

# Fast and accurate semantic annotation of bioassays exploiting a hybrid of machine learning and user confirmation

Bioinformatics and computer aided drug design rely on the curation of a large number of protocols for biological assays that measure the ability of potential drugs to achieve a therapeutic effect. These assay protocols are generally published by scientists in the form of plain text, which needs to be more precisely annotated in order to be useful to software methods. We have developed a pragmatic approach to describing assays according to the semantic definitions of the BioAssay Ontology (BAO) project, using a hybrid of machine learning based on natural language processing, and a simplified user interface designed to help scientists curate their data with minimum effort. We have carried out this work based on the premise that pure machine learning is insufficiently accurate, and that expecting scientists to find the time to annotate their protocols manually is unrealistic. By combining these approaches, we have created an effective prototype for which annotation of bioassay text within the domain of the training set can be accomplished very quickly. Well-trained annotations require single-click user approval, while annotations from outside the training set domain can be identified using the search feature of a well-designed user interface, and subsequently used to improve the underlying models. By drastically reducing the time required for scientists to annotate their assays, we can realistically advocate for semantic annotation to become a standard part of the publication process. Once even a small proportion of the public body of bioassay data is marked up, bioinformatics researchers can begin to construct sophisticated and useful searching and analysis algorithms that will provide a diverse and powerful set of tools for drug discovery researchers.

## Abstract

Bioinformatics and computer aided drug design rely on the curation of a large number of protocols for biological assays that measure the ability of potential drugs to achieve a therapeutic effect. These assay protocols are generally published by scientists in the form of plain text, which needs to be more precisely annotated in order to be useful to software methods. We have developed a pragmatic approach to describing assays according to the semantic definitions of the BioAssay Ontology (BAO) project, using a hybrid of machine learning based on natural language processing, and a simplified user interface designed to help scientists curate their data with minimum effort. We have carried out this work based on the premise that pure machine learning is insufficiently accurate, and that expecting scientists to

28 find the time to annotate their protocols manually is unrealistic. By combining these approaches,  
29 we have created an effective prototype for which annotation of bioassay text within the domain  
30 of the training set can be accomplished very quickly. Well-trained annotations require single-  
31 click user approval, while annotations from outside the training set domain can be identified  
32 using the search feature of a well-designed user interface, and subsequently used to improve  
33 the underlying models. By drastically reducing the time required for scientists to annotate their  
34 assays, we can realistically advocate for semantic annotation to become a standard part of the  
35 publication process. Once even a small proportion of the public body of bioassay data is marked  
36 up, bioinformatics researchers can begin to construct sophisticated and useful searching and  
37 analysis algorithms that will provide a diverse and powerful set of tools for drug discovery  
38 researchers.

## 39 **Introduction**

40 In recent decades scientific data has been almost entirely digitized: authors prepare their  
41 manuscripts and presentations using a collection of text, graphics and data processing software.  
42 Consumers of scientific data regularly download documents from publishers' websites, search  
43 for content in databases, and share data with their colleagues electronically, often in an entirely  
44 paperless fashion. Dozens of commercial and academic research groups are actively working  
45 on ways to use software to analyze this rapidly expanding corpus of data to provide facile  
46 information retrieval, and to build decision support systems to ensure that new research makes  
47 the best possible use of all available prior art.

48 Despite the near complete migration from paper to computers (Khabisa & Giles 2014), the style  
49 in which scientists express their results has barely changed since the dawn of scientific  
50 publishing. Whenever possible, ideas and facts are expressed as terse paragraphs of English  
51 text, kept as short as possible to minimize printing costs, and as stripped down diagrams that  
52 often summarize vast numbers of individual data points in a form that can be visualized statically  
53 by a scientific peer. These methods of communication have remained consistent because they  
54 are effective for their primary purpose, but this presents a major hurdle to computer software  
55 that is attempting to perform data mining operations on published results.

56 In the case of biological assays, experiments designed to measure the effects of introduced  
57 substances for a model of a biological system or disease process, the protocols are typically  
58 described in one or more textual paragraphs. Information about the target biology, the proteins  
59 or cells, the measurement system, the preparation process, etc., are all described using  
60 information rich jargon that allows other scientists to understand the conditions and the purpose.  
61 This comprehension process is, however, expert-specific and quite time consuming. While one

62 scientist may read and understand dozens of published assay descriptions, this is not scalable  
63 for large-scale analysis, e.g. clustering into groups after generating pairwise metrics, or  
64 searching databases for related assays.

65 One of the most promising approaches to solving this problem is to express the assay design  
66 experiments with terminology from a semantically rich ontology, which has the advantage of  
67 being readily understood by software (Jonquet et al. 2010; Jonquet et al. 2009; Roeder et al.  
68 2010). Efforts such as the BioAssay Ontology (BAO) project (Abeyruwan 2014; Vempati et al.  
69 2012; Visser et al. 2011) were specifically designed to address this issue, and is part of a  
70 pantheon of ontologies for expressing the chemistry and biology definitions and relationships  
71 that are essential to drug discovery. Having all relevant scientific data expressed in semantic  
72 form enables an inordinate number of options for building compelling decision support software,  
73 but the biggest hurdle is the expression of the data. Expecting scientists to alter their  
74 documentation habits to use computer-friendly ontologies rather than human-friendly natural  
75 language is unrealistic, especially given that the benefits do not start to accrue until a critical  
76 mass is achieved within the community. On the other hand, there has been a considerable  
77 amount of research toward designing software to perform fully automated parsing of otherwise  
78 intractable text and diagrams, and add annotations in a machine-friendly format. Many of these  
79 efforts have been found to be valuable for certain scenarios where the high error rate is  
80 tolerable. For example, allowing a scientist to search the entire patent literature for chemical  
81 reactions may be a very useful service even with a low signal to noise ratio, because the effort  
82 required to manually filter out false positives is relatively low, and the portion of false negatives  
83 may be no worse than more traditional methods (Hawizy et al. 2011; Jessop et al. 2011a;  
84 Jessop et al. 2011b).

85 Nonetheless, such fully automated extraction procedures are likely to continue to have a very  
86 high error rate for most scientific subject areas for the conceivably near future, and the poor  
87 signal to noise ratio prevents most kinds of analysis from being effective. To address this urgent  
88 issue, we have developed methods for combining automated extraction and manual curation in  
89 order to optimize for both goals: minimal additional burden on practicing scientists, and minimal  
90 transcription errors during the semantic markup process.

91 There are already examples of hybrid manual/automatic annotation technologies, for example  
92 PubTator,(Wei et al. 2013) which is designed to help identify a variety of keywords in order to  
93 classify papers within the PubMed collection. The web interface provides an initial attempt to  
94 identify keywords that correspond to semantic content in the chemical or biological domain, and  
95 allows the user to confirm them or add their own. On the other hand, some of the large scale  
96 curation efforts, such as ChEMBL, provide funding for expert curators to manually annotate

97 bioassay data, but this is too labor intensive to execute in detail, and is currently limited to  
98 identifying the target (Gaulton et al. 2012). Our objective in this work is to provide the necessary  
99 capabilities to annotate bioassay protocols, in a significant level of detail, such that the semantic  
100 content is a relatively complete description of the assay. We can draw upon existing  
101 vocabularies, such as the BioAssay Ontology (BAO), and other ontologies, which in turn  
102 references, for the means to complete this description. To achieve the objective of reducing the  
103 burden on the individual scientist to the bare minimum, we have made use of natural language  
104 processing and machine learning techniques, and coupled the algorithms to a prototype user  
105 interface with a workflow design that iterates back and forth between automated inference and  
106 operator approval.

107 Rather than starting with the lofty objective of having an algorithm provide the right answers all  
108 of the time, we merely require it to eliminate most of the wrong answers. To the extent that we  
109 are able to achieve this comparatively realistic goal, this allows us to create a user-facing  
110 service for which the scientist simply selects correct semantic markup options from a short list of  
111 options proposed by the software. This is as opposed to the entirely manual curation approach,  
112 which would require the operator to navigate through a densely packed hierarchy of descriptors.  
113 By reducing the burden of markup to mere minutes by somebody who is not familiar with  
114 semantic technology, and has had no special training for use of the software, it is quite  
115 reasonable to expect scientists to use this software as part of their standard write-up and  
116 submission process.

117 As the number of correctly annotated bioassay protocols grows, it will improve the training set  
118 and the machine learning algorithm will correspondingly improve in accuracy. Once the currently  
119 high barrier to adoption has been overcome, and semantic markup of scientific knowledge such  
120 as biological assay experiments is routine, assay protocols will be as readable to computer  
121 software as they are to expert scientists. The informatics capabilities that this will unlock are  
122 essentially limitless, but the first most clear example is the ability to search assays for specific  
123 properties, e.g. target, assay type, cell line, experimental conditions, etc. Being able to  
124 conveniently organize and aggregate assays by particular characteristics, cluster by similarity, or  
125 assemble chemical structures and activity from multiple assays based on customizable criteria,  
126 are all advantages that have a direct impact on drug discovery, which are currently held back by  
127 the lack of semantic annotation. Once the corpus of marked up annotations becomes large, it  
128 will also be possible to construct data mining algorithms to study large scale trends in bioassay  
129 data, which will result in entirely new kinds of insight that are currently not possible.

## Methods

### ***Ontologies***

The primary annotation reference for this project is the BioAssay Ontology (BAO), which is available from <http://bioassayontology.org>, and can be downloaded in raw RDF format. The BAO classes refer to a number of other ontologies, and of particular relevance are the Cell Line Ontology (CLO) (Sarntivijai 2011), Gene Ontology (GO) (Balakrishnan et al. 2013; Blake 2013), and NCBI Taxonomy (Federhen 2012), all of which are used for annotations within the training set. All of the source files for these ontologies were loaded into a SPARQL server (Apache Fuseki)(Website 2014a). SPARQL queries were used to organize the available values that correspond to each of the property groups.

### ***Training data***

In order to test the methodology of using text to create suggested annotations, we made use of a corpus of annotated bioassays that were that were provided by the BAO group (Schurer et al. 2011; Vempati et al. 2012) (See supplementary material). As part of the testing process for the BioAssay Ontology project, a simple annotation user interface was created in the form of an Excel spreadsheet template. Approximately 1000 assays were selected from PubChem, and each of these was painstakingly annotated, leading to an output document taking the form of: <assay ID> <property> <value>.

For each assay, 20-30 annotations were incorporated into the training set. The property values were individually mapped to the BAO space, e.g. 'has assay method' is mapped to the URI [http://www.bioassayontology.org/bao#BAO\\_0000212](http://www.bioassayontology.org/bao#BAO_0000212), which is a part of the BAO ontology. Values that are string literals are not included in the training data. Those which map to a distinct URI are typically part of the BioAssay Ontology directly, or part of other ontologies that are referenced, such as the Cell Line Ontology (CLO), Gene Ontology (GO) and NCBI Taxonomy. Once the annotations had been suitably collated for each distinct assay, the NCBI PubChem assays were obtained by a simple script making a call to the PUG RESTful API (Website 2014b). In each case, the *description* and *protocol* sections of the resulting content were merged into a free text document. The manner in which these two fields are used by scientists submitting new assay data varies considerably, but they are generally complete. For the collection of text documents obtained, it was necessary to manually examine each entry, and remove non-pertinent information, such as attribution, references and introductory text. The residual text for each case was a description of the assay, including information about the target objective, the experimental details, and the materials used. The volume of text varies from

163 concisely worded single paragraph summaries to verbosely detailed page length accounts of  
164 experimental methodology. These reductively curated training documents can be found in the  
165 supplementary information.

### 166 ***Natural language processing***

167 There has been a considerable amount of effort in the fields of computer science and linguistics  
168 to develop ways to classify written English documents in terms of classified tokens that can be  
169 partially understood by computer software (Kang & Kayaalp 2013; Leaman et al. 2013; Liu et al.  
170 2011; Santorini 1990). We made use of the OpenNLP project(Website 2014c), which provides  
171 *part of speech* (POS) tagging capabilities, using the default dictionaries that have been trained  
172 on general purpose English text. The POS tags represent each individual word as a token that is  
173 further annotated by its type, e.g. the words "report" and "PubChem" were classified as an  
174 ordinary noun and a proper noun, respectively:

175 (NN report)

176 (NNP PubChem)

177 Blocks of text are classified in an increasingly specific hierarchical form, e.g.

178 (NP (DT an) (JJ anti-cancer) (NN drug))

179 (VP (VBG developing) (NP (JJ potential) (JJ human) (NNS therapeutics)))

180 (NP (NP (NN incubation)) (PP (IN with) (NP (NN test) (NN compound))))

181 (NP (NP (DT the) (JJ metabolic) (NN activity)) (PP (IN of) (NP (DT a) (NN suspension)  
182 (NN cell) (NN line))))

183 (VP (VB measure) (SBAR (WHADVP (WRB when)) (S (VP (VBG developing) (NP (JJ  
184 potential) (JJ human) (NNS therapeutics))))))

185 (NP (JJ luciferase-based) (NN cell) (NN proliferation/viability) (NN assay) (NN endpoint))

186 An assay description of several paragraphs can generate many hundred distinct instances of  
187 POS-tagged blocks. These marked up tokens contain a far larger amount of information about  
188 the composition of the sentence than the words themselves. While building a model by  
189 correlating words with annotations would be expected to achieve poor results, including markup  
190 information about how the words are used in conjunction with each other might be able to  
191 achieve far greater discrimination. For example, the POS-tagged block "(NP (DT an) (JJ anti-  
192 cancer) (NN drug))" represents the words [an, anti, cancer, drug]. Each of these 4 words taken  
193 out of context could be found in almost any assay description, but when they are associated  
194 together in context, contribute an important statement about the corresponding biochemistry.

195 By collecting all sizes of POS-tagged blocks, up to a certain limit, it is possible to give many  
196 different depths of linguistic structure the opportunity to distinguish themselves within a model.  
197 In some cases a single word can have significant meaning on its own, especially proper nouns  
198 or jargon (e.g. "luciferase"), and are likely to have a high correlation to certain kinds of  
199 annotations (e.g. use of a luciferase-based assay). Other words are general to the English  
200 language, or occur frequently in assay descriptions, such that they only have value in their  
201 proper context (e.g. "interaction").

202 One of the useful properties of scientific writing is that authors have self-organized around a  
203 narrow range of styles for presenting information such as assay descriptions. While the explicit  
204 intent may not have been for the benefit of computerized natural language processing, the  
205 motivation is the same: scientific authors also read many other published descriptions, and it is  
206 in the best interests of the community to maintain a certain degree of consistency as well as  
207 brevity. Because the literary style lacks prose and has a relatively little variation, there are  
208 certain blocks of words, as identified by the POS-tagging, that are frequently correlated with  
209 particular concepts, and hence the semantic annotations.

### 210 ***Machine learning models***

211 A collection of hundreds of assay descriptions will result in thousands of distinct POS-tagged  
212 blocks after processing each of them with natural language analysis, and while certain blocks  
213 are likely to be specifically correlated with certain annotations, there are many more with only  
214 weak correlation or none at all. Matching thousands of potentially important tags with hundreds  
215 or thousands of annotations requires the selection of an algorithm with favorable scaling  
216 properties, and is well beyond the scope of manual curation.

217 In our initial explorations, we chose to apply a variation of Bayesian inference, which has been  
218 used successfully in other aspects of computer aided drug discovery. The Laplacian-modified  
219 naïve Bayesian variant is frequently used in conjunction with chemical structure based  
220 fingerprints (Hassan et al. 2006; Mussa et al. 2013; Nidhi et al. 2006; Rogers et al. 2005), as it is  
221 highly tolerant of large numbers of parameters. The score for each annotation is calculated as:

$$\text{score} = \sum_n \ln \left[ \frac{A_n + 1}{T_n \cdot P + 1} \right]$$

222 where  $n$  is the tagged natural language block,  $A_n$  is the number of documents containing the  
223 annotation and the tagged block,  $T_n$  is the total number of documents with the tagged block, and  
224  $P$  is the fraction of documents containing the annotation. The score is computed by adding up

225 the logarithms of these ratios, which circumvents issues with numeric precision, but produces a  
226 score with arbitrary scale, rather than a probability.

227 When we considered each individual annotation as a separate observable, building a Bayesian  
228 model using the presence or absence of each distinct POS-tagged block gave rise to a highly  
229 favorable response for most annotations, as determined by the receiver-operator-characteristic  
230 (ROC) curves. Selected examples of these models are shown in Figure 1: (a) shows  
231 annotations with high training set coverage that perform well, due in part to having relatively  
232 unambiguous word associations, while (b) shows well covered annotations that perform poorly,  
233 due to being reliant on terms that can be used in a variety of contexts that do not necessarily  
234 imply the presence of the annotation, and hence make it more difficult for the model to eliminate  
235 false positives. Similarly, (c) shows the perfect recall for less well covered annotations, which  
236 are easily identified due to very specific terms, while (d) shows a relatively poor response due to  
237 small training set and terminology with variations in wording style.

238 One of the disadvantages of using this Laplacian corrected variant is that the computed value is  
239 not a probability, but rather a score with arbitrary range and scale. This means that it is not  
240 possible to compare the outcomes from two separate models, which is a problem, since the  
241 objective of this technology is to *rank* the scores that are obtained from each separate model. In  
242 order to achieve the ranking, the scores need to be directly comparable, and hence be suitable  
243 for providing a list of suggestions for which annotations are most likely to be associated with the  
244 text.

245 In order to make the scores from each of the models comparable, each model requires a  
246 calibration function. This can be accomplished effectively by defining a simple linear correction  
247 for each model, of the form  $y = ax + b$ , which is applied to each score prior to inter-model  
248 comparison. Selecting appropriate values for  $a$  and  $b$ , for each model, can be achieved by  
249 picking initial values that map each of the model outcomes to the range 0..1. By adjusting the  
250 scale and offset of the linear calibration functions for each of these models, the overall ability of  
251 the models to correctly rank the extant annotations with a higher score than those which are not  
252 observed can be evaluated. It is straightforward to define a scoring term that measures the  
253 ability of the calibrated models to distinguish between correct and incorrect annotations. This  
254 score can be optimized by iteratively adjusting the calibration terms to get the best overall  
255 separation in ranking.

256 Besides consistent use of linguistic descriptions of assays, one of the other observations about  
257 the annotations defined for these assay protocols is that they are not in any way orthogonal: the  
258 degree to which the annotations are correlated is very high. For example, if it is known that the

259 assay uses *luciferin* as a substrate, the probability that it also involves *luminescence* as a  
260 detection method is far higher than it would be if the prior fact had not already been established.

261 Given that the calibrated Bayesian models have been established to perform very well at placing  
262 the top few highest ranking annotations for the data used in this study, once these top scoring  
263 annotations have been confirmed by the user, the amount of information that can be inferred  
264 about the assay may be significantly greater, due to the high degree of correlation.

265 This second order correlation was implemented by building another set of Bayesian models with  
266 each possible annotation considered separately as an observation. For each document, each  
267 annotation's likely presence is modeled against the presence or absence of all the other  
268 annotations recorded for the document, e.g. when building the correlation model for annotation  
269 *A*, if document *i* contains annotations *A*, *B* and *C*, then it is considered to be "active", with priors  
270 *B* and *C*; if document *j* contains annotations *B*, *C* and *D*, it is considered "inactive", with priors *B*,  
271 *C* and *D*.

272 Thus, once one or more annotations have been assigned, the secondary Bayesian models are  
273 consulted, and the score for each of the annotations is modified by applying the correlation  
274 factor. Essentially this means that as the user approves annotations, the prediction scores of the  
275 remaining annotations tends to improve, as the correlations are factored in.

276 Figure 2 provides an indication of how the ranking evolves during the model building steps,  
277 using four example documents. For each of these diagrams, the left hand side shows two bands  
278 which represent the *uncalibrated* predictions, which are linearly normalized so their values fall  
279 between the minimum and maximum scores from the raw Bayesian prediction score. The  
280 annotations that do not apply to the document are shown as red lines, while the annotations that  
281 are present are shown in black. The height of each line is indicative of its score. As can be  
282 clearly seen, the desired predictions score are significantly higher for those present than those  
283 which are absent, but the extent to which the ranking separates the two groups varies, and is  
284 not initially a perfect separation for any of these examples.

285 The main area of each diagram shows the progression of the relative predictions: at the  
286 beginning of the sequence, the scores are ranked by the inter-model *calibration* functions, which  
287 typically results in a significant improvement. For each of the subsequent steps, the highest  
288 scoring correct annotation is added to the approved set, and the *correlation* model is updated  
289 and applied. The ranking is redetermined, and the next highest scoring correct annotation is  
290 selected. The diagram indicates the point at which each annotation is selected by plotting a  
291 black circle, and changing the color of the line to green: since it has been confirmed, its ranking

292 order is no longer a concern, though its presence continues to affect the way the correlation  
293 model is applied.

294 In the first example, shown in Figure 2 (a), application of these models in the given sequence  
295 provides a perfect result: in each case the highest scoring annotation yet to be selected is at the  
296 top of the list, with no false positives. In examples (b) and (c), the results are good but not  
297 perfect: the red cross marks indicate when an incorrect annotation was presented as the best  
298 next choice. Since this exercise is simulating curation by a human expert, the elimination of a  
299 top-ranked incorrect proposal is equivalent to being recognized by the user as an incorrect  
300 result, and explicitly excluded from further consideration. If the objective was to provide a pure  
301 machine learning solution, each of these ranking mistakes would represent the accumulation of  
302 bad data, rather than a small increase in the amount of effort required by the operator. In  
303 example (d), the response of the model is relatively poor, with several false positives appearing  
304 close to the top of the list, and the last few correct results being obscured by a large number of  
305 incorrectly ranked proposals.

## 306 **Results**

307 We have designed the algorithm with the goal of ranking the available annotations such that  
308 given a text description of an assay, the annotations that correctly apply to the document are  
309 listed before any which do not. A perfect result is considered to be any case where all of the  
310 correct proposals are ranked first. Because the objective of the machine learning is to assist and  
311 accelerate the human-guided curation, a handful of mis-ordered annotations can be considered  
312 as an inconvenience, rather than the means by which data becomes corrupted.

313 For evaluation purposes, we define a yardstick measure: the null hypothesis is that the  
314 Bayesian-trained model using natural language processing performs no better than a trivial  
315 method, such as ranking all proposed annotations by the frequency with which they occur in the  
316 training set.

### 317 ***Cross validation***

318 The 983 fully annotated assays, with corresponding text from PubChem, were split into training  
319 and test sets using a simple partitioning algorithm. First of all, 208 documents were removed on  
320 account of having the same list of property:value annotations. These documents may differ by  
321 the free text annotations, but these are not included in the training set, and so duplicates need  
322 to be pruned. Of the remaining documents, entries were selectively picked for the test set in  
323 order to ensure that each annotation appears once in any one of the test set documents, but

324 such that the number of instances remaining in the training set was not reduced below 2. The  
325 training set contained 698 documents, the test set 77.

326 The models were rebuilt using just the training set documents, and applied to the test set. For  
327 evaluation purposes, we can consider the ranking of correct vs. incorrect answers to be  
328 instructive for how well the model achieves its stated goal. Figure 3 shows several plots that  
329 show the relative performance of the training and test sets.

330 The data for each plot is created according to the following procedure:

- 331 1. score each available annotation based on the model derived from the training set data;
- 332 2. pick the highest scoring annotation: if it is correct, add a positive mark, remove the  
333 annotation, and goto 1;
- 334 3. it is not correct, so add a negative mark, remove the annotation, and goto 2.

335 This essentially simulates an expert operator who only looks at the current top scoring  
336 annotation, and either approves it, or excludes it from further consideration. The process stops  
337 when all correct annotations have been approved.

338 Figure 3 illustrates this process graphically from several vantagepoints. In 3 (a), all of the test  
339 set documents are considered: for each line, running from left to right, a correct top ranking  
340 annotation is marked with a black square, while an incorrect top ranking annotation is marked  
341 with a purple square. Once all of the correct annotations have been picked, the remaining space  
342 is marked in grey. As can be seen, for the majority of cases the correct annotations are quickly  
343 picked out. Nonetheless there are a number of test documents that contain a small number of  
344 outliers, i.e. required annotations that are ranked very poorly, with many false positives getting a  
345 higher score.

346 Figure 3 (b) shows the same datapoints, except that only the actual annotations are given a  
347 color. The color is determined by a heatmap pattern, for which *green* indicates predictions that  
348 were derived from a well-populated model with many examples, while *red* indicates those for  
349 which very little training data was available. As can be seen, the outliers that rank very poorly  
350 relative to the false positives are all colored red, which strongly suggests that poor performance  
351 is due to sparsity of training data, rather than flaws with the method.

352 In Figure 3 (c), the method for scoring documents is set to the *frequency* of each annotation in  
353 the overall training set, e.g. if an annotation occurs 100 times in 698 documents, its score is set  
354 to 0.143. The same proposed ranking order is used for all documents, regardless of the text  
355 description. This is used to test a reasonable null hypothesis, which is that picking the most  
356 common annotations is an effective way to separate correct from incorrect. While it can be

357 clearly seen that the null hypothesis performs better than a random guess, at least for purposes  
358 of identifying true positives, it is vastly inferior to the proposals generated by the trained  
359 Bayesian-derived models, on account of the fact that every document has a very large number  
360 of false positives that need to be eliminated before the annotation is complete.

361 Figure 3 (d) shows the same process as for (a), except that in this case the training data is  
362 used, i.e. the models are used to predict the same documents from which they were trained.  
363 These results are superior to applying the models to the test set, which is to be expected.

### 364 ***Operator workflow***

365 The ultimate goal of combining machine learning with a user interface for bioassay annotation is  
366 to have the models predict all the correct annotations with close to perfect accuracy, and have  
367 the expert operator confirm these predictions. In practice this is realistic only when the  
368 document being annotated consists of cases that are well covered in the training set. Due to the  
369 nature of science, there will always be new methods being developed, which means that some  
370 of the corresponding annotations may have insufficient examples to create a model. It is also  
371 possible that the choice of phrasing for some of the assay details differs significantly from the  
372 language used by the examples in the training set, which can reduce the efficacy of the models,  
373 until additional data can be incorporated and used to re-train them.

374 For these reasons, the user interface needs to satisfy two main scenarios: 1) when the  
375 predictions are correct, and 2) when the document is unable to accurately predict the  
376 annotations. For the first scenario, confirming the correct annotations should be a matter of  
377 quickly scanning the highest scoring proposals and confirming the assignments. In these cases,  
378 the user interface must aspire to being unobtrusive. However, in the second scenario, when the  
379 correct annotation does not appear at the top of the list, the interface needs to provide ways for  
380 the user to hunt down the necessary annotations. We have conceived several options to help  
381 the user deal with this case. In near-ideal cases, the user may find the correct annotation by  
382 simply looking slightly further down the list of proposed annotations. Alternatively, the user may  
383 filter the results by selecting a particular category of annotations, and browse through this  
384 refined subset to find the correct annotation. Finally, if the user needs to include an annotation  
385 that is present in the ontology, but has not been included in the list of proposals because there is  
386 not enough data to build a model, the interface can provide assistance in searching through all  
387 of the unscored options. Furthermore, there will also be occasions when the desired annotation  
388 does not exist in the ontology, e.g. a previously unreported biological pathway, in which case it  
389 may be desirable to allow the user to enter the information as plain text. While this has little

390 immediate value for semantic purposes, it could be considered as a placeholder for future  
391 additions to the underlying ontology, which could be upgraded retroactively.

392 A mockup of the core elements of this interface is shown in Figure 4, which shows the same  
393 layout principles for the proof of concept application that we created for testing the machine  
394 learning methods and corresponding workflow. The box shown at the top left allows the user to  
395 type in free text. This could be cut-and-pasted from another application, or it could be typed in  
396 manually. The list immediately below shows a series of annotations, consisting of *property* and  
397 *value*. These are ranked highest first. When the system is working perfectly, the user can click  
398 on the *approve* button for the highest scoring annotation, shown at the top of the list. If the  
399 highest scoring annotation is not correct, the user may look further down the list in order to find  
400 one that is correct; or, they may *reject* an incorrect proposal. In either case, the proposals are  
401 recomputed, and a new list of options is shown.

402 On the right hand side of the screen is shown all of the available properties, which are used to  
403 organize the annotations: for each property or category, there can be zero-or-more assigned  
404 annotations, of the property:value form. This simple hierarchical arrangement clearly shows the  
405 annotations that have been assigned so far, and which properties have as yet no associations.  
406 Making the property icons clickable is a way to allow filtering of the annotation list, i.e. only  
407 showing the potential annotations that match the selected property. In this way, the operator can  
408 carefully pick out assignments for each of the property groups, which is a workflow that  
409 becomes important when working with documents that do not fall within the domain of  
410 pretrained data. This process of picking out the correct assignment can either be done by  
411 scrolling through the list of all possible annotations ranked according to the predictive score, or  
412 by partial text searching.

### 413 ***Domain example***

414 Figure 5 shows the annotation of an assay, which can be found in PubChem (Assay ID 761).  
415 The annotation text has been composed by concatenating the assay description and protocol  
416 text fields, and trimmed to remove superfluous content, which is shown in (a). This case is an  
417 example where the performance of the machine learning models is strong, but still requires a  
418 well-designed user interface for the portions that are less well covered.

419 Steps (b) through (y) show each of the assignment steps: in most of these examples, the 5  
420 highest ranked annotations are shown. In most of the initial steps, the top ranked case is a  
421 correctly predicted annotation. A green checkbox is used to indicate that the user confirms that  
422 presence of the annotation, and in the following step, the list of proposals is updated to reflect  
423 the modified scores, which take into account the correlation effects. In cases (l), (q), (r) and (t),

424 the top ranked prediction is incorrect, and a red cross mark indicates that the user explicitly  
425 excludes the annotation from further consideration. In step (w) the desired annotation is further  
426 down the list, and so the user scrolls the proposals in order to select the next correct one. In  
427 step (x), the user needs to add the annotation *bioassay type : binding* assay, which has not  
428 been ranked well in the overall scheme, and so the list of annotations is filtered by selecting the  
429 *bioassay type* property, to only show these corresponding values. In step (y) the user is looking  
430 to find the *GPCR signal pathway* annotation, which is not a part of the training set, due to  
431 insufficient data to build a model. In order to locate this annotation, the user enters a search  
432 string to narrow down the list and locate it.

433 In Figure 5 (z), the complete list of annotations, divided into property categories, is shown. This  
434 list is updated dynamically as each of the annotations is added to the collection. The properties  
435 for *cell line*, *assay kit* and *inducer* have no corresponding annotations, since these are not a part  
436 of the assay.

### 437 **Semantic output**

438 The purpose of adding semantic annotations to bioassays is to enable a diverse range of  
439 queries and automated analysis, and one of the most effective ways to enable this is load the  
440 annotation markup into the same framework as the original BioAssay Ontology definition and all  
441 of its related dependencies.

442 The output from an annotated description can easily be expressed in terms of RDF triples. The  
443 properties and values are already mapped into the BAO space. A new URI needs to be defined  
444 for each of the assays being annotated. For example, the annotation example used earlier,  
445 converted into RDF "Turtle" format, is shown in Figure 6.

446 Once in this format, the assertions can be loaded into an existing SPARQL server. At this point  
447 the content becomes accessible to the full suite of semantic technologies. Combining the  
448 generic querying capabilities of the SPARQL syntax, with the semantic structure of the BioAssay  
449 ontology, allows a variety of ad hoc questions to be answered.

450 For example, finding a list of annotated documents that make use of a specific assay kit:

```

451 SELECT ?aid WHERE
452 {
453     ?assaykit rdfs:label "HTRF cAMP Detection Kit" .
454     ?has rdfs:label "has assay kit" .
455     ?document ?has ?assaykit .
456     ?document cdd:PubChemAID ?aid
457 }

```

458 This simple query extracts a list of assay identifiers for anything that makes use of a specific  
 459 manufacturer's cyclic AMP detector. Note that the property and value URIs are matched by  
 460 cross referencing the label. Based on the training data, this query returns AID numbers 933,  
 461 940, 1080, 1402, 1403, 1421, 1422 and 488980.

462 A slightly more advanced query can extract information other than just document identifiers:

```

463 SELECT ?instrument ?aid WHERE
464 {
465     ?document bao:BAO_0002855 bao:BAO_0000110 .
466     ?document bao:BAO_0000196 bao:BAO_0000091 .
467     ?document bao:BAO_0000207 bao:BAO_0000363 .
468     ?document bao:BAO_0002865 ?q .
469     ?q rdfs:label ?instrument .
470     ?document cdd:PubChemAID ?aid
471 }
472 ORDER BY ?instrument ?aid

```

473 In this case the restrictions are specified by directly referencing the BAO tags, which searches  
 474 for all protein-small molecule interaction assays, with inhibition as the mode of action, using  
 475 fluorescence intensity measurements. For each match, the detection instrument is looked up  
 476 and cross referenced by label:

EnVision Multilabel Reader	622
PHERASTAR Plus	1986
ViewLux ultraHTS Microplate Imager	2323
ViewLux ultraHTS Microplate Imager	485281
ViewLux ultraHTS Microplate Imager	489008

477 The inheritance hierarchy of the BioAssay Ontology, and the ontologies it references, can also  
 478 be utilized in queries. The following query looks for assays that target GPCRs of mammals:

```
479 SELECT ?organism ?aid WHERE
480 {
481     ?mammal rdfs:label "mammalian" .
482     ?target rdfs:subClassOf* ?mammal .
483     ?target rdfs:label ?organism .
484     ?document bao:BAO_0002921 ?target .
485     ?q rdfs:label "G protein coupled receptor" .
486     ?document bao:BAO_0000211 ?q .
487     ?document cdd:PubChemAID ?aid
488 }
489 ORDER BY ?organism ?aid
```

490 The target variable is used to match any organism URI that is a subclass of mammals. The  
491 result is a number of assays for humans, rats and mice.

492 Each of these examples shows how the semantic markup of the annotated assays can be put to  
493 the test with very direct and specific adhoc questions. These queries can be composed on the  
494 fly by software that provides a more intuitive user interface, or they can be used for developing  
495 new kinds of analyses by experts. They can be applied to just the bioassay data in isolation, or  
496 they can be spliced into the greater semantic web as a whole, and linked to all manner of other  
497 information resources, e.g. screening runs measuring drug candidates, or medical  
498 knowledgebases that go into more detail about the biological systems being assayed.

### 499 ***Future work***

500 The hybrid interactive/machine learning approach to bioassay annotation is currently a proof of  
501 concept product. The prototype user interface is presently being evaluated by scientists with an  
502 interest in improving software annotation of biological data, and we are actively assessing the  
503 results in order to improve the workflow. The long-term goal is to provide the user interface in  
504 the form of a web application, which will be incorporated into larger products that provide data  
505 capture functionality, such as the CDD Vault developed by Collaborative Drug Discovery Inc. or  
506 potentially public databases such as PubChem. The semantic annotations will be recorded  
507 alongside the text description, and immediately accessible, sharable, searchable and used by a  
508 variety of features that can provide reasoning capabilities based on this data.

509 One of the obvious advantages of having user-approved annotations stored in a centralized  
510 location is that the machine learning models can be retrained at periodic intervals, which will  
511 ensure that the ease with which users can rapidly annotate their assays continues to improve as  
512 more data is submitted. Also, as more data becomes available, the domain of the models will  
513 continue to grow: annotations that were previously left out of the model building process due to  
514 insufficient case studies will be added once they have been used.

515 Another potential advantage of centralization is to provide a pathway for new semantic  
516 annotations, i.e. when the BioAssay Ontology and its dependencies do not provide an  
517 appropriate term, users can resort to using a free text placeholder. Such annotations can be  
518 examined on a regular basis, and either a manual or automated process can be devised to  
519 collect together repeated use of related terms, and define a new annotation (e.g. for a new class  
520 of biological target or a new measurement technique). This requires a single authority to decide  
521 on a universal resource identifier (URI) for the new term, which could be done by the service  
522 provider hosting the data, who may also take the opportunity to retroactively upgrade the  
523 existing examples of free text labels to use the freshly minted semantic annotation. We have  
524 also demonstrated creating a file containing RDF triples for the resulting annotations for a  
525 document, and are looking into harmonizing the data format with the Assay Definition Standard  
526 format (ADS/ADF)(de Souza et al. 2014; Website 2014d).

527 In addition to working with potential users of this software, we are also looking to incorporate  
528 more public content, from large collection services such as PubChem (Wang et al. 2014; Zhang  
529 et al. 2011), BARD (de Souza et al. 2014), ChEMBL(Bellis et al. 2011) and OpenPHACTS  
530 (Williams et al. 2012). There are a number of research groups exploring ways to add semantic  
531 markup to drug discovery data, including bioassays, and many of these annotations can be  
532 mapped to the BAO annotations that we have chosen for this project. Even though we have  
533 found in our internal evaluation efforts that annotation time can be plausibly reduced to a matter  
534 of minutes, this is still a significant burden to impose on busy scientists, especially if participation  
535 is voluntary. As we consider deployment of the service, it is important to ensure that the benefits  
536 of assay annotation are realized as early as possible, rather than waiting for critical mass, which  
537 might otherwise not be achieved. Allowing scientists to use their annotated assays to easily  
538 search for similar assays within a database, or as a convenient way to label and categorize their  
539 own collections of assays, are anticipated to be effective strategies to make the technology  
540 useful during the early adoption phase.

541 Thinking broadly, one interesting possible use case for the annotation scheme is to run it in  
542 reverse: to have the software use the annotations to assemble a paragraph of plain English text,  
543 which is suitable for incorporation into a manuscript. In this case the workflow would likely be  
544 quite different, e.g. the user types in a poorly formatted collection of terms involved in the assay  
545 in order to help the inference engine rank the likely suggestions, selects the appropriate terms,  
546 and then has the text produced by the software. Such a service could be of significant use to  
547 scientists who are not experienced with writing assay procedures according to the standard  
548 style guides.

549 As part of our ongoing work, we are evaluating our selection of annotations from the underlying  
550 ontology. Our initial prototype is strongly influenced by the training data that we have available,  
551 which is the result of hundreds of hours of work by qualified domain experts. We are actively  
552 working with biologists and medicinal chemists to determine which properties are of primary  
553 importance, and which are secondary, and to expand our collection of training data to reflect the  
554 priorities of active drug discovery researchers.

555 Beyond the use of bioassays and BAO annotations for training data, the methodology  
556 developed is broadly applicable and not specific to this domain. We anticipate that there are a  
557 number of other distinct subject areas of scientific publications that would be amenable to this  
558 treatment, e.g. experimental details of chemical reactions, computational chemistry protocols,  
559 and other types of biological protocols beyond drug discovery, such as stem cell differentiation.

## 560 **Conclusion**

561 We have built a proof of concept framework that involves using machine learning based on plain  
562 text assay descriptions and curated semantic markup, and matched this with a user interface  
563 that is optimized for making machine-assisted annotation very rapid and convenient when  
564 applied to text input that is well within the domain, and moderately efficient for annotating  
565 assays that fall outside of the training set. By optimizing both the machine learning and user-  
566 centric workflow at the same time, we avoid falling into the traps of both extremes, because both  
567 parts complement each other. Annotation of plain text by purely automated methods has been  
568 limited by the need to obtain an unrealistic level of accuracy, while purely manual annotation has  
569 to overcome a very high motivational barrier, given that most scientists are too busy to take on  
570 additional burdens, without an immediate benefit. By establishing that adding a very modest  
571 amount of human effort to a well designed automated parser can achieve highly accurate  
572 results, we believe that we can make a strong case for the use of this technology in the hands of  
573 practicing scientists.

574 As the quantity of semantically rich annotated data increases, the opportunities for delivering  
575 value to scientists increases in tandem. Making annotation easy is the first step, but it needs to  
576 be followed by new capabilities. For example, the creators of assay screens should be able to  
577 easily compare their experiments with others contained within the knowledgebase, and obtain a  
578 list of experiments and published papers with common features. Researchers performing drug  
579 discovery modeling studies should be able to gather together compounds that have been  
580 screened under certain conditions, and use the annotations to make a judgment call as to  
581 whether the measured activities can be incorporated into the same model. Additionally,  
582 researchers can search for artifacts, such as compounds that are disproportionately active in

583 luminescent assays. New biological activities may also become mineable; for example, common  
584 hits between cell-based assays and target based assays may reveal unknown molecular  
585 mechanisms.

586 Beyond the specific domain of bioassay annotation, we believe that the hybrid approach to high  
587 level markup is appropriate to many different areas of science, where use of English text jargon  
588 or anachronistic diagrams is the norm for conveying concepts that are amenable to a highly  
589 structured description. The understandable reluctance of scientists to redesign their  
590 communication methods for the benefits of software, and the inability of software to provide  
591 substantially useful results without such richly marked up data, is a proverbial chicken vs. egg  
592 scenario that can be observed throughout the scientific disciplines. Combining machine learning  
593 with modest demands on scientists' time, and rapid iteration of improved functionality, is a viable  
594 strategy for advancing the goals of computer assisted decision support.

## 595 **Acknowledgments**

596 The development of BAO and annotation / markup of assays was supported by NIH grants RC2  
597 HG005668 and U01HL111561 to SCS. Modeling and software development was supported by  
598 NIH SBIR grant 1R43TR000185-01A1 to BAB.

# Figure 1

Selected leave-one-out ROC plots for annotations, using Bayesian learning models derived from marked-up natural language processing.

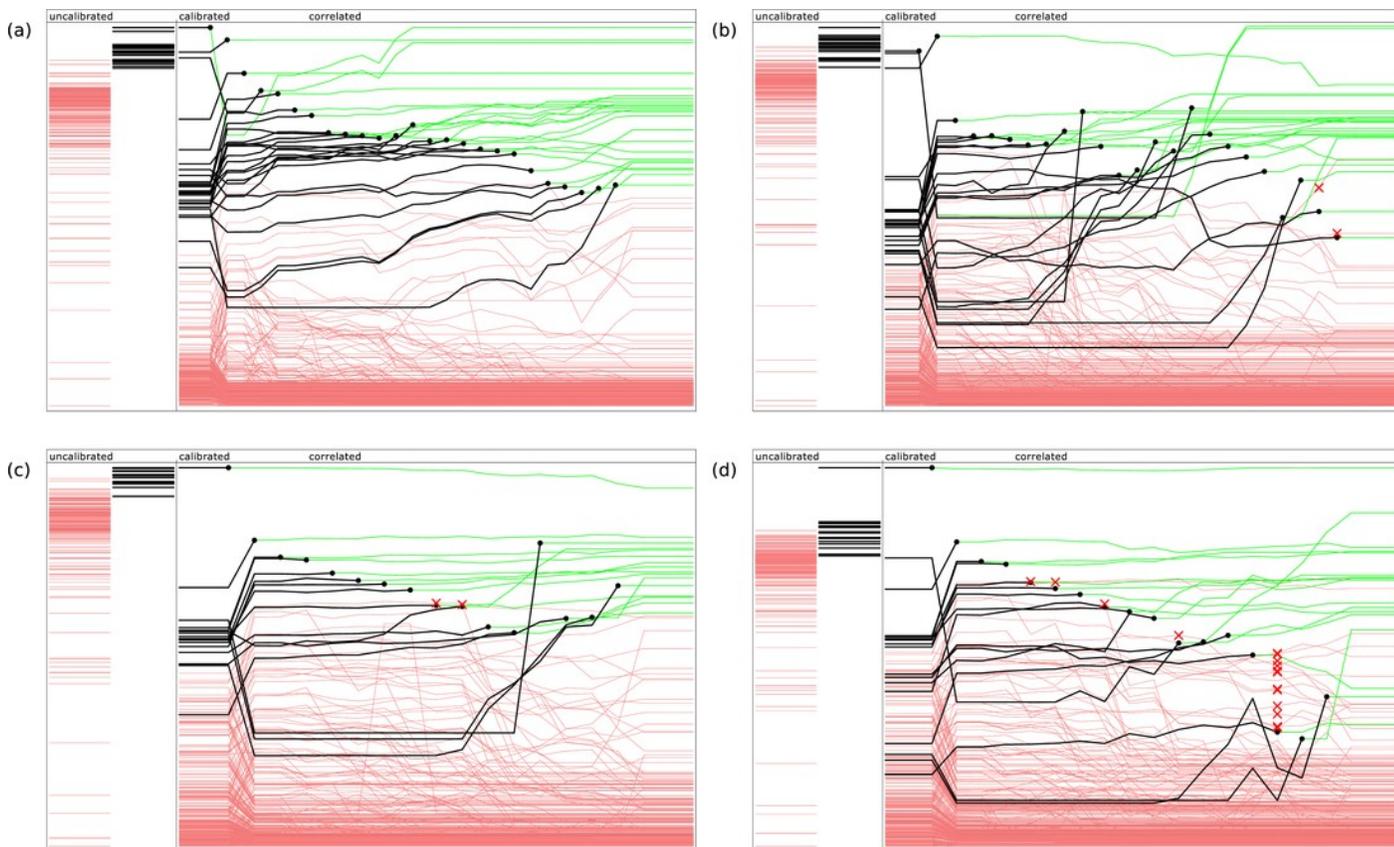

**Figure 1:** Selected leave-one-out ROC plots for annotations, using Bayesian learning models derived from marked-up natural language processing.

# Figure 2

Representative examples of model building in action.

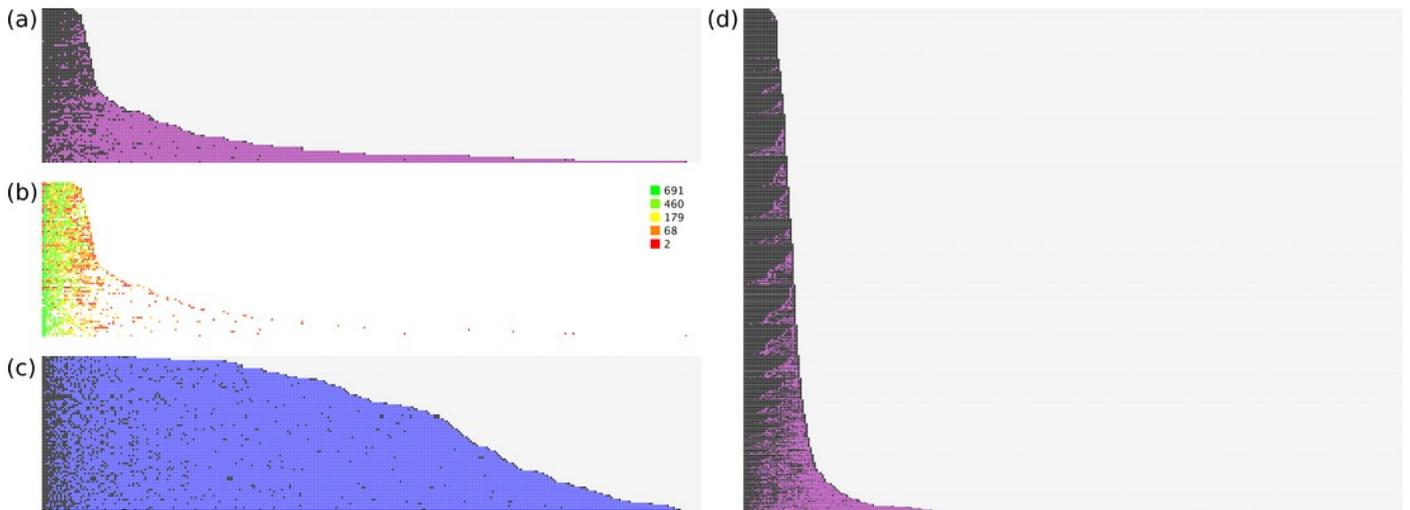

**Figure 2:** Representative examples of model building in action, showing relative ranking of uncalibrated, calibrated, and stepwise application of the correlation models. The four examples refer PubChem entries by assay ID: (a) 574, (b) 436, (c) 348 and (d) 346.

# Figure 3

Effectiveness of ranking of activities

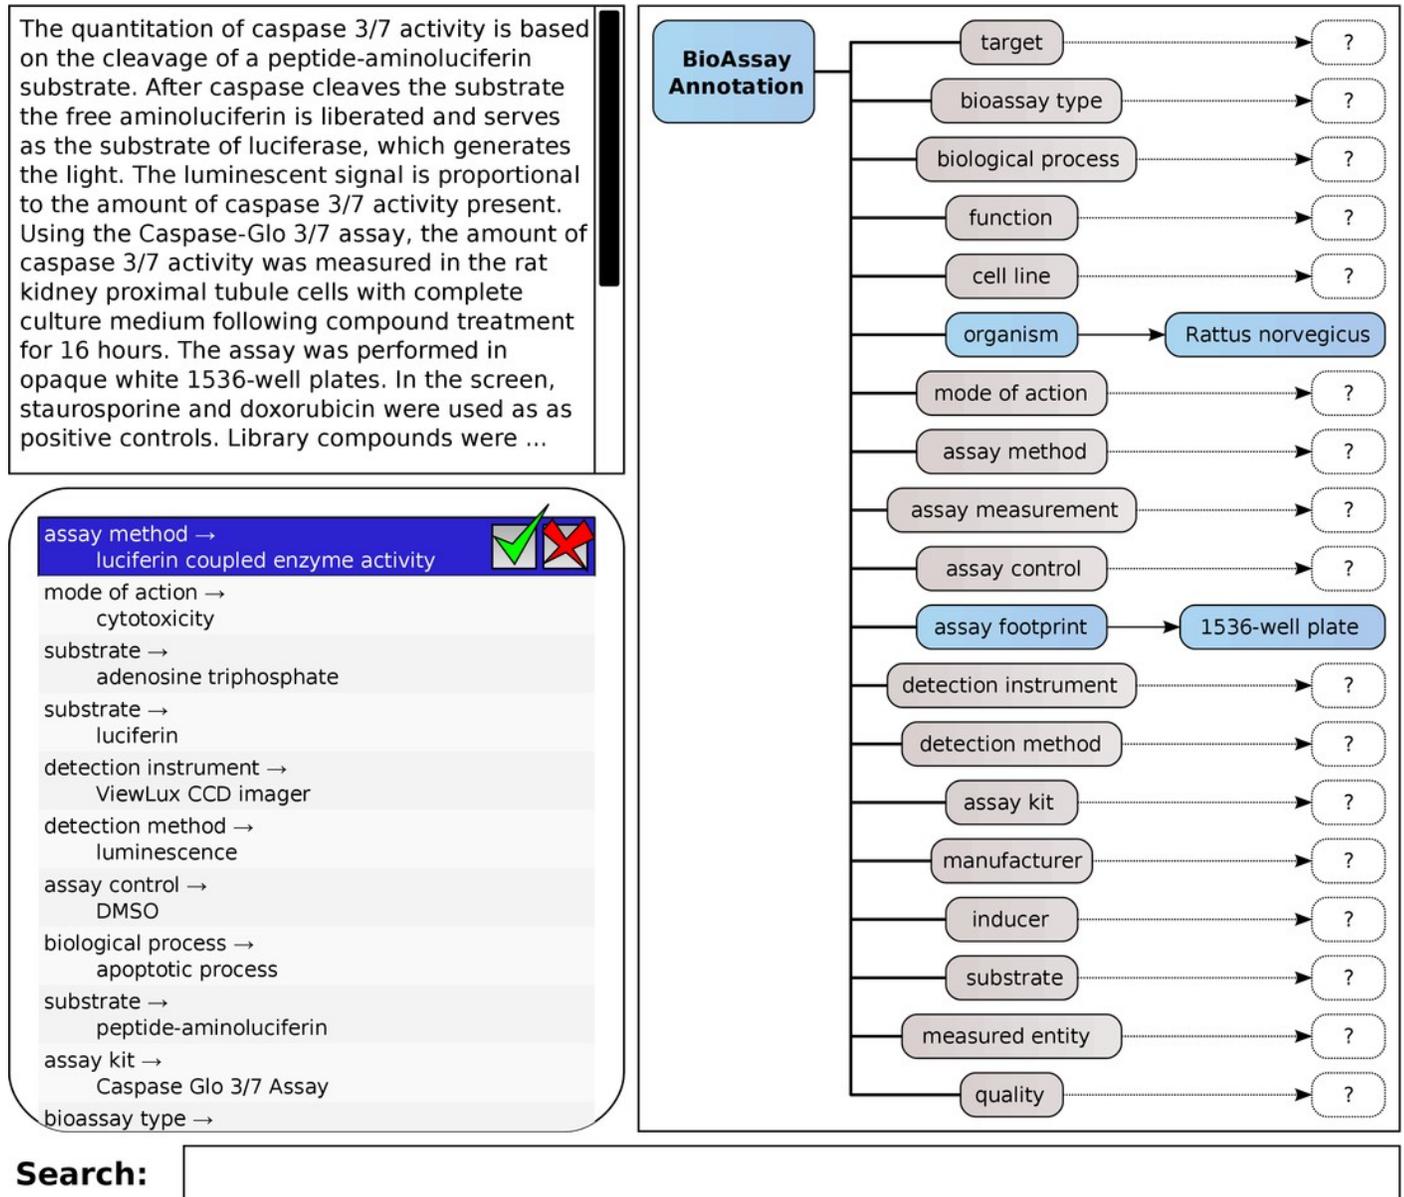

**Figure 3:** Effectiveness of ranking of activities: (a) hit/miss for test data; (b) heatmap for model size; (c) null hypothesis; (d) hit/miss for training data.

# Figure 4

A mockup of an interactive graphical user interface for annotating bioassays, with guidance from pretrained models.

**Figure 4:** A mockup of an interactive graphical user interface for annotating bioassays, with guidance from pretrained models.

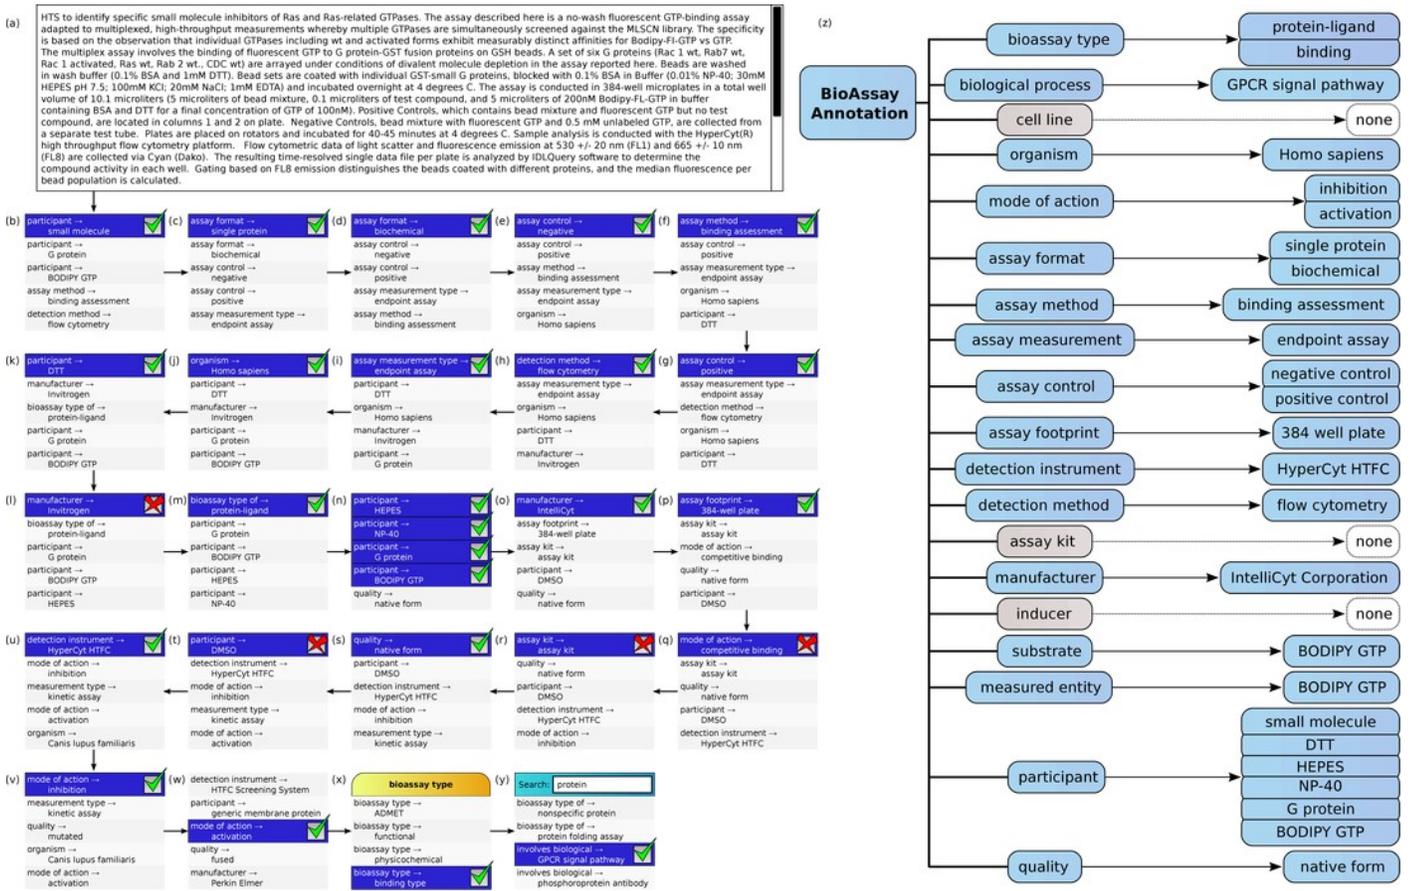

# Figure 5

Stepwise annotation process for PubChem Assay ID 761

**Figure 5:** Stepwise annotation process for PubChem Assay ID 761,
