Factors and associations for physical activity in severely obese adults during a two-year lifestyle intervention

Objective: This study of severely obese adults participating in a two-year lifestyle intervention investigates associations between the independent variables: change in self-efficacy for physical activity (PA) in the face of psychological barriers, perceived behavioural control over PA, and PA self-identity and the dependent variable of change in objectively assessed PA. The intervention comprised four residential periods in a rehabilitation centre and combined diet, physical activity, and cognitive behavioural therapy. Materials and methods: Forty-nine severely obese adults (37 women, mean body mass index 42.1 kg/m^2) were included in the study. Assessment was done four times using questionnaires and an accelerometer. A linear mixed model based on restricted maximum likelihood was used in analyses for change over time. Associations were studied using linear regression analyses. Age, gender, and change in body mass index were used as control variables. Results: In the adjusted analyses, change in perceived behavioural control over PA was associated with change in PA (Stand. coeff. = 0.32, p = .005). Change in PA was not associated with either change in self-efficacy over PA in the face of psychological barriers (Stand. coeff. = 0.13, p = .259) or PA self-identity (Stand. coeff. = -0.07, p = .538). Conclusion: Perceived behavioural control may be a valid target to increase and maintain PA in severely obese adults participating in lifestyle interventions. More research is needed to investigate the process of behaviour change in this population.

Introduction

A web of political, societal, and environmental factors contributes to the growing prevalence of overweight and obesity in Western countries (Swinburn et al., 2011). Alarmingly, the group classified as severely obese has increased the most (Sturm, 2007; Midthjell et al., 2013). In obesogenic societies (Swinburn et al., 2011), the health services have responsibility to ameliorate the ailing health, functioning, and quality of life experienced by severely obese individuals (van Nunen et al., 2007). Thus, various obesity surgeries and lifestyle interventions have been developed. Obesity surgery brings about physiological and functional changes, enforcing altered eating behaviours and thus leading to weight loss (Kissler & Settmacher, 2013). By contrast, lifestyle interventions work exclusively through individual modifications and self-management of health-related behaviour (Kirk et al., 2012). A weight loss of 5-10% is regarded sufficient to gain health effects and reduce the risk of obesity-related comorbidities (Tsigos et al., 2008; Dalle Grave, Calugi & El Ghoch, 2013). The most extensive weight losses are obtained through obesity surgery (Karlsen et al., 2013), whereas subjects attending lifestyle interventions seem to develop more favourable dietary patterns (Johnson et al., 2013). Both intervention types improve health-related quality of life (Karlsen et al., 2013).

In combination with diet modification, physical activity (PA) constitutes a core component of many lifestyle interventions for severely obese adults (Kirk et al., 2012; Dalle Grave, Calugi & El Ghoch, 2013). Studies have shown that PA impacts on weight loss and its maintenance (Catenacci & Wyatt, 2007; Butryn, Webb & Wadden, 2011), improves body composition (Lee et al., 2005; Kay & Fiatarone Singh, 2006; Goodpaster et al., 2010), reduces risk of cardio-metabolic comorbidities (Fogelholm, 2010; Goodpaster et al., 2010), and is positively associated with quality of life (Bond et al., 2006; Lerdal et al., 2011; Jepsen et al., 2013) in severely obese subjects. Thus, given the chronic nature of severe obesity, adherence to PA is important (Tsigos et al., 2008), but unfortunately PA decreases with increasing body mass index (BMI) (Tudor-Locke

38 et al., 2010; Hansen et al., 2013). Severely obese subjects face many barriers to PA, such as the

39 excess body weight itself (Wiklund, Olsén & Willén, 2011; Christiansen, Borge & Fagermoen,

40 2012) and exposure in public (Wiklund, Olsén & Willén, 2011). A persistent increase of PA seems

41 to be difficult (Borg et al., 2002; Tate et al., 2007). Thus, lifestyle interventions should target and

42 strengthen patients' resources for PA through provision of knowledge and skills and

43 reinforcement of psychological factors that are likely to influence PA. Hence, self-efficacy for

44 PA, perceived behavioural control over PA, and PA self-identity have been proposed as targets for

45 PA interventions (Hagger, Chatzisarantis & Biddle, 2002; Jackson, Smith & Conner, 2003;

46 Lorentzen, Ommundsen & Holme, 2007; Hansen et al., 2014).

47   According to Bandura (Bandura, 1997), self-efficacy covers "a belief about what one can do

48 under different sets of conditions with whatever skills one possesses" (p. 37). Self-efficacy is

49 dynamic and modifiable (Bandura, 1997), and in relation to PA, it includes the capability of

50 adoption and maintenance of PA in the face of psychological barriers such as feeling depressed,

51 worried, angry, or stressed (Lorentzen, Ommundsen & Holme, 2007). Self-efficacy for PA in the

52 face of psychological barriers has shown positive associations with change in PA in community

53 samples (Lorentzen, Ommundsen & Holme, 2007). The related concept of perceived behavioural

54 control refers to a person's "belief as to how easy or difficult performance of the behaviour is

55 likely to be" (Ajzen & Madden, 1986, p. 457). Perceived behavioural control predicts PA

56 behaviour (Hagger, Chatzisarantis & Biddle, 2002) and plays a role in PA behaviour change in

57 community samples (Lorentzen, Ommundsen & Holme, 2007). Identity is a third factor

58 influencing human behaviour. Hence, there is a reciprocal reinforcing relationship between a

59 behaviour-specific identity and repetition of that behaviour. Furthermore, identity is a product of

60 interaction with others (Charng, Piliavin & Callero, 1988). PA identity, i.e., "identifying oneself

61 as a physically active person" (Lorentzen, Ommundsen & Holme, 2007, p. 95), has shown

62 positive associations with self-reported PA (Jackson, Smith & Conner, 2003) and change in PA

63 (Lorentzen, Ommundsen & Holme, 2007) in community samples.

64   Common outcome variables in research on lifestyle interventions for severely obese adults

65 are body weight and risk factors for medical comorbidities (Anderson, Conley & Nicholas, 2007;

66 Goodpaster et al., 2010; Danielsen et al., 2013; Karlsen, Sohagen & Hjelmesaeth, 2013). Because

67 the pathway for these outcomes is behaviour change, it is pivotal to understand factors involved

68 in the behaviour change process. However, to our knowledge, no studies have investigated

69 associations in patterns of change between psychological factors and objectively assessed PA in

70 severely obese adults during a lifestyle intervention. Thus, the aim of this study was to investigate

71 associations between the independent variables: change (Δ) in self-efficacy, Δ perceived

72 behavioural control, and Δ self-identity and the dependent variable of Δ PA. The study hypothesis

73 was that there would be positive associations in the patterns of change between self-efficacy for

74 PA in the face of psychological barriers, perceived behavioural control over PA, and PA identity

75 and objectively assessed PA in severely obese adults participating in a two-year lifestyle

76 intervention.

77 **Materials and methods**

78 Participants and setting

79   The Haugland Obesity Study has a two-year prospective design. We assessed severely obese

80 patients before, during and between residential periods in Red Cross Haugland Rehabilitation

81 Centre (RCHRC) in Norway, where they participated in a two-year lifestyle intervention. The

82 programme was funded by the public health services. For those with jobs, the social welfare

83 system paid sick leave benefits during the residential periods. Referral to RCHRC was done by

84 general practitioners. Referred patients were called in to a two-week stay, wherein motivation for

85 change and ability to function in a group were assessed and participation in the programme was

86   decided. Due to limited capacity of the centre, the time from referral to this assessment stay was

87   up to two years. Fifty-three patients, divided in four groups, started the actual intervention (the

88   time point which constituted the baseline of the present study) and were all offered inclusion in

89   the present study. After the intake of these four groups, the public health services reduced the

90   funding to RCHRC and cut down the intervention for new patients to a one-year programme with

91   shorter residential stays. Thus, we had to discontinue inclusion of participants.

92   Inclusion criteria for the intervention were age between 18-60 years, and BMI ≥ 40 kg/m^2

93   with or without comorbidities, or ≥ 35 kg/m^2 with comorbidities, such as type 2 diabetes,

94   treatment-resistant hypertension, and sleep apnoea (Norwegian Directorate of Health, 2009).

95   Exclusion criteria were: referral to, or, previous obesity surgery; pregnancy; severe

96   cardiovascular disease; alcohol or substance abuse; and mental illness or physical impairment

97   that would prevent adherence to the intervention.

98   Intervention

99   The lifestyle intervention was a multi-component programme developed by the health

100   professionals at RCHRC, built on recommendations for best practice (Shaw et al., 2005; Kirk et

101   al., 2012; Dalle Grave, Calugi & El Ghoch, 2013; Olander et al., 2013) and prior experience. The

102   objective was to strengthen favourable PA and diet-related behaviour. The intervention covered

103   15 weeks over two years with four residential periods of six, three, three, and three weeks'

104   duration. A team of physicians, nurses, physiotherapists, exercise therapist, and dietician – many

105   with training in cognitive behavioural therapy (CBT) (Shaw et al., 2005) – delivered mandatory

106   practical and theoretical sessions on PA, diet, and CBT. The PA consisted of supervised and un-

107   supervised out- and indoor activities, in groups and individually. Brisk walking, swimming,

108   strength training, ball games, and aerobics were the predominant activities during the residential

109   periods, bringing on moderate to high intensities of PA. The scheduled PA lasted 20-60 minutes

110   per session, in total nine to eleven hours per week. In addition, the patients were encouraged to

111   carry out PA on their own initiative. Taking preferences, limitations, and sustainability into

112   account, each patient developed a plan for PA for home periods and discussed it with staff.

113   Patients were recommended to combine endurance and strength training and undertake at least 60

114   daily minutes of PA, which could be divided in intervals of down to ten minutes (Becker et al.,

115   2004). Thus, no standard exercise programme was performed in the home periods. The main goal

116   regarding diet was adaptation to a sustainable, healthy diet and a favourable eating-pattern. The

117   meal plan at RCHRC was based on the Nordic Nutrition Recommendations (Becker et al., 2004)

118   with three low-fat, high-fibre, and energy-reduced meals and two to three snacks per day. Most of

119   the meals were provided by the canteen. However, the patients prepared some of their meals in

120   supervised groups, and they ate together. They were advised to follow the same dietary principles

121   at home. Thus, severe energy-restriction was not applied. In total, eleven group sessions of CBT,

122   led by members of the health care team, took place, five during the six-week residential period

123   and two during each of the subsequent three three-week periods. Before the end of each session,

124   home work was given, and the following session started with a review of that. In sessions 1-5,

125   during the first stay, the methods and instruments of CBT were introduced and related to change

126   in PA and eating. When the patients came back for the subsequent periods, experiences from the

127   home periods were discussed in sessions 6-11 within the framework of CBT. For eight patients

128   who expressed a need, individual CBT was also provided.

129   Planning, barrier identification, and relapse prevention and management were practiced to

130   strengthen self-management of PA and eating (Olander et al., 2013). The group-based activities

131   aimed at stimulating peer support (Olander et al., 2013). Self-monitoring in home periods was

132   promoted using PA diaries (Olander et al., 2013) in which patients reported on PA and a few

133   added information on diet and success stories. All patients sent their diaries to RCHRC every

134   month. There was no other structured follow-up between the residential periods. Patients were

135   encouraged to contact their general practitioner if they needed more support and relatives were

136   not involved in the intervention.

137   Measures and procedures

138   Data were collected four times between February 2010 and October 2012 (Figure 1). The first

139   collection, baseline, was done prior to the start of the intervention, the second at the end of the

140   first residential stay and the third before the third stay, one year from baseline. The final data

141   collection took place before the fourth and last stay, two years from baseline. Socio-demographic

142   data in this study are baseline data.

143   Psychological factors

144   The psychological factors were assessed using self-reported questionnaires. Self-efficacy for PA

145   was assessed using a five-item measure. The participants indicated the extent to which they were

146   confident in their ability to perform planned PA in the face of psychological barriers (i.e., feeling

147   tired, depressed, anxious, angry, and stressed) on a seven-point scale from 1 ("not at all

148   confident") to 7 ("very confident"). The scale is a shortened and moderated version of the

149   original instrument developed by Bandura (2001). The version used in this study has

150   demonstrated excellent internal consistency with a Cronbach alpha coefficient of 0.91 (Hansen et

151   al., 2014). Another five-item measure was used to assess perceived behavioural control. The

152   participants rated their agreement with three positive (e.g., "I have total control over being

153   regularly physically active") and two negative statements (e.g., "Being regularly physically active

154   is difficult for me") on a seven-point scale from 1 ("totally agree") to 7 ("don't agree at all"). The

155   scale is an extended and moderated version of the original instrument developed by Norman &

156   Smith (1995). The version used in this study has demonstrated acceptable internal consistency

157   with a Cronbach alpha coefficient of 0.67 (Hansen et al., 2014). PA self-identity was assessed

158 using a three-item measure. The participants indicated the extent to which they agreed with

159 statements such as "Being physically active is a big part of who I am" on a five-point scale from

160 1 ("fits poorly") to 5 ("fits well"). The scale is a shortened and moderated version of the original

161 instrument developed by Anderson & Cychosz (1994). The version used in this study has

162 demonstrated excellent internal consistency with a Cronbach alpha coefficient of 0.91 (Hansen et

163 al., 2014). All three instruments have shown positive cross-sectional associations with objectively

164 assessed PA in adults (Hansen et al., 2014).

165 Physical activity

166 PA was measured using the accelerometer Actigraph GTI M (Actigraph, Fort Walton Beach, FL,

167 USA), which is a hip-worn electronic movement sensor that converts acceleration into the

168 arbitrary unit "counts". The counts increase with the magnitude of the work rate for walking. The

169 participants were instructed to wear the accelerometer on the right hip for seven consecutive

170 days, except while sleeping or during water activities. The second assessment was completed

171 towards the end of the first residential stay whereas the others took place in home periods (Figure

172 1). The data were analysed with the Actigraph software ActiLife v. 5.3. A wear-time of $\geq$ ten

173 hours per day for $\geq$ four days was the criterion for a valid measure. Periods of $\geq$ 60 consecutive

174 minutes without counts were defined as non-wear-time, allowing for up to two minutes of counts

175 greater than zero within these 60 minutes (Trost, McIver & Pate, 2005; Sirard et al., 2011). The

176 counts were summed and averaged over the total wear-time to indicate the overall PA in counts

177 per minute (CPM). The accelerometer has been found to be valid in severely obese adults

178 (Aadland & Anderssen, 2012) and accelerometer-assessed PA has superior validity compared to

179 self-reported data (Prince et al., 2008).

180 Socio-demographic information and anthropometry

181 Socio-demographic information was obtained from questionnaires. Height was measured without

182 shoes to the nearest 0.5 cm with a wall mounted stadiometer (SECA, Germany). Weight was

183 measured on a bioelectrical impedance analysis device (BC 420S MA, Tanita Corp, Tokyo,

184 Japan) and reported to the nearest 0.1 kg.

185 Ethics

186 Written informed consent was obtained from all participants prior to the data collection, in

187 accordance with the Helsinki Declaration. Ethical approval was obtained from the Regional

188 Committee for Medical and Health Research Ethics for South-East Norway (registration number

189 2010/159).

190 Statistical analysis

191 Before calculating the mean values for the psychological factors, the three positively worded

192 items for perceived behavioural control were reversed. Thus, higher mean values indicated

193 stronger self-efficacy, perceived control, and identity. Cronbach alpha was used to determine the

194 internal consistency of the instruments.

195   Data on civil status were dichotomized into "married/cohabiting" vs "single/divorced",

196 educational level into "< 15 years of education" vs "≥ 15 years of education" (i.e.,

197 college/university), and employment into "not working" (i.e., being unemployed or receiving

198 pensions or benefits) vs "working". BMI was calculated as weight in kilograms divided by the

199 square of the height in meters.

200   A linear mixed model based on restricted maximum likelihood estimation with random

201 intercept for subjects was used in all analyses for change over time (Twisk, 2003), using least

202 significant difference from baseline. Effect size (ES) for change was calculated by subtracting the

203 two-year score from the baseline score, divided by the standard deviation (SD) at baseline. ES

204 were judged against the standard criteria proposed by Cohen: Small change (0.2 to < 0.5),

205 moderate change (0.5 to < 0.8), and large change ($\geq$ 0.8) (Ellis, 2011).

206   The associations between the independent variables: Δ self-efficacy for PA in the face of

207 psychological barriers, Δ perceived behavioural control over PA, and Δ PA self-identity and the

208 dependent variable of Δ PA were analysed using linear regression, applying delta scores between

209 time points ($\Delta y_1 = y_1 - y_0$; $\Delta x_1 = x_1 - x_0$; $\Delta y_2 = y_2 - y_1$, etc.) (Twisk, 2003). For the independent

210 and dependent variables and BMI, the differences between baseline and week six ($\Delta 1$), between

211 week six and year one ($\Delta 2$), and between year one and year two ($\Delta 3$) were used. The linear

212 mixed model was omitted because the interpretation of the regression coefficients in such a

213 model is difficult, due to mixing of longitudinal (with-in subject) changes and the cross-sectional

214 (between-subject) differences (Twisk, 2003). Age, gender, and Δ BMI served as covariates in the

215 multiple regression analyses. A total of $N = 71$ observations was included in the regression

216 analyses. Residuals were normally distributed in all models.

217   Baseline subject characteristics are presented as percentages for categorical data and mean

218 values (SD) for continuous variables. The estimates, obtained from the linear mixed model, for

219 the psychological factors, PA, and BMI are presented as means with 95% confidence intervals

220 (CI) for the four assessment points. We performed a drop-out analysis with the chi-squared test

221 for difference in gender and the independent samples t-test for differences in other variables.

222   The statistical analyses were done using SPSS v. 20.0 (SPSS Inc., Chicago, USA). A two-

223 sided p-value $\leq$ 0.05 indicated statistical significance.

224 **Results**

225   Forty-nine patients (37 women, 75.5%) consented to participate in the study. Baseline

226 characteristics are presented in Table 1. Other details of the participants have been presented

227 previously (Jepsen et al., 2013; Aadland et al., 2014).

228   Drop-outs and available data for all time points are displayed in Figure 1. At year two,

229   twenty-two participants (44.9%, 16 women and six men) were lost to follow-up. Reasons for

230   dropping out of the intervention included pregnancy, referral to obesity surgery, having reached

231   personal weight goal, health problems, or obligations that interfered with the intervention. Six

232   participants dropped out for unknown reasons and five withdrew from the study due to problems

233   with the study protocol (repeated blood tests and assessments of maximal oxygen consumption

234   which were included in the Haugland Obesity Study). The participants lost to follow-up did not

235   differ from those who completed the study with regards to gender, age, BMI, PA, or

236   psychological factors at baseline, or initial changes (during the first six weeks) in BMI, PA, or

237   psychological factors. Missing data for psychological factors resulted from participants being

238   absent when the questionnaires were administered at RKHRC. Furthermore, some of the

239   accelerometer-obtained data failed to fulfil the validity requirements.

240   The internal consistency of the measures of self-efficacy, perceived behavioural control, and

241   self-identity, calculated at baseline, were acceptable to excellent using Cronbach alpha

242   coefficients of 0.92, 0.67, and 0.93, respectively.

243   Table 2 shows that PA increased significantly from baseline to the end of the first residential

244   period and remained increased at the one-year follow-up. However, after two years the increase

245   in PA was not maintained (ES = 0.24). All three psychological factors were significantly

246   strengthened at the end of the first residential period (Table 2). However, self-efficacy for PA in

247   the face of psychological barriers decreased thereafter and at one year the improvement had

248   vanished (ES = 0.14). In contrast, perceived behavioural control over PA (ES = 0.51) and PA self-

249   identity (ES = 0.74) remained stronger at year one and two. Compared to baseline, BMI was

250   significantly lower at the three subsequent assessments. However, the weight loss achieved

251   during the first year was only partly maintained at year two (Table 2). The mean weight loss from

252   baseline constituted 4.8% after six weeks, 6.4% at year one, and 3.3% at year two.

253   Table 3 shows the associations between change in the psychological factors and Δ PA over the

254   two-year intervention. Δ perceived behavioural control was the only independent variable that

255   was significantly associated with Δ PA during the two years.

256   **Discussion**

257   In the present two-year study of associations between change in psychological factors for PA and

258   Δ PA in severely obese adults, we found that Δ perceived behavioural control was associated with

259   Δ PA. By contrast, Δ self-efficacy and Δ self-identity showed no association with Δ PA. Although

260   not directly comparable, our findings differ from a cross-sectional study using the same measures

261   which revealed positive relationships between PA and all the three psychological factors, with

262   self-identity for PA showing the strongest association (Hansen et al., 2014).

263   It has been proposed that scales on perceived behavioural control reveal aspects of two

264   different dimensions, namely control and difficulty (Sparks, Guthrie & Shepherd, 1997). With

265   respect to the instrument used in this study, the positively worded items may capture control

266   while the negative tap into difficulties, which could explain the Cronbach alpha of 0.67. Still,

267   perceived behavioural control over PA was the only independent variable that worked as

268   hypothesised. Not only was it strengthened during the intervention with a moderate ES (Ellis,

269   2011), but the change of it was also associated with Δ PA. Perceived behavioural control has

270   shown cross-sectional associations with self-reported PA in adult obesity surgery patients (Hunt

271   & Gross, 2009) and overweight and obese adolescents (Plotnikoff et al., 2013). However, to our

272   knowledge, no studies have examined this variable during lifestyle interventions and related it to

273   Δ PA.

274   Although self-efficacy, as such, is a global concept (Bandura, 1997) the measure used in this

275   study was limited to self-efficacy in the face of psychological barriers to PA. The initial

276   strengthening had disappeared at later assessments and was not associated with behaviour

277 change. This could be interpreted as if the intervention did not target or succeed in strengthening

278 self-efficacy in the face of psychological barriers, or it may indicate that psychological barriers

279 did not play a central role in the PA of these subjects. Other barriers, such as time limitations,

280 which we have not investigated, may be of greater significance (Biddle & Fox, 1998). Still, a

281 longitudinal study found a positive relationship between moods and PA in overweight to obese

282 adults with diabetes. However, the data were reported by lifestyle coaches, not patients (Venditti

283 et al., 2014), implying a possible responder bias (Ahmed et al., 2012).

284   Next, the intervention strengthened the PA self-identity with a moderate ES (Ellis, 2011).

285 Embarrassment, poor experience, and non-identification with PA may be obstacles to PA in obese

286 adults (Biddle & Fox, 1998; Hills & Byrne, 2006). So the strengthening of PA identity could be

287 regarded as positive (Biddle & Fox, 1998). However, in our study we could not confirm that

288 strengthened identity translates into more PA. In community samples, PA identity has shown

289 positive correlations with objectively measured (Hansen et al., 2014) and self-reported (Jackson,

290 Smith & Conner, 2003) PA. Thus, this phenomenon deserves attention in future research and in

291 clinical practice.

292   Regarding the impact of body weight, cross-sectional data have demonstrated an adverse

293 relationship between BMI and objectively assessed PA (Hansen et al., 2013) and BMI and

294 perceived behavioural control over PA (Caperchione et al., 2008). However, when controlling for

295 Δ BMI, Δ perceived behavioural control and Δ PA still showed associations in the present study.

296   Overall, the findings suggest that factors associated with PA in community samples (Jackson,

297 Smith & Conner, 2003; Lorentzen, Ommundsen & Holme, 2007; Hansen et al., 2014) should not

298 be generalised to samples of severely obese adults in lifestyle interventions without caution and

299 testing. Social and environmental factors, including family, work place, and community, may

300 predict and mediate the mechanisms of change in PA in this population (Vartanian & Shaprow,

301 2008; Wiklund, Olsén & Willén, 2011). Thus, future research could take broader perspectives and

302 adopt an ecological approach (Bauman et al., 2012).

303   Our study confirms the findings from other studies (Borg et al., 2002; Tate et al., 2007) that

304 maintenance of PA is an unresolved challenge. With regards to the overall PA, the initial and year

305 two PA (Table 2) were similar to the PA of American obese adults (288 CPM) (Tudor-Locke et

306 al., 2010) and their Norwegian counterparts (women: 276 CPM, men: 290 CPM) (Hansen et al.,

307 2013), whereas the mean value from the second assessment (Table 2) was well above the 344

308 CPM for American normal weight (Tudor-Locke et al., 2010) and 352 CPM for women and 368

309 CPM for men of normal weight in Norway (Hansen et al., 2013).

310   Regarding weight loss, the one-year reduction of BMI (Table 2) was within the criterion for

311 success, defined as 5-10% reduction from the start of an intervention (Tsigos et al., 2008; Dalle

312 Grave, Calugi & El Ghoch, 2013). However, patients had regained some of the weight at year

313 two which is a common challenge in lifestyle interventions (Dalle Grave, Calugi & El Ghoch,

314 2013).

315   The present study offered novelty and strength as it used data from four time points and

316 therefore could provide information about patterns of change throughout the two-year

317 intervention. In addition, assessing PA objectively with accelerometers is superior to self-reported

318 PA (Prince et al., 2008). However, accelerometers fail to capture water activities, bicycling, and

319 strength training (Warren et al., 2010). For the present study, this limitation probably caused a

320 25% underestimation of the true overall PA for the second assessment (Aadland et al., 2014), as

321 such activities were common during the residential period. Still, for the purpose of the study, we

322 decided to avoid reporting of intensity-specific PA, due to difficulties of interpretation when

323 applying count thresholds to separate different intensities of PA generally (Orme et al., 2014) and

324 in the severely obese population specifically (Aadland & Steene-Johannessen, 2012).

325 Underestimation of PA was probably a minor problem when assessing trends over the home

326   periods, because patients generally did not engage in such activities (Aadland & Robertson,

327   2012), and because the underestimation would be equally distributed over time.

328   The main weakness of this study was the relatively high proportion of drop-outs and missing

329   data. Although the drop-out analysis did not reveal differences between the completers and the

330   non-completers, bias cannot be ruled out. However, by using the mixed model based on

331   maximum likelihood estimation and including all valid observations from all four time points, the

332   statistical power increased. Still, our results are based on associations and thus, causal

333   relationships cannot be inferred. Lastly, the participants were a self-selected, treatment-seeking

334   group, participating in a specific intervention programme and there was no control group. While

335   common in clinical studies, these weaknesses limit the generalisability of our results. For

336   transparency and usefulness, we have therefore attempted to report rigorously on the intervention

337   and the flow of the participants (Vandenbroucke et al., 2007).

338   **Conclusion**

339   Little is known about factors related to the process of change of PA behaviour in severely obese

340   adults participating in lifestyle interventions. We hypothesised that the independent variables: Δ

341   self-efficacy for PA, Δ perceived behavioural control over PA, and Δ PA self-identity would be

342   associated with the dependent variable of Δ PA in the sample of severely obese adults who

343   participated in a two-year programme. However, such an association was only confirmed

344   between Δ perceived behavioural control and Δ PA. More research is required to investigate PA

345   behaviour change processes in severely obese both in non-residential and residential settings and

346   with larger samples and stronger design. An ecological framework may provide a good structure

347   (Bauman et al., 2012), with both quantitative and qualitative methods being suitable.

348   The findings of the present study indicate that perceived behavioural control may be a valid

349   target for increase and maintenance of PA in severely obese adults.

350 **Acknowledgements**

351 We thank the staff at RCHRC for their assistance in the data collection and express our sincere

352 gratitude to the participants.

353 Conflict of interest

354 The authors have no conflict of interest to declare.
