Since hundred millions of years the interactions between plants and insect are essential in terrestrial ecosystems, as they composed one of the main trophic level in forest communities. Plant-insect interactions are correlated with many different environmental factors (such as the diversity of plants or climatic parameters) but these relations are still poorly understood, especially since human activities may have disturbed these relationships. This study put forward the first comparison between three European fossil leaves assemblages from late Cenozoic (Willershausen, Berga) and early Quaternary (Bernasso). The plant-insect interactions were estimated through insect activity traces identified on the leaf blade. Half of the leaves showed some kind of interaction in Willershausen (Germany) while 25% and 35% of the leaves were affected by insects in Berga (Germany) and Bernasso (35%) respectively. Proportions of specialized damages are significantly higher in Bernasso, which may suggest a more important thermal and hydric seasonality than in Willershausen and Berga. Convergent results reveal that temperature and precipitation seasonality seem to have a larger influence on plant-insect interaction difference than the annual average of these climatic parameters as it traditionally discussed. This is the first time in fossil record that seasonality is highlighted to be a potential factor impacting the plant-insect interaction.

ABSTRACT

Plant and insect interactions are essential in terrestrial ecosystems and have been so for hundreds of millions of years, as they compose one of the main trophic levels in forest communities. Plant-insect interactions are correlated with many different environmental factors (such as the diversity of plants or climatic parameters) but these relations are still poorly understood, especially since human activities may have disturbed these relationships. This study put forward the first comparison between three European fossil leaves assemblages from late Cenozoic (Willershausen, Berga) and early Quaternary (Bernasso). The plant-insect interactions were estimated through insect activity traces identified on the leaf blade. Half of the leaves showed some kind of interaction in Willershausen (Germany) while 25% and 35% of the leaves were affected by insects in Berga (Germany) and Bernasso (35%) respectively. Proportions of specialized damages are significantly higher in Bernasso, which may suggest a more important thermal and hydric seasonality than in Willershausen and Berga. Convergent results reveal that temperature and precipitation seasonality seem to have a larger influence on plant-insect interaction difference than the annual average of these climatic parameters as it traditionally discussed. This is the first time in fossil record that seasonality is highlighted to be a potential factor impacting the plant-insect interaction.

INTRODUCTION

Climate is a major factor affecting the extension, structure, and composition of terrestrial ecosystems (Taylor et al., 2012; Frank et al., 2015). Hence, past climatic oscillations are of special importance for understanding and interpreting biotic changes in the past (e.g., DeChaine & Martin, 2006) and are of interest in terms of forecasting the biotic response to future global warming (Meehl et al., 2007). Nowadays, it is clear that Human activities have now reached a global impact affecting components of the Earth system as a whole (Turner et al., 1990; Heller & Zavaleta, 2009) while these impacts on terrestrial biotas are still poorly understood (Knight & Harrison, 2012). Nevertheless, previous studies on fossil insect herbivory have provided a variety of ecological and evolutionary information, such as climate (e.g., Wappler, 2010; Wappler et al., 2012), the evolutionary impact of plant radiations (e.g., Labandeira, 2012; Labandeira & Currano, 2013), food web dynamics (e.g., Wappler & Grímsson, 2016), extinction patterns (e.g., Labandeira, 2002; Labandeira, Johnson & Wilf, 2002; Donovan et al., 2016), and ecosystem recovery after extinction events (e.g., Wappler et al., 2009; Labandeira, Kustatscher & Wappler, 2016). They have also shown that biodiversity loss may greatly impede trophic interactions and change the overall food web structure of ecological systems (Haddad et al., 2009). Moreover, there is increasing concern about the loss of biological diversity from ecosystems (Hooper et al., 2012). The Plio–Pleistocene fossil record offers an exceptional possibility for conducting a meta-analysis for the estimation of the evolution and dynamics of associations between plant species and their dependent insect-herbivore species, as descriptions of Plio–Pleistocene floral changes (Tzedakis, Hooghiemstra & Pälike, 2006; Médail & Diadema, 2009; Postigo Mijarra et al., 2009; Magri, 2010; Migliore et al., 2012). Although a few isolated records of specialized phytophagy categories have been reported from the Pliocene (Straus, 1977; Givulescu, 1984; Titchener, 1999), only a single systematic survey of plant–arthropod interactions has been carried out on an early Pleistocene flora (Adroit et al., 2016). Thus, an ideal setting for the evaluations of relationships among global climate and biodiversity under conditions warmer than today, but with a similar paleogeographic configuration (Raymo *et al.* 2011; Rohling *et al.* 2009) is possible throughout the famous upper Pliocene fossil Lagerstätten Willershausen (3.2 – 2.6 Ma; MN 16/17; (Hilgen, 1991; Mai, 1995) and the comparisons with Berga (Germany, late Pliocene) and the French Pleistocene locality of Bernasso (Adroit et al., 2016). Willershausen and Berga outcrops are of similar age (Piacenzian)

and are located in the surroundings of the Harz Mountains, Germany (Figure 1). The Willershausen paleoforest was dominated by typical taxa of hilly mesophytic woodland (Ferguson & Knobloch, 1998; Knobloch, 1998) such as *Acer*, *Aesculus*, *Carpinus*, *Fagus*, *Quercus*, *Sassafras*, *Tilia* (Mai, 1995; Knobloch, 1998) and other taxa such as *Parrotia*, *Zelkova* and *Liquidambar* were also characteristic elements of Willershausen (Mai, 1995). All of these taxa were also found in Berga (Mai & Walther, 1988). The presence of these taxa indicates relatively warmer conditions in Europe than today during the late Pliocene (Uhl et al., 2007; Thiel, Klotz & Uhl, 2012). Most plant fossil evidence from Central Europe outcrops (Haywood, Sellwood & Valdes, 2000; Uhl et al., 2007; Williams et al., 2009; Thiel, Klotz & Uhl, 2012) and data from marine isotopes, geological evidences (Driscoll & Haug, 1998; Haug, Tiedemann & Keigwin, 2004) are directing in the same way. The decreasing temperatures throughout the Pliocene (Thunell, 1979; Ravelo et al., 2004) lead to the dominant European vegetation changing gradually from highly diverse subtropical and warm-temperate forests to temperate deciduous forests with East Asian and partly North American affinities (Mai, 1995). Through the comparison of three European forest plant communities of the Plio-Pleistocene, the aim of this study was to understand how climatic parameters could have impacted insect interactions of fossil leaves. It has been expected to observe different patterns of plant-insect interactions according to the climatic conditions in each fossil leaf assemblage. Variations of insect herbivory between the three fossil plant communities were statistically correlated plant diversity and climatic parameters to highlight similarities and differences between the 3 contexts. Our study will present a baseline data on the categories of arthropod interactions among plant species at the Pliocene-Pleistocene transition. This will provide a basis for quantitative analyses of individual biotas and improved reconstructions of Plio-/Pleistocene trophic webs in the future.

STUDIED AREA

Willershausen, Lower-Saxony, Germany

Geological studies of Willershausen dated back to the end of the 19th century (e.g., Wegele, 1914); see details in (Wegele, 1914; Ferguson & Knobloch, 1998; Meischner, 2000). The absence of bioturbation gave rise to one of the exceptionally well preserved floras and faunas (Briggs et al., 1998). The Willershausen site was a lake which developed in a pond due to the dissolution of underlying Permian evaporites and tumbled of the Triassic and Early Jurassic

sediments (Briggs et al., 1998; Meischner, 2000; Kolibáč et al., 2016). Today, Willershausen is an abandoned clay mining operation and it is included in the Geopark Harz, Braunschweiger Land, Ostfalen since 2012. This paleolake was ca. 200m in diameter and approximately 10m deep with a narrow sand beyond which the sides inclined abruptly towards the bottom of the lake (Meischner, 2000). Willershausen geology has been described by (Von Koenen, 1895) and detailed compilations can be found in (Vinken, 1967), (Ferguson & Knobloch, 1998; Meischner, 2000).

The leaves used in this study are stored in different museum collections in Germany. The majority (6546 leaves) is located at the Geoscience center of the University of Göttingen (GZG.W collection). Additional fossil leaves are stored in the Staatliches Museum für Naturkunde Stuttgart (SMNS.W collection, 957 leaves), in the collections of TU Clausthal of Clausthal-Zellerfeld (320 leaves), in the Naturkundemuseum im Ottoneum of Kassel (NMOK.W, 236 leaves) and in the Senckenberg Natural History Collections Dresden (14 leaves). Some of the best well-preserved fossil specimens are presented in Figure 2.A. The flora from Willershausen comprised a rich vegetation community including the presence of *Acer*, *Alnus*, *Betula*, *Carpinus*, *Carya*, *Fagus*, *Pterocarya*, *Populus*, *Quercus*, *Tilia*, *Ulmus*, *Zelkova* (Straus, 1977; Ferguson & Knobloch, 1998; Knobloch, 1998). The vertebrates *Anancus* (*Mastodon*) *arvernensis* and *Tapirus* were found in Willershausen and seems to indicated a Piacenzian age (late Pliocene, ca. 3.2 – 2.4 Ma; MN 16/17; (Mai, 1995), which is corroborate by the presence of *Parrotia persica* and *Liquidambar europaeum* (Mai, 1995).

Most plant fossil evidence from Willershausen (*vide infra*) indicates warmer conditions than today (Ferguson & Knobloch, 1998). The mean annual temperature (MAT) in Willershausen was estimated between 10.6°C and 15.6°C on the base of the leaf morphology and of diversity of plant species niches (Uhl et al., 2007); these different approaches explain the wide range of temperature estimated. The mean temperature of the coldest month (CMMT) is estimated between 0.6°C and 3.2°C and the mean annual precipitation (MAP) between 897 and 1151 mm per year (Uhl et al., 2007; Thiel, Klotz & Uhl, 2012).

Berga, Thüringen, Germany

Berga was a lake in which compressions and impressions (some with the cuticles preserved) of leaves were found in silty sediments (Mai & Walther, 1988). It is 70km far from the

Willershausen outcrop. The stratigraphic age of the Berga sediments is estimated on the basis of sedimentological correlations referring to the Piacenzian (ca. 3 Ma – 2.6 Ma) (Bachmann et al., 2008).

This leaf collection (534 specimens) is housed in the collection of the Senckenberg Natural History Collections Dresden, Germany. It contained many fossils of different origins (Mai & Walther, 1988), including 30 angiosperms leaf taxa (Figure 2.B). They represent different environments: a freshwater plant community, a swamp and riparian associations and a zonal mixed broadleaved conifer forest (which dominates the taphocoenosis). The temperatures were estimated with the same approaches than Willershausen; MAT is comprised between 7.4°C and 16.6°C, the CMMT is between -4.3°C to +0.6°C and the MAP is between 897 and 1297 mm per year (Uhl et al., 2007; Thiel, Klotz & Uhl, 2012).

Bernasso, France

Bernasso was a lake developed when a basaltic flows shut on a canyon valley (Leroy & Roiron, 1996). Diatomites were formed and fossil leaves, often with rest of cuticle, were preserved. It is located close to Lunas (Hérault, southern France) (Leroy & Roiron, 1996; Adroit et al., 2016). The fossil deposit is dated from the early Pleistocene on the basis of K/Ar analysis (Ildefonse et al., 1972) on a basaltic dyke that crosses the diatomite layers. A complementary analysis on cyclostratigraphy (Suc & Popescu, 2005) and paleomagnetism (Ambert et al., 1990) corroborated these results and estimated an age around 2.16 to 1.96 Ma.

The collection included 800 fossil leaves and 535 specimens well-preserved were described in (Adroit et al., 2016). These same specimens were also used for comparisons in the present study. The fossil leaves were conserved the Institut des Sciences de l'Evolution de Montpellier in France. Different preparation of fossil leaves were done by (Leroy & Roiron, 1996) and their impact on interpretation were discussed in (Adroit et al., 2016). The flora represents a mesothermic forest, mixing Mediterranean and Caspian elements (Suc, 1978; Leroy & Roiron, 1996). The MAT in Bernasso was estimated about 14-15°C and the MAP is around 1500 mm/y (Leroy & Roiron, 1996). It is important to note that CLAMP results in Bernasso suggest a probably lower temperature (Girard et al., in review).

DATA ANALYSES

Plant-insect interaction identifications

The plant-insect interactions were identified following the Damage Type Guide (Labandeira et al., 2007). The damages type (DTs) are divided in 7 Functional Feeding Groups (FFG): hole feeding, margin feeding, skeletonization, surface feeding, piercing & sucking, mining and galling. Leaves without damage were also categorized in an eighth FFG called the undamaged leaves. The leaves were examined under a binocular Leica MZ95 and all photographed with a Canon EOS 350D camera fitted with a Canon EF-S 60-mm f/2.8 macro lens. A Nikon Coolpix E4500 was used sometimes for precise pictures through the binocular. All pictures were developed using Adobe Lightroom CC v.2015 especially in order to improve contrast of the leaf. The insect interactions on leaves were scored according to the richness, frequency and distribution on the different plant species for each outcrop. For each DT, a host specificity value has been attributed by (Labandeira et al., 2007) that allowed to classify our DTs into generalist interactions (made by polyphagous organisms) and specialized interactions (made by monophagous organisms) (Labandeira, 2002). Detailed plates of fossil leaves from Willershausen are available in Table S1 including the original descriptions of the plant-insect interactions made by (Straus, 1977) and our actual updates with the guide of insect (and other) damage types on compressed plant fossils (Labandeira et al., 2007). The results obtained for Willershausen and Berga were compared to those recently published for the outcrop of Bernasso (Adroit et al., 2016). For some comparisons with Bernasso, new values were calculated based on raw data.

Leaf Mass per Area

Leaf mass per area (LMA) was estimated by using the robust relationship between petiole width squared and leaf mass standardized by leaf area (Royer et al., 2007). Generally, plants with a low LMA have thinner leaves with a short lifespan and should also have high nutrient concentrations, thus being more palatable for insects (Coley & Barone, 1996; Royer et al., 2007). Because of the difficulties in having specific measurements needed to obtain the LMA, we considered plant species statistically represented, i.e. when at least 10 specimens were measured (as it was done in (Currano et al., 2016)

Statistical analyses

For each outcrop, the statistical analyses were performed on two different databases as described in (Knor et al., 2012). The first one is the whole assemblage of plant-insect interactions. The second one considers only the interactions of the species that are significantly represented (more than 20 leaves). The quantitative analyses were done in R version 3.1.2 (R Development Core Team, 2014). The differences among the proportions of occurrences from all FFG were tested with Chi²-test. The remaining information needed for this test was obtained by using the generalized linear model of binominal distribution. Sample-based rarefaction curves were done to compare the different damage richness between the different outcrops (Gotelli & Colwell, 2001). At last, in order to observe the different distributions of plant-insect interactions among the paleoforests, principal component analysis (PCA) were performed with the software Past3 (v3.14) (Hammer, Harper & Ryan, 2001) in a biplot way. The data matrix used for it comprises the diversity of each eight FFGs on every plant species for each outcrop.

RESULTS

Comparisons of plant-insect interactions

In Willershausen 50.4% of the leaves are damaged, and only 25.1% in Berga. This percentage was 34.6% in Bernasso (Adroit et al., 2016). These differences are statistically significant ($p < 0.001$) (Figure 3, Table S2).

The frequencies of generalist interactions are 42.8% for Willershausen, 17.8% for Berga and 19.8% for Bernasso (Adroit et al., 2016). Only Willershausen frequency is significantly different from the others ($p < 0.001$). Willershausen leaves have especially much more hole feedings (26.9%) and margin feedings (9.9%) than Berga (respectively 12.7% and 1.9%) and Bernasso leaves (respectively 9.8% and 7%) (Figure 3).

The frequencies of specialized interactions are 11.2% for Willershausen, 8.4% for Berga and 17.9% for Bernasso (Adroit et al., 2016). Only the Bernasso frequency is significantly different from the others ($p < 0.001$). This difference is mainly due to the important quantity of galling in Bernasso (12%) which is significantly higher than in Willershausen and Berga, respectively 7% and 6% ($p < 0.01$) (Figure 3).

Rarefaction tests on plant species diversity highlight that Willershausen has more plant species (>100) than Berga (33) and Bernasso (20) (Figure 4). However, the DT richness in Willershausen (36 DTs) and Berga (25 DTs) are lower than in Bernasso (40 DTs) (Figure 4).

LMA per species at Willershausen

The LMA calculations in Bernasso and Berga were not possible due to the low quantity of leaves per species and the bad preservation of many fossil leaves. The LMA was calculated only on leaves in Willershausen. For the 10 species on which LMA was determinable, values in Willershausen vary from 46.18 g/m² to 79.26 g/m² (Figure 5, Table S3). For the same 10 species, the percentage of damaged leaves varies between 38.8 and 71.2 % (Figure 5, Table S3). Lastly, on the figure 5, we clearly observed (with also standard deviation in Table S3) that there is no significant difference of herbivory according to the different values of LMA.

Structure of the paleoforests with the damage distribution on plant species

Figure 6 presents the different PCA realized for the 3 outcrops with the data of plant and DT diversities. For each outcrop, only the first two axes are presented as for Willershausen they represent 77% (Figure 6A), for Berga 93% (Figure 6B) and for Bernasso 91% (Figure 6C) of the whole distribution.

For Willershausen (Figure 6A) the FFGs hole feeding and skeletonization are positively correlated with PCA-axis 1 (respectively 0.76 and 0.61) and undamaged is negatively correlated with this axis (-0.97) (Data S1). Skeletonization and galling are positively correlated with PCA-axis 2 (respectively 0.62 and 0.63) while hole feeding is negatively correlated with this axis (-0.73) (Data S1). Concerning the species, three pools of plant species can be distinguished. The *Tilia* (*T. saportae*, *T. cf. saviana*), the *Ulmus* (*U. caprinifolia*, *U. campestris*), the *Fagus* (*F. grandifolia*, *F. pliocenica*), *Acer integerrimum* and *Quercus roburoides* are all along the positive part of the PCA-axis 1. The leaves of these species have the highest DT diversity of hole feeding and skeletonization. A second set of taxa is composed, for the most evident species, by *Acer cappadocicum*, *A. laetum*, *Carya minor*, cf. *Magnolia* sp1 and 2, *Populus willershausensis*, *Quercus praeerucifolia* and *Zelkova ungeri*. They are along the negative part of the PCA-axis 1 and along the positive part of the PCA-axis 2. They are mainly affected by the FFG galling (specialized interaction) or have no damage. At last, the third set of species is composed of Fagales (*Fagus sylvatica*, all the *Quercus*, *Alnus* and *Betula* species) and is in the negative part of the PCA-axis 2. These leaves are mainly undamaged or only impacted by hole feeding (generalist interaction).

For Berga (Figure 6B) the FFGs hole feeding, skeletonization and undamaged are positively associated with the PCA-axis 1, respectively with a correlation of 0.56, 0.73 and 0.99 (Data S1). Hole feeding and skeletonization are also correlated with the PCA-axis 2, negatively for hole feeding (-0.79) and positively for skeletonization (0.66) (Data S1). Concerning the species, we can note that *Taxodium dubium*, *Zelkova ungeri*, *Cercidiphyllum crenatum* and *Acer integerrimum* are correlated with this undamaged category. *Fagus attenuata*, *Acer tricuspidatum* and *Quercus* sp. are mainly correlated with hole feeding.

For Bernasso (Figure 6C; (Adroit et al., 2016), the skeletonization and galling are positively correlated with the PCA-axis 1 (0.82 and 0.92) while undamaged is negatively correlated with this axis (-0.94) (Data S1). Hole feeding and skeletonization are positively correlated with PCA-axis 2 (0.92 and 0.25) while undamaged and galling are negatively correlated with this axis (-0.25 and -0.37) (Data S1). *Acer monspessulanum* and *Sorbus domestica* are in the positive part of the PCA-Axis 1 while the other are in the negative one (to note that *Parrotia persica* is close to zero). Concerning the PCA-axis 2, *Acer monspessulanum*, *Carpinus orinetlais* and *Carya minor* are in the positive part of the PCA-axis 2 while the others are in the negative part (to note that *Zelkova ungeri* is close to zero).

Furthermore, *Zelkova ungeri* is a species found in the 3 outcrops (Figure 6) and comparing to its position in the different PCAs, we can note that *Z. ungeri* is mostly associated with the FFG undamaged. However, for other common plant species, their relative position on the PCAs could be different. *Acer integerrimum* in Berga (Figure 6B) is mostly associated with the FFG undamaged while in Willershausen is opposite to this FFG as it is mainly associated to the FFG hole feeding and more weakly with skeletonization, margin and galling (Figure 6A).

Comparing Willershausen and Bernasso (Figure 6A & 6C), *A. monspessulanum* is mainly associated to skeletonization and galling in Willershausen (Figure 6A) and in Bernasso it is with skeletonization, galling too but also with hole feeding (Figure 6C).

Sorbus domestica and *Carpinus orientalis* are both associated to the FFG undamaged in Willershausen (Figure 6A). In Bernasso, *S. domestica* is associated with galling and skeletonization and *C. orientalis* is associated with hole feeding and undamaged (Figure 6C). *Carya minor* is associated to skeletonization and galling in Willershausen (Figure 6A) while in Bernasso it is associated to undamaged and hole feeding (Figure 6C). *Parrotia persica* is

associated to galling and undamaged in Bernasso (Figure 6C) while in Willershausen, it is associated with the FFGs skeletonization and galling (Figure 6A).

DISCUSSION

Floristic richness and herbivory representativeness

All genera and many plant species from Berga are also present in Willershausen (Table S4) that can be expected because they have similar age and geographic proximity. Bernasso had nearly the same composition of plant genera found in Willershausen (except *Ilex* only found in Bernasso) and also the majority of plant species (Table S4) despite its geographical situation and its younger age. There is quite a difference of plant richness between Bernasso and Berga, but the genera are the same (Table S4). This may suggest a difference in specific richness between those paleoforests. However, it could also be due to the fossil collections themselves. The great difference of collection size between the three outcrops could have led to artificial difference of plant species richness (Table S2). However, rarefaction data tests indicate that there is in fact highest richness of plant species in the Willershausen outcrop compared to Berga and Bernasso outcrops when the collections are similarly re-sized (Figure 4).

Sampling effort tests indicate that enough specimens were taken into account to have a representative overview of the interactions on plant species found into the different outcrops (Figure 4). The large standard deviation observable on the Willershausen rarefaction curves on Figure 4 is due to this size of the fossil collection that includes around 8.000 specimens while the others are only 534 for Berga and 535 for Bernasso.

Absence of correlation between LMA and plant-insect interaction

In Willershausen, no significant correlation between the LMA of plant species used and the herbivory was observed (Figure 5) while previous studies (Currano et al., 2008; Currano, Labandeira & Wilf, 2009; Wappler et al., 2009) showed a negative correlation between the LMA and the damage on the leaves. These correlations were measured on leaf assemblages including both deciduous and evergreen plant species. In the case of Willershausen, only deciduous plant species have been measured. Finally, the relationship between LMA and leaf damage by insect feeding is not evident (Poorter et al., 2009). For example, a small increase of secondary defense compounds is not really affecting LMA but could significantly reduce the herbivory rate (Coley,

1988). Moreover, under different resource availabilities for plants, (Züst & Agrawal, 2017) have shown that LMA values could be similar between leaves while their nutrient concentrations were totally different.

Parameters involved in insect damages differences

Climatic conditions seem to be in relation with variations in richness and frequency of plant-insect interactions (Currano et al., 2016). If an increase of temperature seems to stimulate insect herbivory (Zvereva & Kozlov, 2006), it is still complex to understand the complete role of temperature in the modulation of herbivory (DeLucia et al., 2012).

(Thiel, Klotz & Uhl, 2012) indicated, through leaf morphological analyses, that temperatures estimated for Willershausen were approximately 3°C higher than those for Berga. These paleoforests were geographically very close to each other (less than 70 km) and at a similar latitude (51°N) (Figure 1). Today the nearest meteorological stations of these locations (Willershausen: Göttingen, Lower-Saxony; Berga: Nordhausen, Thüringen) indicates the same mean annual temperature also for the coldest and warmest months over the last years (www.worldweatheronline.com). Such current similarities make the argument for similar paleoclimates of the two fossil localities if they were strictly of the same age. However, between 3 Ma and 2.5 Ma, CO₂ concentration progressively decreased (Kürschner et al., 1996; van de Wal et al., 2011) implicating a continuous decrease of mean annual temperatures (Willeit et al., 2015). Consequently, as Willershausen was warmer than Berga, the paleoforest of Willershausen grew under higher atmospheric CO₂ concentration than the Berga paleoforest. It seems to be corroborate by the higher damage frequency observed in Willershausen that can have been favored by an increase of C/N ratios and an increase of photosynthesis rates (due to the high CO₂ concentration) (Bezemer & Jones, 1998; Stiling & Cornelissen, 2007; DeLucia et al., 2012). However, Willershausen and Berga had different sedimentological contexts and the preservation of the fossil leaves did not follow the same taphonomical constrains in the two outcrops. This could have influenced interpretation of the climate trough morphological analyses.

For this reason, (Thiel, Klotz & Uhl, 2012) were in favor of the Co-existence approach for climate interpretation which estimated similar temperature for Berga and Willershausen. It has been highlighted that the diversity of insects is often correlated to diversity of plant species (Siemann, Tilman & Haarstad, 1996; Wright & Samways, 1998; Knops et al., 1999; Mulder et

al., 1999) and should be expected to have higher damage richness in the more diverse paleoforest (Price, 1991, 2002). Thus, the higher richness and frequency of damage in Willershausen than in Berga could also be due to a higher insect diversity. Nevertheless, despite its higher plant diversity Willershausen had less DT richness than Bernasso (Figures 3, 4). Bernasso had also more damage richness and frequency than Berga (Figures 3, 4). Thus, these observations make this assumption unsustainable for our case study.

For Bernasso, the latitudinal position is different from Berga and Willershausen, as it located 1,000 km to the South. It has been highlighted that the insect diversity increases getting closer to the tropics (Hutchinson, 1959; Klopfer, 1959; Klopfer & MacArthur, 1960; MacArthur, 1972; Coley & Barone, 1996; Fraser, 2017). The southern position of Bernasso could partly explain the measured damage type richness. Nevertheless, the quantity of damage is not exclusively link to the insect diversity (Currano, Labandeira & Wilf, 2010). Latitudinal differences could led to a difference of thermal seasonality (Saikkonen et al., 2012) which is the key to the latitudinal gradient of insect diversity (Archibald et al., 2010). (Leroy & Roiron, 1996) indicated that Bernasso paleoforest grew under temperatures of 14–17°C and precipitations of 1300-1500 mm/a. Recently, Girard et al. (in review) re-estimated Bernasso climate with different approaches and some results, based on leaf morphological traits, estimated temperatures in Bernasso to be cooler than estimations of (Leroy & Roiron, 1996), while the pollen analysis from the same study tend to corroborate previous estimations done by (Leroy & Roiron, 1996).

Berga has a low temperature of the coldest months (from -6.4°C to 2°C) compared to Willershausen which had the highest temperatures (from -0.5°C to 5.1°C) (Uhl et al., 2007; Thiel, Klotz & Uhl, 2012). These lower temperatures during the cold period could explain the lowest damage frequency observed in Berga. Indeed, insects are poikilotherms, meaning that their body temperature is extremely dependent to the environment temperature (Meglitsch, 1972). Cooler temperatures decrease the insect metabolism (leading to diapause of insects) and the quantity of generations per year (Archibald et al., 2010), consequently it could also reduce the herbivory rates during the year (Bale & Hayward, 2010). Concerning Bernasso, the different estimations of temperatures, included the CMMT, are lower than those of Willershausen (Uhl et al., 2007; Thiel, Klotz & Uhl, 2012), thus the lowest frequency of damage could also be due to a lower insect metabolism in Bernasso than in Willershausen. The lowest frequency of damage in Berga than in Bernasso could also be due to insect diapause in the case of coolest temperatures

are lower in Berga. However, the estimated temperatures of Bernasso overlap the ones of Berga (especially for the coolest temperatures) and therefore complicate any interpretations about the damage frequency between these two paleoforests. Moreover, it is important to note that no data about insect richness of these different paleoforests are available. Although as it could be assumed that insect richness between Willershausen and Berga could be similar because outcrops are geographically and temporally similar, the insect richness of Bernasso could be quite different. Consequently, in case of differences in the insect faunas, the previous relation could be disturbed as some insects, such as larvae of *Thaumetopoea pityocampa*, feed plant during winter season (Battisti et al., 2005; Buffo et al., 2007), when others insects have no or lower activity (Hahn & Denlinger, 2007).

More precisions provided by proportion of generalized/specialized damages

The comparison of plant-insect interaction between different locations or through different time periods could still be upset by local disturbances (fires, floodings, etc.) or other constraints (such as different soils) that are not perceptible in fossil record and could impacted damage pattern in general (Currano et al., 2011; García, Castellanos & Pausas, 2016). Moreover, taphonomic biases, especially fossil preservation and different excavation histories, could also interfere with our analyses. For example, the damage frequency observed in fossil record could be partly distorted because the damaged leaves had less chance to be preserved in the fossil record than the complete and undamaged leaves (Ferguson, 2005). For all these reasons, we suggested complementing analyses by comparison of the proportions of generalized and specialized damage patterns. (Leckey et al., 2014) indicate that the proportion of generalist and specialist herbivores may change between different forests because the difference of abiotic parameters (such as climate). There are the lowest proportions of specialist interactions (mainly based on galling) in Willershausen and Berga, and conversely the highest proportion is in Bernasso (Figure 3), this may due to climatic factors (e.g., Leckey et al., 2014). Indeed, precipitation in Bernasso was higher than in Willershausen and Berga (Leroy & Roiron, 1996; Uhl et al., 2007) and hydric seasonality was probably more important in Bernasso (Girard et al., in review). This is in agreement with the proposed Mediterranean climate for Bernasso that provided heavy constrain to plants here due to less water availability during the dry season (Bagnouls & Gaussen, 1957;

Daget, 1977, 1984). The higher seasonality conditions in Bernasso compared to conditions proposed for Berga and Willershausen could also be supported the idea that regional conditions of Northern Atlantic realm were more marked by higher seasonality during Pleistocene than the Pliocene (Williams et al., 2009; Hennissen et al., 2015; Utescher et al., 2017). Water stress should have a positive impact on galling diversity (especially the frequency), as many studies already mentioned that galling is an adaptation of stressful environment (Fernandes & Martins, 1985; Fernandes & Price, 1988, 1992; Price et al., 1998; Lara, Fernandes & Gonçalves-Alvim, 2002). In addition, (Cuevas-Reyes et al., 2003), who studied the development of galling, showed that it exists a negative correlation between gall-forming insect species richness and plant species richness. It could also partly explain the highest proportion of specialized interactions in Bernasso. Additionally, a forest in its late successional stage, as it has been proposed for Bernasso (Leroy & Roiron, 1996; Adroit et al., 2016), tend to favor the richness of gall-inducing insects (that increase the proportion of specialized interaction) (Fernandes, Almada & Carneiro, 2010; Adroit et al., 2016).

This global comparison of specialized and generalized damages between the fossil leaf assemblage of Bernasso, Willershausen and Berga are also observable precisely on the common plant species statistically represented on each outcrop. However, the FFGs and especially the undamaged feature on some plant taxa are similar or could be slightly different between the fossil leaf assemblage (Figure 6). It tends to confirm that the abiotic parameters are important determinant factors involving significant variation of herbivory between different paleoenvironments (Cuevas-Reyes et al., 2004, 2003; Leckey et al., 2014). Biotic parameters can also be involved in the difference of interaction structures. For example, a decrease in food quality caused by higher concentration of carbon in plants could also have a negative impact on herbivory (Stiling & Cornelissen, 2007), but in general, it is compensated by an increase of insect feeding (Bezemer & Jones, 1998). The impact of biotic factors seems to be further confirmed as in Willershausen we can note that most Fagales (Betulaceae: *Alnus*, *Betulus*, *Carpinus*; Fagaceae: *Fagus*, *Quercus*; Juglandaceae: *Carya*, *Juglans*) are all associated to hole feeding and to undamaged feature (Figure 6A). This measurement cannot be due to hazard but it probably reflects an effect of some biotic parameters (such as genetic background, plant competition, host specificity, etc.).

CONCLUSION

In the actual context where plant-insect interactions are essential to understand the food web of the paleo/-forests (May, 1988; Wilf, 2008; Cornelissen, 2011), this study allows the first comparison of the plant-insect interaction structure of three Plio-Pleistocene leaf assemblages. Such a comparison highlighted that relationships between climate parameters (such as temperature and precipitation) and plant-insect interactions are not evident in European paleoforests around the Neogene – Quaternary transition. Temperature and precipitation undoubtedly have major impacts on herbivory rate and our results suggest that the annual variation of those climatic parameters (i.e. seasonality) could have a greater influence on plant-insect interactions than the average annual of these parameters. This makes sense as the insects' response to climatic variation is very sensitive (Bale & Hayward, 2010) and could be predicted with their feeding behavior on leaves (Bale et al., 2002). These statements about the impacts of seasonality on plant-insect interactions should to be considered for further studies in the fossil record.

ACKNOWLEDGEMENTS

We wish to thank Tony Jijina (University of Wyoming, Laramie, WY, USA), Gentry Catlett (Miami University, Oxford, OH, USA) and Samantha Moody (Bonn University, Germany) for English improvement in our manuscript. Thank you to Dr. Alexander Gehler from Geoscience Centre of the University of Göttingen for giving us access to Willershausen's fossil collections. Special thanks to Dr. Allowen Evin (ISEM - Montpellier) and Dr. Zdeněk Janovský (Charles University, Prague) for their advices on statistical methods.

Figure 1(on next page)

The location of Willershausen and Berga outcrops

A- The location of Germany in Europe. B- The locations of both outcrops in Germany. C- Zoom on the area near Göttingen. On the scale, each dash (black or white) represents 5km. The data from the maps A and B come from Natural Earth database

(<http://www.naturalearthdata.com>)

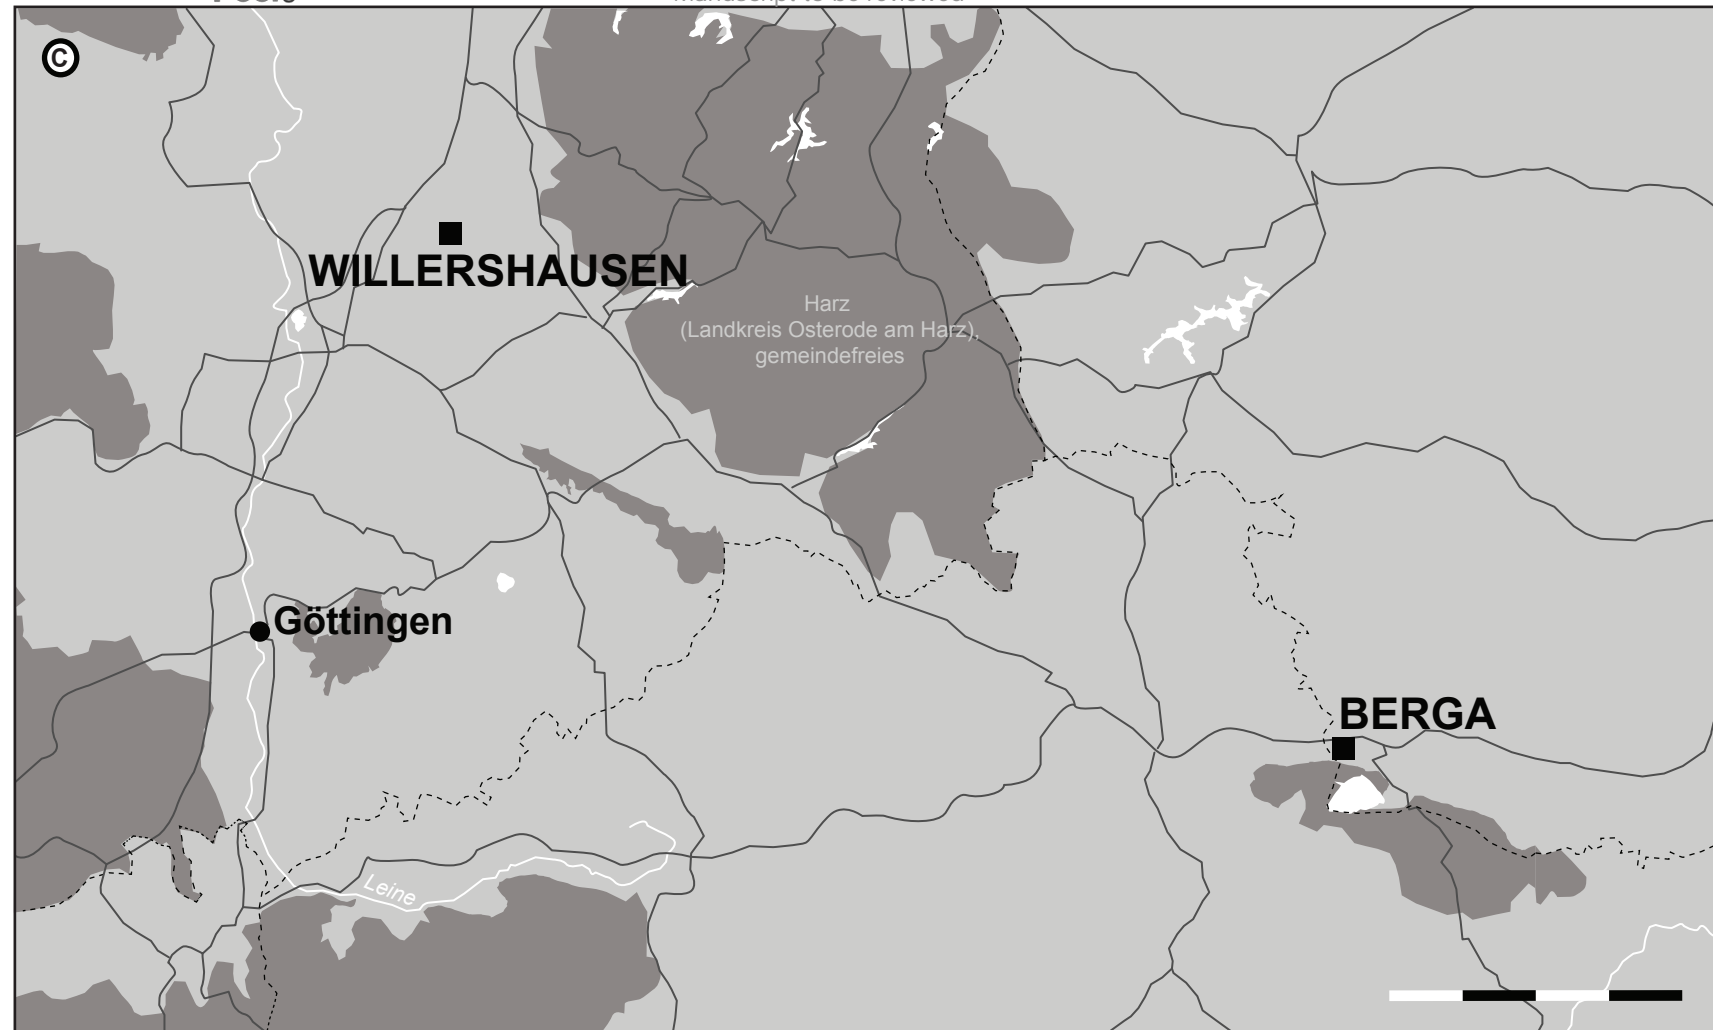

Figure 2 (on next page)

Samples of fossil leaves from the German outcrops

Plate 1. Fossil leaves from Willershausen (Göttingen coll.). A- *Ulmus caprinifolia* with Hole feeding (DT05). B- *Alnus spaethii* with Margin feeding (DT14). C- *Fagus* sp with Piercing & Sucking (DT168). enlarged in 'd'. F- *Ulmus campestris* with Mining (DT109) enlarged in 'e'. G- *Quercus praeerucifolia* with Gallling (DT145) enlarged in 'h'. J- *Ulmus caprinifolia* with Skeletonization (DT17). K- *Populus tremula* with Surface feeding (DT30) enlarged in 'i'.

Plate 2. Fossil leaves from Berga (Dresden coll.). L- *Cercidiphyllum crenatum*. M- *Fagus attenuata* with Hole feeding (DT01). N- *Juglans* sp. with Galls (DT34) . O- *Pterocarya paradisiaca*. P- *Quercus pseudocastanea* with Gallling (DT116). Q- *Quercus castaneifolia*.

White scale bar represents 1cm, black scale bar represents 0.5cm.

Figure 3(on next page)

Quantitative distribution of plant-insect interactions from Willershausen, Berga outcrops and the fossil deposit of Bernasso (Adroit et al., 2016).

Significant difference ($\alpha < 0.05$) from an outcrop to another one is marked by an asterisk. The percent of generalized and specialized damages are computed with the damaged leaves, thus their sum is 100%.

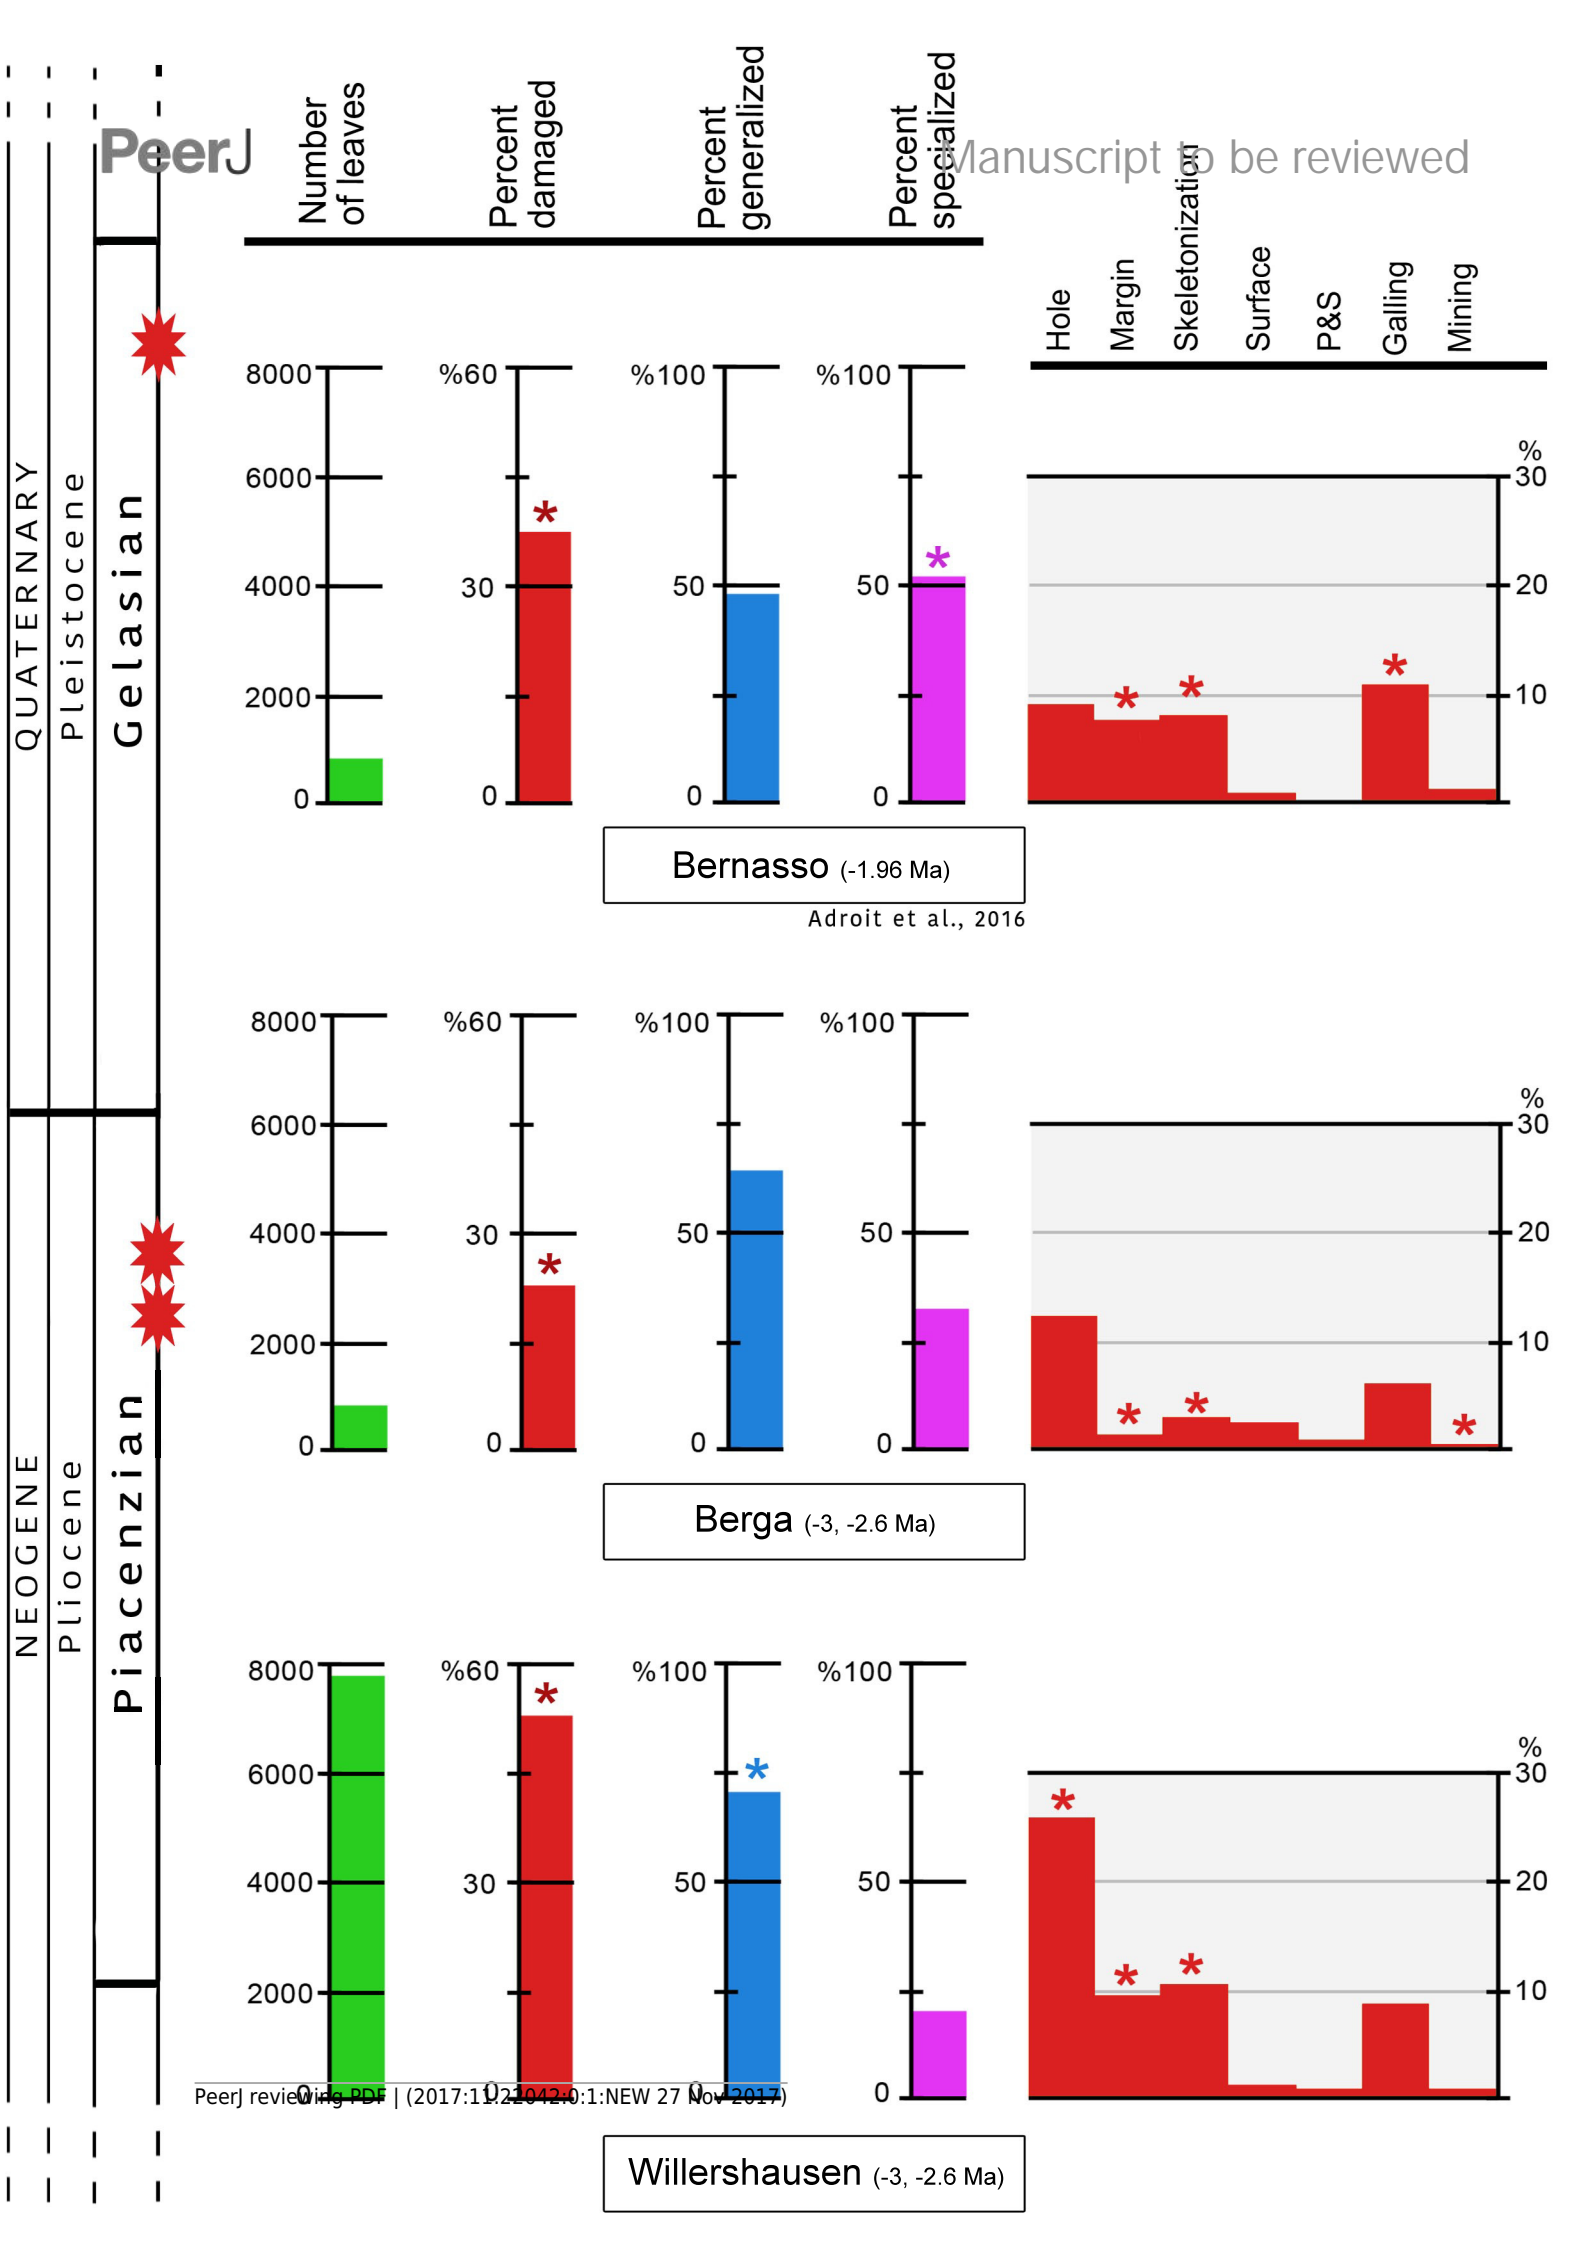

Figure 4(on next page)

Rarefaction curves on the leaves from Willershausen, Berga and Bernasso (Adroit et al. 2016).

The grey curves represent Berga, the blue curves represent Willershausen outcrop and the orange curves represent Bernasso. The shaded area represents the standard deviation below and above the average of the resamples, with the method from Heck et al. (1975).

Rarefaction curves represent the number of specimens by: A- Richness of plant species; B- Richness of damage type (DT); C- Richness of generalized damage; D- Richness of specialized damage

A

B

C

D

Figure 5 (on next page)

Percent of leaves damaged according to the leaf mass per area (LMA).

The LMA was estimated using the method of Royer et al. (2007). Each dot represents a plant species. Each species was considered only if at least 10 leaf from the species were measurable.

Percent of leaves damaged

Leaf Mass per Area (g/m²)

Figure 6(on next page)

Principal components analysis (PCA) of plant species according to the diversity of damage type (DT).

A- Willershausen, B- Berga, C- Bernasso. Due to large amount of plant species names on A- Willershausen, the species names near the axes intersection were replace by alphabetic letter for visibility concerns: a- *Malus pulcherrima*, b- *Prunus mahaleb*, c- *Fagus sylvatica*, d- *Sorbus gabbrensis*, e- *Populus tremula*, f- *Populus willershausensis*, g- *Zelkova caprinifolia*, h- *Betula pubescens*, i- *Betula_sp1*, j- cf_ *Toona*.
