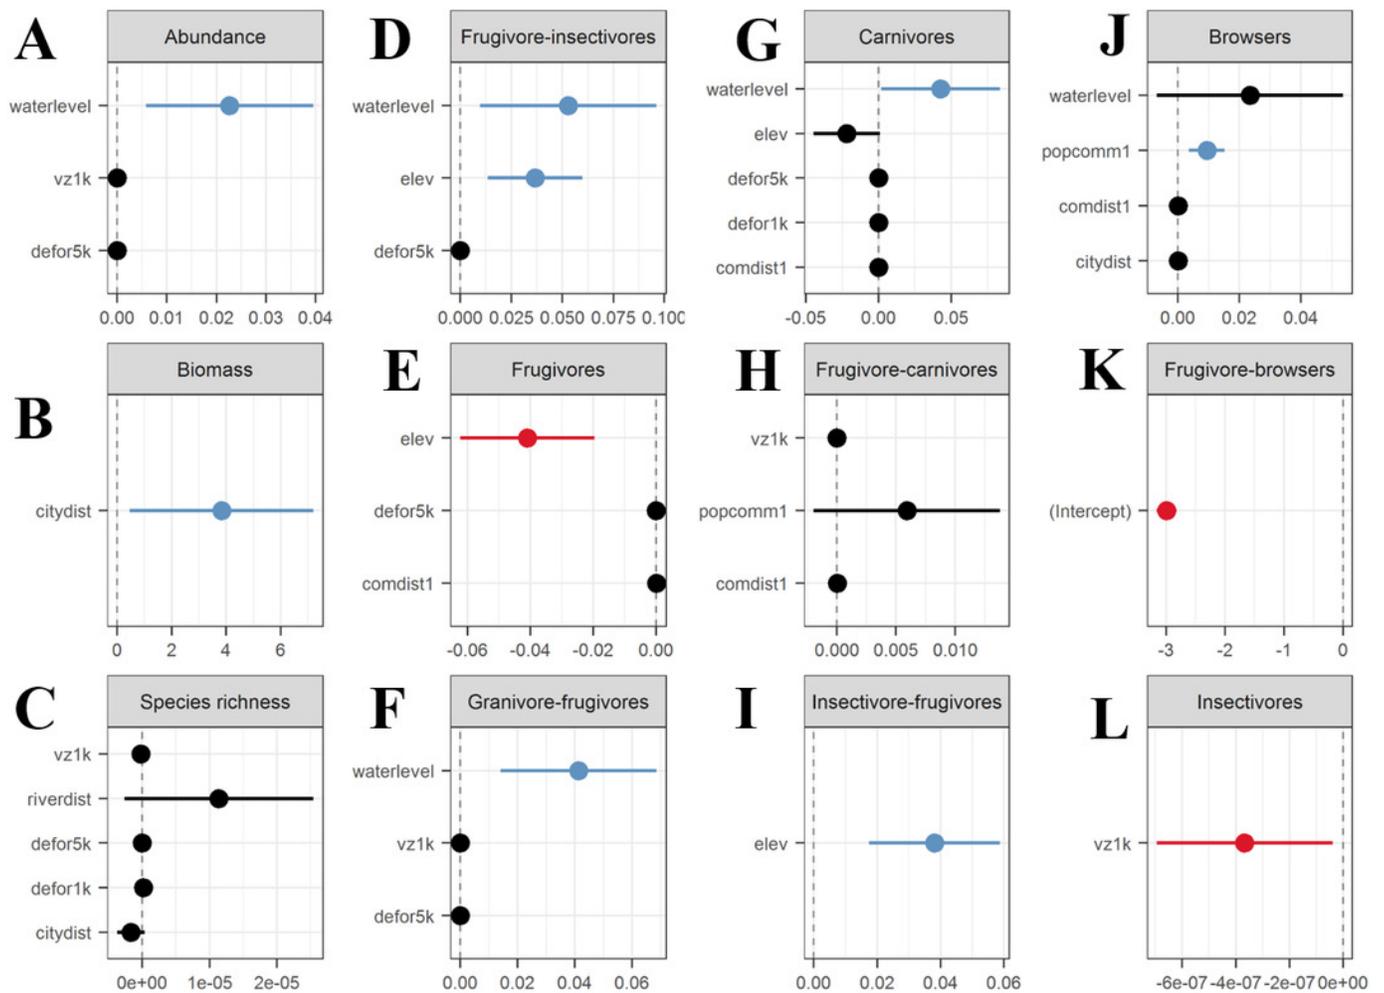

Figure 5

Coefficient estimates (\pm 95% confidence intervals) showing the magnitude and direction of effects of different explanatory variables retained in the best performing GLMs.

(A) aggregate abundance, (B) aggregate biomass of all species, (C) species richness (D-L) numbers of detections of each trophic guild.

Regression coefficients \pm 95% CI

Table 1 (on next page)

Camera trapping effort at Amazonian flooded and unflooded forests, along the Juruá River, Amazonas, Brazil (see Fig. 1).

Sample Design	Flood pulse phase	Number of active CTS	
		<i>Terra Firme</i>	<i>Várzea</i>
Sample design 1	From high to low water	193	
Sample design 2	High-water	30	-
Sample design 2	Low-water	30	26
Total		253	26

1

Table 2 (on next page)

Covariates used to investigate the seasonal dynamics of terrestrial vertebrates in Amazonian flooded and unflooded forests, along the Juruá River region, western Brazilian Amazonia

1

Covariate	Abbreviation	Description
Area of <i>várzea</i> forest	vz0.5k	Area (m ²) of seasonally flooded forest within a 500m circular buffer centered at each CTS
	vz1k	Area (m ²) of seasonally flooded forest within a 1000m circular buffer centered at each CTS
	vz5k	Area (m ²) of seasonally flooded forest within a 5000m circular buffer centered at each CTS
Distance to <i>várzea</i> forest	vzdist	Euclidean distance from each CTS to the nearest <i>várzea</i> forest
Deforestation area	defor0.5k	Total area (m ²) of deforestation within a 500m circular buffer centered at each CTS
	defor1k	Total area (m ²) of deforestation within a 1000m circular buffer centered at each CTS
	defor5k	Total area (m ²) of deforestation within a 5000m circular buffer centered at each CTS
Distance to nearest deforestation	defordist	Euclidean distance from each CTS to the nearest deforestation patch
Community size	popcomm1	Number of residents of the local community nearest each CTS

Table 2 continued

Distance to local	commdist1	Euclidean distance from each CTS to the nearest local community
-------------------	-----------	---

community

Distance to urban center	citydist	Euclidean distance from each CTS to the nearest urban center
Elevation	elev	Elevation (m) of the CTS above the main channel of the Juruá river.
River distance	riverdist	Distance from each CTS to the midpoint of Juruá river
Water level	waterlevel	Mean daily water level of the Juruá river during the deployment period of each CTS

2

Table 3 (on next page)

Terrestrial vertebrate species detected by camera trapping stations (CTS) deployed in this study in Amazonian flooded and unflooded forests, along Juruá river, Amazonas, Brazil.

Class	Order	Species	English vernacular name	Trophic guild
AVES	GRUIFORMES	<i>Psophia leucoptera</i> (Spix, 1825)	Pale-winged trumpeter	Frugivore-Insectivore
	STRUTHIONIFORMES	<i>Crypturellus spp</i> (Brabourne & Chubb, 1914)	Small tinamous	Granivore-frugivore
	GALLIFORMES	<i>Tinamus sp</i> (Hermann, 1783)	Great tinamous	Granivore-frugivore
MAMMALIA	CARNIVORA	<i>Mitu tuberosum</i> (Spix, 1825)	Razor billed curassow	Frugivore
		<i>Panthera onca</i> (Linnaeus, 1758)	Jaguar	Carnivore
		<i>Procyon cancrivorus</i> (G.[Baron] Cuvier, 1798)	Crab-eating-racoon	Frugivore-insectivore
		<i>Puma concolor</i> (Linnaeus, 1771)	Puma	Carnivore
		<i>Herpailurus yagouaroundi</i> (É. Geoffroy Saint-Hilaire, 1803)	Jaguarundi	Carnivore
		<i>Leopardus wiedii</i> (Schinz, 1821)	Margay	Carnivore
		<i>Leopardus pardalis</i> (Linnaeus, 1758)	Ocelot	Carnivore
		<i>Speothos venaticus</i> (Lund, 1842)	Bush dog	Carnivore
		<i>Eira barbara</i> (Linnaeus, 1758)	Tayra	Frugivore-Carnivore
		<i>Atelocynus microtis</i> (Sclater, 1883)	Small-eared-dog	Frugivore-Carnivore
CINGULATA		<i>Nasua nasua</i> (Linnaeus, 1766)	Coati	Frugivore-insectivore
		<i>Priodontes maximus</i> (Kerr, 1792)	Giant armadillo	Insectivore-Frugivore
		<i>Dasypus spp</i> (Linnaeus, 1758)	Armadillo	Insectivore-Frugivore
Class	Order	Species	English vernacular name	Trophic guild

	CETARTIODACTYLA	<i>Tayassu pecari</i> (Link, 1795)	White lipped peccary	Granivore-Frugivore
		<i>Pecari tajacu</i> (Linnaeus, 1758)	Collared peccary	Granivore-Frugivore
		<i>Mazama spp</i> (Rafinesque, 1817)	Brocked deer	Browser
MAMMALIA	PERISSODACTYLA	<i>Tapirus terrestris</i> (Linnaeus, 1758)	Tapir	Browser
	PILOSA	<i>Tamandua tetradactyla</i> (Linnaeus, 1758)	Southern tamandua	Insectivore
		<i>Myrmecophaga tridactyla</i> (Linnaeus, 1758)	Giant anteater	Insectivore
	RODENTIA	<i>Myoprocta pratti</i> (Pocock, 1913)	Green acouchy	Granivore-frugivore
		<i>Dasyprocta fuliginosa</i> Wagler, 1832	Black agouti	Granivore-frugivore
		<i>Cuniculus paca</i> (Linnaeus, 1766)	Paca	Frugivore-browser
