Abstract

Synechocystis gathered momentum in modelling studies and biotechnological applications owing to multiple factors like fast growth, ability to fix carbon dioxide into valuable products, and the relative ease of genetic manipulation. *Synechocystis* physiology and metabolism, and consequently, the productivity of *Synechocystis* -based photobioreactors, are heavily light modulated. Here, we set up a turbidostat-controlled lab-scale cultivation system in order to study the influence of varying orange-red light intensities on *Synechocystis* growth characteristics and photosynthetic activity. *Synechocystis* growth and photosynthetic activity were found to raise as supplied light intensity increased up to 500 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$ and to enter the photoinhibition state only at 800 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$. Interestingly, reverting the light to a non-photo-inhibiting intensity unveiled *Synechocystis* to be able to promptly recover. Furthermore, our characterization displayed a clear correlation between variations in growth rate and cell size, extending a phenomenon previously observed in other cyanobacteria. Further, we applied a modelling approach to simulate the effects produced by varying the incident light intensity on its local distribution within the photobioreactor vessel. Our model simulations suggested that the photosynthetic activity of *Synechocystis* could be enhanced by finely regulating the intensity of the light incident on the photobioreactor in order to prevent cells from experiencing light-induced stress and induce their exploitation of areas of different local light intensity formed in the vessel. In the latter case, the heterogeneous distribution of the local light intensity would allow *Synechocystis* for an optimized usage of light.

53 Introduction

54 *Synechocystis* sp. PCC6803 (hereafter *Synechocystis*) was the first photosynthetic organism
 55 to have its genome fully sequenced (Kaneko et al., 1996). A wealth of transcriptomic (Anfelt
 56 et al., 2013; Beck et al., 2014; Angermayr et al., 2016), proteomic (Fang et al., 2016) and
 57 metabolomic (Yang, Hua & Shimizu, 2002; Yoshikawa et al., 2013), studies allowed to
 58 investigate *Synechocystis* regulatory, signalling and metabolic pathways in finer details than
 59 in any other cyanobacterium. *Synechocystis* has attracted much interest as model organism in
 60 product-oriented industrial biotechnology due to the ability to effortlessly recycle carbon
 61 dioxide (CO₂) into valuable fuels and chemicals, the simplicity of its culture conditions, the
 62 ease of genetic manipulation and its relatively fast cell growth compared to higher plants
 63 (Janssen et al., 2003; Angermayr, Hellingwerf & Teixeira de Mattos, 2009) . Genetic
 64 engineering of cyanobacteria has demonstrated the opportunity to channel solar energy into
 65 the formation of various commodity products (Angermayr, Gorchs Rovira & Hellingwerf,
 66 2015; Zhou et al., 2016). In the last decades, *Synechocystis* has served in many genetic
 67 engineering studies as biofactory for the production of a variety of products (Yu et al.,
 68 2013a; Singh et al., 2017), , such as ethanol (Gao et al., 2012), isobutanol (Varman et al.,
 69 2013), lactate (Angermayr, Paszota & Hellingwerf, 2012; Joseph et al.) and
 70 polyhydroxyalkanoate (Luengo et al., 2003), which can be widely utilized in biotechnology
 71 and industrial fields.

72 The intensive exploitation of this microorganism for industrial uses strongly depends on the
 73 choice of optimal growth conditions, main operational parameters including culture density
 74 (Esteves-Ferreira et al., 2017; Straka & Rittmann, 2018) , pH (Touloupakis et al., 2016),
 75 temperature (Panda et al., 2006), mixing rate and light environment (Touloupakis et al., 2016;
 76 Singh et al., 2009a). Even though extensive investigation showed that *Synechocystis*

77 productivity is sensitive to most of the aforementioned operational parameters (Yu et al.,
 78 2013; Burrows & Wong, 2009; Nanjo et al., 2010; Chaves, Kirst & Melis, 2015), it is
 79 undoubted that productivity is tightly coupled with the light absorption efficiency of optical
 80 energy conversion systems. Therefore, light management during *Synechocystis* cultivation in
 81 photobioreactors (PBRs) is by far the most remarkable factor to account for in order to boost
 82 the practical exploitation of this microorganism. *Synechocystis* is able to absorb energy across
 83 the visible spectrum, mainly through three classes of pigments: bilins (Gan & Bryant, 2015),
 84 chlorophyll *a* (Chl *a*), which is associated with Photosystem II (PSII) and Photosystem I
 85 (PSI) reaction centre cores (Vermaas, 1996), and carotenoids (Glazer, 1977; Colyer et al.,
 86 2005). Achieving high performance in PBRs requires high intensity light, which nonetheless
 87 can cause light associated damages. A number of studies sought to dilute the supplied light
 88 intensity by optimizing the light spectra distribution. These attempts were encouraged by the
 89 integration of light emitting diodes (LEDs) within indoor PBRs (Ooms et al., 2017). Tailoring
 90 light wavelength spectrum affords improved growth conditions stability and reproducibility
 91 and has been shown to lead to concrete achievements in biomass productivity and ultimately
 92 in the accumulation of useful products. For example, a perfect fit of the red light with the
 93 absorption peak of the Chl *a* and phycocyanobilin was observed to lead to an increased
 94 growth in cyanobacteria during cultivation (Wyman & Fay, 1986; Wang, Fu & Liu, 2007;
 95 Pcc & Alphen, 2018). In other cases, dynamic adjustments of light wavelength during
 96 cultivation of *Chlorella vulgaris* and *Haematococcus pluvialis* allowed to increase the
 97 microorganism productivity (Katsuda et al., 2004).

98 It is well known that the exposure of photosynthetic organisms to strong solar irradiation
 99 results in inhibition of the electron transfer activity of PSII, referred to as photoinhibition
 100 responses (Powles, 1984). This phenomenon derives from an imbalance between the
 101 photodamage brought to PSII and the repair mechanisms for such damage (Murata et al.,

102 2007). Despite the numerous studies conducted on this topic highlight that the main target
 103 of photoinhibition is the D1 protein of PSII reaction centre (Tyystjärvi, 2013), the
 104 molecular mechanisms of PSII photoinhibition are not yet completely understood. Upon
 105 exposure of photosynthetic organisms to strong irradiation, two mechanisms contribute to the
 106 photodamage of PSII, which are called acceptor-side and donor-side photoinhibition. In the
 107 acceptor-side mechanism, strong illumination causes the over-reduction of PSII, due to the
 108 double reduction of the primary quinone acceptor (Q_A) that, in such condition, can no longer
 109 serve as an electron carrier. The recombination between the doubled reduced form of Q_A and
 110 the primary radical pair $P680^+$ and $Pheo^-$ leads to the formation of the triplet state of the
 111 $P680$, which can react with molecular oxygen leading to generation of the reactive form of
 112 oxygen (ROS) singlet oxygen (1O_2) (Mulo et al., 1998; Vass et al., 1992b). Due to the
 113 extremely short lifetime of this ROS, 1O_2 is thought to impair mainly the proteins and lipids
 114 nearby its production site (Triantaphylidès & Havaux, 2009). Conversely, the donor-side
 115 photoinhibition is not mediated by ROS and occurs when the reduction of the PSII is slower
 116 than its oxidation, due to inactivation of the oxygen evolving system. This leads to an
 117 extended lifetime of the radicals $TyrZ^+$ and $P680^+$ that act as strong oxidants against the
 118 surrounding proteins and lipids, resulting in a damage to the PSII (Bumann & Oesterhelt,
 119 1995).

120 In this work, we investigated the effect of increasing intensities (in the range 50-1460 μmol
 121 $\text{photons m}^{-2} \text{s}^{-1}$) of orange-red light on the autotrophic growth of *Synechocystis* in a
 122 turbidostat-controlled lab scale PBR. Monitoring *Synechocystis* physiological state under
 123 varying light regimes, we found that growth rate, cell size and PSII activity were influenced
 124 by light intensity, albeit in slightly different ways. *Synechocystis* cells proved to be resilient
 125 to high light stress conditions, suffering photoinhibition only above 800 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$,
 126 and showed a remarkable ability to recover from the complete state of photoinhibition

127 experienced at $1460 \mu\text{mol photons m}^{-2} \text{ s}^{-1}$ when reverting light to $200 \mu\text{mol photons m}^{-2} \text{ s}^{-1}$.

128 Further, we combined the experimental analyses with system modelling and the related multi-
129 physics analysis to investigate the influence of local light intensity distribution on
130 photoinhibition of microorganism.

131 **Materials and methods**

132 **Strain and preculture conditions**

133 For all experiments, we used wild-type *Synechocystis* sp. PCC 6803, a glucose-tolerant
134 derivative kindly provided by Devaki Bhaya (Department of Plant Biology, Carnegie
135 Institution for Science, Stanford, California, USA). The cells were grown in flasks in 25 ml
136 of BG11 medium (Stanier et al., 1971) with a modified protocol as described in (Van Alphen
137 & Hellingwerf, 2015). Precultures were grown for 4 days at 30°C in a shaking incubator at
138 120 rpm (New Brunswick Innova 44) under constant illumination of orange-red (632 nm) and
139 blue (451 nm) light (10:1 photon ratio) at $30 \mu\text{mol photons m}^{-2} \text{ s}^{-1}$, measured with a LI-250
140 quantum sensor (LI-COR, USA).

141 **PBR growth conditions**

142 A *Synechocystis* preculture was used to seed the PBR. The culture was grown in a flat panel
143 PBR model FMT150.2/400 Photon System Instruments (Nedbal et al., 2008) in a final
144 volume of approximately 380 ml in the BG-11 medium modified as described above,
145 supplemented with 10 mM of NaHCO_3 .

146 The PBR (**Fig. 1**) is provided with a combined pH/temperature probe, a Clark-type dissolved
147 O_2 (dO_2) probe (all probes Mattler-Toledo), and an integrated densitometer that measures the
148 optical density (OD) at 720 and 680 nm.

149 The cyanobacterial suspension was illuminated from one side with orange-red light (636 nm)
150 by high-power LEDs. The light regimes applied by the LED board provided cells with the
151 following light intensities as measured outside the PBR, opposite of and at the centre of the

152 light panel: 50, 200, 300, 500, 800, 950 and 1460 $\mu\text{mol photons m}^{-2} \text{ s}^{-1}$. The cells were
 153 subjected to increasing light intensity every 24 h. The 24 h period of light acclimation was
 154 sufficient for establishing stable (variance < 1%) growth rate and dissolved oxygen in the
 155 culture medium for each light intensity except for the light regime of 1460 $\mu\text{mol photons m}^{-2}$
 156 s^{-1} , where stable values were not obtained. The temperature and pH were kept constant at
 157 30°C and 8.0, respectively, by automatically adjusting pCO_2 using a gas mixing system
 158 GMS150 (Photon Systems Instruments). CO_2 was provided in a mixture with N_2 with a gas
 159 flow of 150 ml min^{-1} controlled by a mass flow controller (Smart Mass Flow Model 5850S,
 160 Brooks Instruments). The PBR was run in turbidostat mode with the OD_{720} , measured by the
 161 integrated densitometer, calibrated to the bench-top spectrophotometer OD_{730} to maintain the
 162 OD_{730} at approximately 0.4 (turbidostat set to a maximum deviation of 3%) at 50 μmol
 163 $\text{photons m}^{-2} \text{ s}^{-1}$. The turbidostat mode allowed the culture to hold cell density constant and to
 164 remain in exponential phase under all tested light conditions. Dissolved molecular oxygen
 165 was normalized to the values obtained at 50 $\mu\text{mol photons m}^{-2} \text{ s}^{-1}$.

166

167

168 **Dry weight, cell size and count measurements**

169 At the end of each 24 h step of light increment, 22 ml of culture were harvested to perform in
 170 parallel dry weight measurements and cell size analysis.

171 For the determination of dry cell weight, cellulose acetate membranes (0.2 μm , Whatman)
 172 were washed with milli-Q water (Merck Millipore Reference), left to dry for 24 h at 90°C in a
 173 stove (Electrolux) and weighted with an analytical balance (AB204, Mettler Toledo).
 174 Subsequently, the membranes were used for filtering 20 ml of sampled culture. After washing
 175 once with milli-Q water to remove salts, the membrane filter was left to dry overnight in the
 176 stove at 90°C and finally weighted again. In parallel, the OD_{730} of the sampled cells was

177 measured with a spectrophotometer (Lightwave II, Biochrom) and used to normalize the dry
178 cell weight per OD₇₃₀.

179 The average cell size and cell number were measured with the CASY counter instrument
180 (Roche Applied Science). A volume of 20 µl of harvested culture was diluted with 10 ml of
181 CASY ton solution. The average cell size was measured working in a range of calibration
182 between 0-5 µm with a capillary of 60 µm.

183

184 **Model description**

185 The 3D multi-physics model of the PBR was developed on the COMSOL 5.3® platform and
186 allowed us to simulate different phenomena such as fluid dynamic, light transmission in
187 different media, cyanobacterial growth kinetics and mass transfer by formulating the
188 corresponding equations. **Fig. 1D** shows the design of the 3D model based on the reactor
189 geometry. Free tetrahedral meshing was applied to the created model prior to analysis.
190 Meshing size was selected in order to prevent inaccuracy and imprecision of modelling
191 resulting from model meshing.

192

193 **Assumptions, inlet and boundary conditions**

194 To solve the different mass balances and kinetic equations, it is necessary either to state the
195 initial and boundary conditions, which include inlet, outlet and wall conditions, or to discuss
196 the different assumptions, which clarify the limitations of the created model:

- 197 i. the inlet velocity of recycling gas was measured experimentally. As there is no liquid
198 exchanging during experiments, the liquid velocity in the inlet/outlet area is equal to
199 0;
- 200 ii. the mass transfer between liquid culture and gas is considered;

- iii. all conditions in the model of the PBR, where both liquid and gas phases are present, were formulated by assuming the gas flux at the reactor boundaries negligible and by setting the liquid velocity at the reactor surface wall different from zero. Slip conditions were applied to all PBR walls;
- iv. since only CO₂/N₂ gas mixture flows through the sparger, its fluid-dynamic model assumed a single phase to be present. Therefore, the wall conditions used for gas flow were slip conditions, which assume that the gas velocity at the sparger solid surface is calculated by the mathematical model;
- v. the working conditions have to be furnished to the model: temperature, inlet gas velocity (or flow rate), initial, inlet and outlet pressure, amount of initial microorganisms and nutrients;
- vi. the influence of nutrient concentration, temperature and light intensity on cyanobacterial growth rate are all considered.

Mathematical model

The mathematical model is described in the following sections. All the variables and parameters employed in the equations are listed and described in the Nomenclature as well as in Table S1. To estimate the necessary parameters, we relied on experimentally determined values or on an inference procedure by fitting model simulations to observed data. Specifically, we compared simulated and experimental data using a statistical analysis of errors based on the Levenberg-Marquardt method, coupled with the second least-squares analysis. Since the method implements a constrained search procedure, it requires specifying lower and upper bounds on the unknown parameters, which were selected within the ranges of values most frequently observed in literature. The parameter space exploration stopped when the model simulation best fit the experimental data.

226 Fluid-dynamic equations

227 We generally need to model different domains inside the bioreactor: a gas-liquid mixture
 228 inside the vessel, and a single gas phase inside the sparger domain. Therefore, the continuity
 229 equations and the momentum balance equations need to be adapted depending on the
 230 modelled domain.

231

232 The general double-phase fluid dynamic continuity equations are formulated through Eqs. (1-
 233 3) and allow to account for the coexistence of the bubble gas phase (dispersed phase, named
 234 by “d” as subscript) and the liquid phase (continuous phase, named by “c” as subscript):

235

$$236 (\rho_c - \rho_d) \left[\nabla \cdot (\Phi_d (1 - c_d) \mathbf{u}_{slip} - D_{md} \nabla \cdot \Phi_d) + \frac{m_{de}}{\rho_d} \right] + \rho_c (\nabla \cdot \mathbf{u}) = 0 \quad (1)$$

237

$$238 \mathbf{u} = \frac{\phi_c \rho_c \mathbf{u}_c + \phi_d \rho_d \mathbf{u}_d}{\rho} \quad (2)$$

239

$$240 \phi_c + \phi_d = 1 \quad (3)$$

241

242 where **Eq. (1)** is the continuity equation, **Eq. (2)** expresses the velocity vector \mathbf{u} , Φ_c
 243 and Φ_d are the volume fractions corresponding to liquid and gas phases respectively, and ρ
 244 is the pseudo-continuous phase density. **Eq. (3)** describes the relation between the volume
 245 fractions for the continuous Φ_c and dispersed Φ_d phases.

246

247 As to the sparger, since a single gas phase exists, we modelled the fluid dynamic variables
 248 trends accounting only for the terms of the **(Eq. 1)** related to the gas phase, which is
 249 expressed by the following equation:

$$\frac{\partial \rho_g}{\partial t} + \nabla \cdot (\rho \mathbf{u})_g = 0 \quad (4)$$

251

252 Regarding the momentum balance equations, we adopted the Navier–Stokes model for the
253 liquid–gas multiphase system, by using the following formulation (Li, Hu & Liu, 2014)

$$\frac{\partial (\rho \mathbf{u})}{\partial t} + \nabla \cdot (\rho \mathbf{u} \mathbf{u}) = -\nabla p - \nabla \cdot \boldsymbol{\tau} + \rho \mathbf{g} + \mathbf{F} \quad (5)$$

255

$$\boldsymbol{\tau} = -\mu \left[(\nabla \mathbf{u} + (\nabla \mathbf{u})^T) - \frac{2}{3} (\nabla \cdot \mathbf{u}) \mathbf{I} \right] \quad (6)$$

257

258 where p is the pressure, \mathbf{g} is the gravity acceleration vector, $\boldsymbol{\tau}$ is the stress tensor and μ is the
259 effective viscosity. For the single-phase sparger model, the momentum balance equations are
260 similar to **Eq.(5)**, where we replaced the effective viscosity with the gas viscosity.

261 In **Eq.(5)**, the effective viscosity includes not only the molecular viscosity μ_i but also
262 turbulent viscosity $\mu_{i,T}$ (Luo & Al-Dahhan, 2011), which accounts for the influence exerted by
263 the turbulent flow **Eq.(7)**.

264 Among the several models introduced to handle the turbulent viscosity, we adopted the
265 standard k - ϵ model to simulate the turbulent flow of the fluid entrained with cyanobacteria in
266 the mechanically stirred PBR. The standard k - ϵ turbulent model is computationally stable,
267 even in the presence of complex physics, and is applicable to a wide variety of turbulent
268 flows.

269 The equations to calculate the effective viscosity within the k - ϵ model are listed below:

270

$$\mu_{eff} = \mu_i + \mu_{i,T} \quad (7)$$

$$\mu_T = \rho C_\mu \frac{k^2}{\epsilon} \quad (8)$$

273

where C_μ is a model constant equals to 0.09 and k is the turbulence kinetic energy which can be calculated by the transport equations (Ali, 2014)

276

$$\rho \frac{\partial k}{\partial t} + \rho \mathbf{u} \cdot \nabla k = \nabla \cdot \left(\left(\mu + \frac{\mu_T}{\sigma_k} \right) \nabla k \right) + P_k - \rho \varepsilon \quad (9)$$

278

Where σ_k is a model constant equals to 1.0, derived from (Wilcox, 2006). To obtain the P_k values we used **Eq.(10)**

281

$$P_k = \mu_T \left(\nabla \mathbf{u} (\nabla \mathbf{u} + (\nabla \mathbf{u})^T) - \frac{2}{3} (\nabla \cdot \mathbf{u})^2 \right) - \frac{2}{3} \rho k \nabla \cdot \mathbf{u} \quad (10)$$

283

where the value of turbulent energy dissipation rate ε was calculated by **Eq.(11)**:

285

$$\rho \frac{\partial \varepsilon}{\partial t} + \rho \mathbf{u} \cdot \nabla \varepsilon = \nabla \cdot \left(\left(\mu + \frac{\mu_T}{\sigma_\varepsilon} \right) \nabla \varepsilon \right) + C_{\varepsilon 1} \frac{\varepsilon}{k} P_k - C_{\varepsilon 2} \rho \frac{\varepsilon^2}{k} \quad (11)$$

287

In this equation, $C_{\varepsilon 1}$ and $C_{\varepsilon 2}$ are constants equal to 1.44 and 1.92, respectively. Finally, in a turbulent bubbly flow model, the difference between gas velocity and liquid velocity consists of two terms: slip velocity and drift velocity (**Eq. (12)**):

291

$$\mathbf{u}_d - \mathbf{u}_c = \mathbf{u}_{slip} - \frac{D_{md}}{(1-c_d)\Phi_d} \quad (12)$$

293

The slip velocity \mathbf{u}_{slip} represents the relative velocity of the phases and the drift velocity is the additional velocity appearing when turbulence is taken into account. The drift velocity can be calculated by **Eq.(13)**, whereas the slip velocity can be calculated by using a pressure-drag balance (**Eq.(14)**):

297

$$u_{drift} = -\frac{D_{md}}{(1-c_d)} \nabla \phi_d \quad (13)$$

300

$$\frac{3C_{drag}}{4d_b} |u_{slip}| u_{slip} \rho_l = -\nabla p \quad (14)$$

302

303 where the drag coefficient C_{drag} can be computed by different formulas (Hartmann et al.,
304 2013). In our case, C_d was computed by **Eq.(15)**:

305

$$C_d = \frac{0.622}{\frac{\xi}{g \rho_l d_b^2} + 0.235} \quad (15)$$

307

308 where ξ is the surface tension coefficient and d_b is the average bubble diameter which was
309 measured as 3 mm through video imaging ($d_b = 3$ mm).

310 **Heat transfer with radiation: light transmission equations**

311 The balance of the radiative intensity, including contributions regarding propagation,
312 emission, absorption and scattering is formulated through the general radiative transfer
313 equation (Modest, 2003) and can be written as follows:

$$\Omega \cdot \nabla I(\Omega) = \kappa I_b(T) - \beta I(\Omega) + \frac{\sigma_s}{4\pi} \int_{4\pi} I(\Omega') \Phi(\Omega', \Omega) d\Omega' \quad (16)$$

316

317 To account for the effect mediated by the bubble volume fraction and cyanobacterial cell
318 concentration, we adapted the Lambert-Beer's law:

$$\frac{I}{I_0} = \exp(-\beta z) \quad (17)$$

321

322 where I is the local light intensity and I_0 represents the incident light intensity, β is the

323 extinction coefficient and z represents the path-length of the light through the material. Eq.

(17) does not account either for the light scattering by bubbles, which change the direction of light transmission, either for the light absorption by cyanobacteria [51]. Therefore, we modified Eq. 17 as follows:

$$\frac{I}{I_0} = \exp \left(-\left(\frac{\beta S}{4} + K_a\right)z \right) \quad (18)$$

Eq. (18) accounts for light absorption by *Synechocystis* cells by means of k_a , which is the absorption coefficient associated with cyanobacteria, and for the scattering associated with the bubble volume fraction through S , the interfacial area per unit volume which is a function of bubble size and bubble number density. By replacing the interfacial area with the bubble volume fraction ϕ_d and the bubble diameter, d_b , Eq. (18) is converted in the equation Eq. (19):

$$\frac{I}{I_0} = \exp \left(-\frac{3\phi_d z}{d_b} - K_a z \right) \quad (19)$$

The difference between Eq. (17) and Eq. (19) is the effect of cyanobacteria light absorption on local light intensity distribution. The average diameter of bubbles was calculated by using the video imaging technique and performing the procedure described in (Ali, 2014; Zhang, Dechatiwongse & Hellgardt, 2015). Eq. (19) was then used in the general radiative transfer equation.

Calculating the radiative heat source requires information on the temperature regime throughout the entire vessel domain, which is obtained solving the general heat transfer balance equation. The general heat transfer balance (Bird, Stewart & Lightfoot, 2002), which takes into account the radiation in participating media, is expressed in Eq.(20)

$$\rho C_p \frac{\partial T}{\partial t} + \rho C_p \mathbf{u} \cdot \nabla T + \nabla \cdot \mathbf{q} = Q + Q_r \quad (20)$$

349 where Q_r is the radiative heat source expressed as **Eq.(21)**

350

$$351 \quad Q_r = \kappa(G - 4\pi I_b) \quad (21)$$

352

353 **Kinetic models and calculation theory: cyanobacterial growth equations**

354 Generally, cyanobacterial growth rate is strongly influenced by various factors such as
 355 temperature, light intensity and nutrient concentration. Temperature usually affects the
 356 activity of enzymes involved in the cellular duplication, whereas light intensity determines
 357 the energy that cells can absorb for their maintenance and growth. Nutrient elements
 358 including sulphur, carbon, phosphorus and nitrogen are necessary for cyanobacteria to
 359 compose their biomass (Dechatiwongse et al., 2014).

360 The kinetics of cyanobacterial growth is usually defined by the Monod model, **Eq.(22)**,
 361 which only considers the effect of nutrient concentration (Vatcheva et al., 2006), because
 362 additional environmental parameters such as temperature and light intensity are always kept
 363 constant during experiments (Solimeno et al., 2015). In the Monod model, as shown in
 364 **Eq.(22)**, the maximum specific growth rate μ_{max} is treated as a constant, but in reality it is a
 365 function of light intensity and temperature. When nutrients are in excess, the growth rate is
 366 independent of nutrient concentration and expressed as:

367

$$368 \quad \mu_{gr} = \mu_{max} \frac{C}{K_s + C}$$

369 (22)

370

371 where C is the concentration of the limiting substrate for growth. In order to take into account
 372 also the effects exerted by nutrients and local light intensity on cyanobacterial growth
 373 kinetics, we decided to evaluate a modified Monod equation: the Aiba model (Aiba, 1982).

The Alba model, shown in **Eq.(23)**, is usually employed to simulate the effect of light intensity on cyanobacterial growth rate: it is capable of modelling the photo-limitation regime under low light intensity, the photo-saturation regime under optimal light intensity, and the photo-inhibition regime under intense light intensity (Zhang et al., 2015). Similarly, the model can also be applied to describe the photo-dependence of the oxygen production rate.

In this equation,

$$\mu_{gr} = \frac{\mu_{max} \cdot I}{I + k_s + \frac{I^2}{k_i}} \quad (23)$$

μ_{max} is the maximum growth rate, and k_s and k_i refer to the light saturation and photo-inhibition, respectively. These parameters are only dependent on cyanobacterial properties and were fitted from experimental observations.

All the variables and parameters used in the mathematical models are listed and explained in the nomenclature and in Table S1 of Supporting Information.

Determination of the photosynthetic efficiency

The photosynthetic efficiency was calculated as grams of biomass formed per mol photons. We calculated the amount of light available to the culture as the input to the PBR, which we called I_{in} , minus the light remaining after the passage through the culture, which we called I_{out} . I_{out} was calculated through model simulations to calculate how much light was absorbed in the reactor volume in 1 hour. We used the growth rate and dry weight values to calculate how much biomass was produced in these square centimetres times the 2.4 cm depth of the culture for the actual volume in one hour.

Results

398 Growth rate, oxygen evolution activity and dimension of cells are dynamically regulated
399 by light intensity

400 During cultivation, orange-red light was used since it resulted in an optimal light regime for
401 growing *Synechocystis* in our PBRs system. Conversely, light with wavelengths lower than
402 580 nm (green-blue) or higher than 670 nm (far-red) proved to be not efficient for its growth
403 (Singh et al., 2009). This knowledge served as a prerequisite to set up experiments aiming to
404 quantitatively evaluate the effects of increasing intensities, ranging between 50-1460 μmol
405 $\text{photons m}^{-2} \text{s}^{-1}$, of red-orange light on the adjustments of the physiological state in
406 *Synechocystis*. We studied the long-term photoinhibition in *Synechocystis* grown at
407 increasing light intensities by analysing changes in the growth rate, the physiological
408 parameter of oxygen evolution activity and the cell size at each incremental step of light
409 intensity. By running the PBR in turbidostat mode, *Synechocystis* was grown in a semi-
410 continuous regime so that cells were constantly maintained in the exponential growth phase.
411 Firstly, we measured *Synechocystis* growth rate to evaluate its generation time, and the
412 amount of oxygen dissolved in the medium (dO_2), which provides an indication of the PSII
413 activity within cell (Schoormans et al., 2015). Both the growth rate of *Synechocystis* (**Fig.**
414 **2A**) and the dissolved oxygen produced by the cells (**Fig. 2B**) were clearly affected by
415 increasing light intensity. The dynamics of both variables could be broadly partitioned into
416 four phases: an initial phase at 50 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$ where cells were not photoinhibited, a
417 second phase up to 500 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$, where *Synechocystis* cells doubling time and
418 PSII activity attained their maximum values, a third photoinhibitory phase up to 1460 μmol
419 $\text{photons m}^{-2} \text{s}^{-1}$ where both parameters dropped off, and a final recovery phase at 200 μmol
420 $\text{photons m}^{-2} \text{s}^{-1}$. Hereafter, the photon irradiance of 50 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$, was considered
421 the control photon irradiance. At this light condition, cells featured a relatively slow
422 metabolism, as evidenced by the modest growth rate of $0.054 \pm 0.003 \text{ h}^{-1}$ (corresponding to a

423 doubling time of ≈ 13 h) and a limited level of oxygen dissolved in the medium (roughly 35
 424 μM). This dissolved oxygen concentration at this photon irradiance was used as reference to
 425 normalize the measurements at all sampled points (normalized reference value at one). At a
 426 photon irradiance of $200 \mu\text{mol photons m}^{-2} \text{s}^{-1}$ *Synechocystis* grew two times faster than in the
 427 control light condition, showing a growth rate of $0.114 \pm 0.005 \text{ h}^{-1}$ (corresponding to a
 428 doubling time of ≈ 6 h), as shown in **Fig. 2A**. When photon irradiance was increased up to
 429 300 and $500 \mu\text{mol photons m}^{-2} \text{s}^{-1}$, the growth rate remained constant yielding values of 0.117
 430 $\pm 0.006 \text{ h}^{-1}$ and $0.114 \pm 0.005 \text{ h}^{-1}$, respectively. Switching photon irradiance from 50 to 200
 431 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$ led to a higher than two-fold increase in the relative amount of oxygen
 432 dissolved in the medium (from 1.00 ± 0.02 to 2.22 ± 0.07 , as shown in **Fig. 2B**), similarly to
 433 the trend displayed by growth rate. However, differently from the *Synechocystis* growth rate,
 434 when we increased photon irradiance to $300 \mu\text{mol photons m}^{-2} \text{s}^{-1}$, the relative concentration
 435 of oxygen kept increasing up to 2.56 ± 0.12 . Such difference in growth rate and dO_2 within
 436 the photon irradiance range from 200 and $300 \mu\text{mol photons m}^{-2} \text{s}^{-1}$ suggests that light could
 437 exert different effects on the PSII functionality and the doubling time of the microorganism.
 438 In particular, the increase in dO_2 concentration measured in the cultivation medium could
 439 indicate a fine tuning of the light/energy conversion by PSII, whereas the unvaried growth
 440 rate observed could result from a limited utilization of the light energy absorbed (Kramer &
 441 Evans, 2011). At a photon irradiance of $800 \mu\text{mol photons m}^{-2} \text{s}^{-1}$ a substantial decrease was
 442 observed for both growth rate ($0.1 \pm 0.012 \text{ h}^{-1}$ corresponding to a doubling time of ≈ 7 h) and
 443 relative amount of dO_2 (2.34 ± 0.11), denoting a light intensity where *Synechocystis* cells
 444 started to get photoinhibited. Further increasing the photon irradiance up to $1460 \mu\text{mol}$
 445 $\text{photons m}^{-2} \text{s}^{-1}$, *Synechocystis* growth rate dropped off to $0.043 \pm 0.020 \text{ h}^{-1}$ (corresponding to
 446 a doubling time of ≈ 16 h), representing roughly half of the maximum growth rate observed
 447 in our experimental set up. Furthermore, over the 24 hours acclimation period at this extreme

448 light treatment, the growth rate was found to be constantly decreasing thus highlighting a
 449 severe state of growth inhibition. Together with the growth rate, the relative dO_2 reached its
 450 minimum of 1.45 ± 0.23 at $1460 \mu\text{mol photons m}^{-2} \text{s}^{-1}$. These results evidenced severe PSII
 451 photodamage caused in *Synechocystis* by its exposure to high light intensity, in accordance
 452 with extensive literature available for cyanobacteria (see review (Murata et al., 2007) and
 453 references therein). To test whether, upon photoinhibition, lowering light intensity could
 454 recover the growth rate of *Synechocystis*, a point of recovery was set to the lowest light
 455 irradiance at which the maximal growth rate was observed (i.e. $200 \mu\text{mol photons m}^{-2} \text{s}^{-1}$).
 456 Upon reverting the photon irradiance to $200 \mu\text{mol photons m}^{-2} \text{s}^{-1}$, cells showed a remarkable
 457 ability to recover completely from the state of photoinhibition, as attested by the increased
 458 growth rate up to $0.102 \pm 0.009 \text{ h}^{-1}$ (corresponding to a doubling time of $\approx 7 \text{ h}$), which is
 459 similar to the maximum growth rate previously measured under the same light condition (**Fig.**
 460 **2A** (black dot) and **Fig. 3**). Similarly, the relative concentration of dO_2 in the medium was
 461 found to increase up to 2.13 ± 0.24 , attesting a full recovery of the PSII activity as well (**Fig.**
 462 **2B** (black dot) and **Fig. 3**). We found that the recovery half-time is approximately 3 h and
 463 that both growth rate and dO_2 remain stable after recovery during the 24 h.
 464 As aforementioned, our phenotypic characterization included *Synechocystis* cell size, which
 465 was found to vary across the experimentally tested conditions. Even though the bacterial life
 466 cycle is usually the major determinant of morphological traits, including cell size, several
 467 studies reported that cyanobacteria modify their morphology to optimize their functionality to
 468 exogenous factors in natural contexts (Montgomery, 2015). However, the mechanisms by
 469 which light conditions, including light intensity, influence cell morphology, including cell
 470 size, are understudied (Pattanaik, Whitaker & Montgomery, 2011). Table 1 shows
 471 *Synechocystis* cell size changes in response to increasing light intensities. At $50 \mu\text{mol}$
 472 $\text{photons m}^{-2} \text{s}^{-1}$ the cell size was $2.11 \pm 0.06 \mu\text{m}$. This size is commonly observed in

473 *Synechocystis* cells cultivated under non-stressful conditions (Du et al., 2016). At a photon
 474 irradiance of 500 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$ *Synechocystis* cells reached the maximum size of 3.29
 475 $\pm 0.13 \mu\text{m}$ while, at the photon irradiance of 800 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$, which was found to
 476 induce photoinhibition, *Synechocystis* cell size decreased to $3.09 \pm 0.23 \mu\text{m}$ and then
 477 gradually to $2.69 \pm 0.21 \mu\text{m}$ at the maximal photoinhibitory photon irradiance of 1460 μmol
 478 $\text{photons m}^{-2} \text{s}^{-1}$. Notably, at the recovery light regime of 200 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$,
 479 *Synechocystis* cells recovered the dimension previously observed under the control photon
 480 irradiance ($3.02 \pm 0.13 \mu\text{m}$). Altogether, cell size, growth rate and PSII functionality behaved
 481 similarly under increasing intensities of orange-red light, by reaching their maximal values at
 482 intensities up to 500 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$ and rapidly decreasing at photoinhibiting light
 483 conditions.

484

485 We then examined the effect of long-term acclimation to increasing intensities of orange-red
 486 light by estimating the Chl *a* content in *Synechocystis* through the measurement of the
 487 $\text{OD}_{680}/\text{OD}_{720}$ ratio (**Table S2**). Our measurements revealed the highest content of Chl *a* at 50
 488 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$ compared to the other photon irradiances tested (**Table S2**). These data
 489 show that at limited light intensity *Synechocystis* sustains its growth by accumulating a high
 490 amount of Chl *a* to maximize light absorption. Increasing the photon irradiance to 200 μmol
 491 $\text{photons m}^{-2} \text{s}^{-1}$, the amount of Chl *a* decreased by around 13%, which reached the minimum at
 492 800 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$. Chl *a* reduction could be provoked by its synthesis inhibition in order
 493 to limit the absorption of harmfully excessive light (Kada et al., 2003; Xu et al., 2004).
 494 Unexpectedly, we observed Chl *a* increased also at 950 and 1460 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$, which
 495 were shown to induce severe cell photoinhibition (**Fig. 2**).

496

497 **Influence of local light intensity distribution on photoinhibition of microorganism**

Our multi-physics analysis focused on the spread of incident light within the *Synechocystis* cultivation apparatus and on the relationships between local light intensity and *Synechocystis* photosynthetic activity, which expectedly influence PBR productivity. The PBR used for culturing *Synechocystis*, the illumination setup and real-time monitoring are extensively described in **Fig. 1**, **Table S3**, **Table S4** and **Fig. S1**. The *in silico* simulations have been developed under identical operational conditions as employed during the experiments, and are aimed at exploring the distribution of local light intensity within the cultivation apparatus as a function of the incident light intensity.

As thoroughly described in the Methods section, current knowledge on mass transfer, fluid dynamics, heat transfer from radiation, and growth kinetics were entirely incorporated to frame the modelling equations (**Table S1**), and the resulting model was implemented within the COMSOL 5.3® computing platform. To obtain suitable estimates for the parameters necessary to our mathematical representation, we relied either on experimentally determined values or on an inference procedure by fitting model simulations to observed data. The observed agreement between model estimates and experimental measurements for growth rate and dissolved oxygen (**Figs. 2** and **3**) demonstrated that our model is built on solid foundations. Moreover, we employed the light intensities recorded in our model simulations to estimate the light-dependent photosynthetic efficiency of the PBR in terms of moles of photons absorbed in the PBR per gram of biomass production, as shown in **Table 2** and **Table S5**.

The observed agreement between model estimates and experimental measurements for growth rate and dissolved oxygen (**Figs. 2** and **3**) demonstrated that our model is built on solid foundations. Moreover, we employed the light intensities recorded in our model simulations to estimate the light-dependent photosynthetic efficiency of the PBR in terms of moles of photons absorbed in the PBR per gram of biomass production, as shown in **Table 2**.

523 These simulation results fully agree with experimental data acquired in previous studies
 524 (Schuermans et al., 2015), and corroborated the plausibility of our modelling framework. The
 525 photosynthetic efficiency of *Synechocystis* turned out to decrease from the highest value,
 526 observed at 50 $\mu\text{mol photons m}^{-2}\text{s}^{-1}$ where 2.70 g of biomass are produced per mol of
 527 photons, to the lowest value observed at 950 $\mu\text{mol photons m}^{-2}\text{s}^{-1}$ where 0.48 g of biomass
 528 are produced per mol of photons. Moreover, the estimates of photosynthetic efficiency
 529 obtained by our model simulations confirmed that efficiency starts to drop fastest in the initial
 530 increase in intensity, which is expected at low OD batch cultures. Model simulations were
 531 then used to get insights into the local light intensity distribution along different combinations
 532 of directional axes within the cultivation apparatus. To ensure comparability of the results
 533 shown throughout our analysis, we normalized the light intensity values corresponding to the
 534 PBR internal space and resulting from our model simulations with respect to the initial
 535 incident intensity on the PBR surface, and we plotted the ratio between the calculated light
 536 intensity and the initial incident intensity

$$R_I = \frac{I_{calc}}{I_{inc}}$$

537 To analyse the distribution of light along all the directions, the trends of R_I were developed
 538 by the YZ and XZ planes (**Fig. 1D** and **Fig. S2**). The light intensity distribution inside the
 539 liquid mixture on six YZ slices for three different incident light intensities, 50, 300 and 950
 540 $\mu\text{mol photons m}^{-2}\text{s}^{-1}$, shown in **Fig. 5**, confirms the ability of our modelling approach to
 541 capture a number of features of radiation spreading within a cultivation system. Boundary
 542 conditions and the coexistence of an upper gas phase and a lower liquid phase are expected to
 543 influence the light intensity distribution. Our modelling approach foresaw that the incident
 544 light gets reduced where the culture and glass of the vessel interface closest to the side where
 545 light is supplied. This reduction amounted to about 3-5%, and was more evident at lower
 546 intensities (**Fig. 5**). Moreover, in the area at the interface between the liquid and gas phases

light intensity was found to display an eyelet-like pattern where the upper region shows higher intensity than the lower one. Additionally, this pattern was more remarkable for lower values of the incident light intensity. Another source of variation in the spatial distribution of light is identifiable in the rotating domain created by the stirring bar (**Fig. S1**). The local liquid movement propelled by the stirring bar rotation is expected to favour the light transmission process (Zhang, Dechatiwongse & Hellgardt, 2015). Our model simulations consistently predicted the increase of light intensity in the stirring bar neighbourhood, which amounted to around 3-5% for low I_{inc} and around 1-2% for high I_{inc} (**Fig. 5C**).

In the interface area between the liquid phase and the bottom steel base, our model predicts a reduction in light intensity owing to the large difference between the absorption and emissivity values of these two domains. Beyond these effects, light intensity generally decreased with the distance from the light source, as shown by the plots at equally spaced slices along the YZ axis (**Fig. 5**) and further confirmed by the plots acquired at three XZ sections (**Fig. 6, Fig. S2**).

The light intensity decay along the path inside the cultivation apparatus was expected since it can be attributed to the compound effect of photon absorption by *Synechocystis* cells and of scattering phenomena (Grima et al., 1994). When varying the incident light intensity, our model simulations showed the extent of light decay to get lower at progressively higher incident light intensity. Decrease in light decay along the path amounting about 18% for I_{inc} of 50 $\mu\text{mol photons m}^{-2}\text{s}^{-1}$, 12% for I_{inc} of 300 $\mu\text{mol photons m}^{-2}\text{s}^{-1}$ and 7% for I_{inc} of 950 $\mu\text{mol photons m}^{-2}\text{s}^{-1}$ were calculated. Our modelling framework was primed to afford the exploration of the relationship between the heterogeneity in local light distribution, which originates from the aforementioned sources, and the *Synechocystis* behaviour in the artificially lit cultivation system. More precisely, we expected the light environment created

571 by the coexistence of regions of higher and lower local light intensity could favour
 572 *Synechocystis* functionalities, as gauged by the experimental measurements shown in **Fig. 2**.
 573 From our model simulation results, it was evident that at 50 $\mu\text{mol photon m}^{-2}\text{s}^{-1}$ the light
 574 penetration inside the culture was extremely low (**Fig. 5A**), suggesting that the cells were
 575 exposed to a period of lower intensity considerably longer than the expected light phase set
 576 experimentally. Under this light condition *Synechocystis* showed low growth rate, limited
 577 amount of oxygen dissolved in the medium (**Fig. 2**), and a higher Chl *a* amount than in the
 578 other tested conditions (**Table S1**), which is likely due to the need of optimizing light
 579 absorption in a scarcely lit environment. Our simulations showed that, upon increasing the
 580 irradiance to 300 $\mu\text{mol photon m}^{-2}\text{s}^{-1}$, light managed to diffuse more deeply within the PBR
 581 interior (**Fig. 5B** and **Fig 6**). The overall increased light availability and the coexistence of
 582 regions of different local light intensities created the most favourable light environment for
 583 *Synechocystis* which indeed reached its maximal growth rate and oxygen dissolved in the
 584 medium (**Fig. 2**). Conversely, the further rise of light intensity up to 950 $\mu\text{mol photons m}^{-2}\text{s}^{-1}$
 585 ¹, and the subsequent suppression of low local light intensity experienced by the cells (**Figs.**
 586 **5C** and **6**), led *Synechocystis* to suffer high light stress reflected in a noticeable decrease in its
 587 growth rate and oxygen evolution activity (**Fig. 2**). Under such light conditions, cells were no
 588 longer able to dissipate the excess of supplied light and entered a photoinhibition state
 589 (Chiang, Lee & Chen, 2011).

590

591 Discussion

592 The experiments conducted were particularly informative for studying the effects of
 593 increasing intensities, ranging between 50-1460 $\mu\text{mol photons m}^{-2}\text{s}^{-1}$, of red-orange light on
 594 the adjustments of the physiological state in *Synechocystis*. Although the PSII photodamage
 595 effect caused by the exposure to high (white) light intensity is well-established in plants

596 (Theis & Schroda, 2016), corresponding quantitative data on photoinhibition by red light in
 597 cyanobacteria are scarce. Furthermore, experimental evidence of the recovery potential in
 598 *Synechocystis* from this light stress has so far been lacking. Importantly, our results
 599 evidenced the adaptive capacity of *Synechocystis* to completely recover from the harmful
 600 condition of photoinhibition under subsequent exposure to an optimal light intensity for
 601 growth. It is already well known that under photoinhibitory conditions, loss of oxygen
 602 evolution capacity of PSII activates the PSII repair cycle and that the rate of the repair
 603 reaction depends on the extent of the PSII damaged centres (Tyystjärvi, 2013). Since the D1
 604 protein is the main target of photoinhibition and its lack within the PSII centre speeds up its
 605 synthesis, an increase of the amount of psbA transcript in *Synechocystis* occurs in high light
 606 (Mohamed et al., 1993) and this high level is maintained for several hours in darkness (He &
 607 Vermaas, 1998). Here the quick recovery of PSII activity observed at 200 $\mu\text{mol photons m}^{-2}$
 608 s^{-1} suggests that the high levels of D1 transcript maintained within the surviving cells at
 609 1460 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$ allows the acceleration of D1 synthesis to reactivate the PSII
 610 activity, once cells have been reverted to the optimal growth irradiance. An exceptional
 611 capacity to cope with fluctuations in a wide range of lights differing for spectral quality and
 612 quantity, as well as pH and temperature, was previously observed in this microorganism by
 613 (Constant et al., 2000) and (Zavřel et al., 2015). Indeed, the ability to readily adapt the
 614 metabolism to different environmental conditions allowed *Synechocystis*, and more in general
 615 cyanobacteria, to proliferate even in extreme environments on Earth (Hernández-Prieto et al.,
 616 2016).
 617 Furthermore, growth rate was found to positively correlate with cell size independently of
 618 light intensity (**Fig. 4**). This trend has been previously observed in *Synechocystis* acclimated
 619 to lower intensities of light (Du et al., 2016) and in *Synechococcus* grown under limited
 620 nutrient supply of phosphate and nitrate (Garcia, Bonachela & Martiny, 2015), and hints at a

621 light coordination of growth rate with cell size. It has been reported that cyanobacteria can
 622 respond to different abiotic stresses by increasing the cell size, accumulating granules of
 623 different nature, e.g. glycogen, upon exposure to high light intensity (Kopečna et al., 2012)
 624 and polyhydroxybutyrate in case of high temperatures (Červený et al., 2015). Even though
 625 the mechanisms that associate cellular growth rate with cell size are still unclear (Amir,
 626 2014), here we suggest that the increase of light intensity could accelerate both the
 627 metabolism and growth rate of *Synechocystis*, favouring the accumulation of higher amounts
 628 of biomass that need to be properly stored, leading the cells to increase their size (Amir,
 629 2014; Ferrezuelo et al., 2012). In general, the variation in cell size observed at incremental
 630 steps of light intensity was accompanied by the maintenance of a relatively constant dry cell
 631 weight per OD730 (Table 1), which suggests that the fluctuations observed in cell size
 632 exposed to increasing light intensities were counterbalanced by opposite fluctuations in the
 633 number of cells per volume.

634 The highest content of Chl *a* at 50 $\mu\text{mol photons m}^{-2}\text{s}^{-1}$ along with its decrease at increasing
 635 orange-red light intensities which we observed upon increasing the orange-red light intensity
 636 are expected since inhibition of Chl *a* synthesis could serve to limit the absorption of
 637 harmfully excessive light. Conversely, the Chl *a* increase observed at 950 and 1460 μmol
 638 $\text{photons m}^{-2}\text{s}^{-1}$, which were shown to induce severe cell photoinhibition (**Fig. 2**), is
 639 unexpected. This observation warrants further investigation but it is plausible to hypothesize
 640 that the observed increase in Chl *a* amount could be partially due to the accumulation of this
 641 pigment in dead cells, which likely reflects the much longer lifetime of Chl molecules with
 642 respect to that of other pigments (Steiger, Schäfer & Sandmann, 1999; Vavilin, Brune &
 643 Vermaas, 2005; Vavilin & Vermaas, 2007; Yao et al., 2011; Yao, Brune & Vermaas, 2012;
 644 Trautmann, Beyer & Al-Babili, 2013; Havaux, 2014). Finally, the recovery of pigment
 645 biosynthesis observed upon acclimation of photoinhibited cells over 24 h at 200 μmol

646 photons $\text{m}^{-2}\text{s}^{-1}$ confirmed the elevated degree of plasticity of this cyanobacterium to cope
647 with extremely high light intensities.

648 The *in silico* simulations were focused to investigate the spatial distribution of local light
649 intensity in the cultivation system on the basis of the incident light intensity and the . Our
650 model simulation allowed a careful, albeit qualitative, evaluation of the complex
651 consequences that variations in light intensity and local light distribution can cause on the
652 *Synechocystis* physiology within an artificially lit cultivation system. In particular, we were
653 able to identify three distinct operative states: i) a light limited state where all the light
654 supplied to the system is maximally exploited by the cells, a condition that is reflected in a
655 linear relation between irradiance and *Synechocystis* physiological parameters, ii) a light
656 optimal state where *Synechocystis* optimizes the utilization of light to support its maximal
657 growth rate and photosynthetic activity, iii) a photo-inhibition state where the excess of
658 incident light becomes harmful for microorganisms growth. Our model simulations suggest
659 that regulating the incident light on the PBR, at least in a range of moderate intensities, could
660 be used to enhance *Synechocystis* growth. Indeed, this model takes into account the formation
661 of areas of different local light intensity within the PBR, whose extent varies as a function of
662 the incident light intensity, and that can be exploited by the microorganism to prevent from
663 experiencing light-induced stress. According to our study, managing local light effects is
664 expected to be worth careful consideration in PBR design for leveraging the microorganism
665 exploitation.

666

667 Conclusions

668 The productivity of PBRs exploiting *Synechocystis* clearly depends on the photosynthetic
669 efficiency of this microorganism. Since this efficiency largely depends on the cyanobacteria
670 ability to manage the light collected in the cultivation apparatus, in this work we thoroughly

671 investigated the impact of the setup of the light conditions in the PBR on *Synechocystis*
 672 growth and photosynthetic activity. Monitoring *Synechocystis* physiological state under
 673 increasing intensities of orange-red light, we found that growth rate, cell size and PSII
 674 activity were influenced by light intensity, although in slightly different ways. *Synechocystis*
 675 cells proved to be resistant to high light stress conditions, showing photoinhibition only
 676 above 800 $\mu\text{mol photons m}^{-2} \text{ s}^{-1}$ combined with a remarkable ability to recover from the
 677 complete state of photoinhibition experienced at 1460 $\mu\text{mol photons m}^{-2} \text{ s}^{-1}$ when reverting
 678 light to 200 $\mu\text{mol photons m}^{-2} \text{ s}^{-1}$. Considering the notable plasticity of *Synechocystis* in
 679 response to changes in light intensity, we searched for unknown features of the PBR light
 680 conditions that could leverage *Synechocystis* behavioural features to enhance the overall PBR
 681 productivity. To this end, we deemed it particularly useful to adopt also an *in silico*
 682 methodology by constructing a PBR model and subsequently use it to simulate the effects of
 683 increasing incident light intensities on the local light intensity distribution. Interestingly, our
 684 results indicate that the formation of areas of different light intensities could be controllable
 685 by tuning the incident light intensity on the PBR. A gain in *Synechocystis* viability is
 686 achievable by increasing the incident light intensity as far as areas of different local light
 687 intensities exist to allow *Synechocystis* cells to escape from the photoinhibition state. It is
 688 useful to note that the observations herein presented are drawn from experiments and
 689 simulations carried out in turbidostat mode (constant OD_{730}) and could vary depending on the
 690 choice of the cultivation mode. Nonetheless, our results provide useful insights in a PBR
 691 modelling perspective and, in particular, suggest that a PBR design would benefit from
 692 considering the management of local light heterogeneity to increase the microorganism
 693 photosynthetic activity, by limiting photoinhibition phenomena, to ultimately maximize the
 694 productivity.

695

Conceived and designed the experiments: Pascal van Alphen, Klaas J Hellingwerf. Performed the biological experiments: Alessandro Cordara. Performed the modelling experiments: Nicolò Vasile. Analyzed the data: Pascal van Alphen, Cristina Pagliano, Klaas J Hellingwerf, Angela Re. Contributed reagents/materials/analysis tools: Pascal van Alphen, Klaas J Hellingwerf, Guido Saracco. Wrote the paper: Alessandro Cordara, Cristina Pagliano, Nicolò Vasile, Angela Re, Pascal van Alphen, Klaas J Hellingwerf. Supervised the study: Filipe Branco dos Santos, Klaas J Hellingwerf, Guido Saracco, Raffaele Pirone.

Nomenclature

707	A	area, m^2
708	c_d	mass fraction of dispersed phase, kg kg^{-1}
709	C	concentration, mol m^{-3}
710	C_p	specific heat at constant pressure, $\text{J m}^{-3} \text{K}^{-1}$
711	D	diffusion coefficients, $\text{m}^2 \text{s}^{-1}$
712	D_{md}	turbulent dispersion coefficient, $\text{m}^2 \text{s}^{-1}$
713	e	enthalpy flux density, $\text{J m}^{-2} \text{s}^{-1}$
714	E_A	activation energy, J mol^{-1}
715	F	force term, $\text{kg m}^{-2} \text{s}^{-2}$
716	G	incident light radiation, W m^{-2}
717	$h_j(T)$	enthalpies heat flux densities, $\text{J m}^{-2} \text{s}^{-1}$
718	I	incident light intensity, W m^{-2}
719	I_b	black body radiation, W m^{-2}
720	\mathbf{J}	diffusion vector
721	k	turbulent kinetic energy, $\text{m}^2 \text{s}^{-3}$
722	K_r	reaction rate constant, $\text{m}^2 \text{s}^{-1}$
723	m	mass of species, kg
724	m_{dc}	mass transfer from dispersed to continuous phase, $\text{kg m}^{-3} \text{s}^{-1}$
725	M	molar mass, kg mol^{-1}
726	n	flux density, $\text{mol m}^{-2} \text{s}^{-1}$
727	n_d	relative mass flux, $\text{mol m}^{-2} \text{s}^{-1}$
728	p	pressure, Pa
729	q	heat flux densities, W m^{-2}
730	Q	volumetric charge density, C m^{-3}
731	Q_r	radiative flux, W m^{-2}
732	R	universal gas constant, $\text{J K}^{-1} \text{mol}^{-1}$

733	T	temperature, K
734	u	velocity vector, m s^{-1}
735	u_c	continuous phase velocity vector, m s^{-1}
736	u_d	dispersed phase velocity vector, m s^{-1}
737	u_{slip}	slip velocity vector, m s^{-1}
738	v_p	the convective velocity, m s^{-1}
739	w	volume fraction
740	x	mass fraction
741		
742	<i>Greek symbols</i>	
743	β	extinction coefficient, m^{-1}
744	ε	turbulent energy dissipation, m^2s^{-3}
745	k_c	effective thermal conductivity coefficient, $\text{W m}^{-1} \text{K}^{-1}$
746	κ	absorbance coefficient, m^{-1}
747	μ	dynamic viscosity, kg f s m^{-2}
748	μ_{gr}	growth rate, h^{-1}
749	μ_T	turbulent viscosity,
750	ν	stoichiometric coefficients
751	ρ	density, Kg m^{-3}
752	σ_s	scattering coefficient, m^{-1}
753	τ	turbulent stress,
754	ϕ_c	continuous phase fraction, -
755	ϕ_d	dispersed phase fraction, -
756	ω	rotational velocity, rad s^{-1}

Figure and table legends

Figure 1: Photobioreactor schematic representation.

(A) Body of the flat panel PBR FMT150.2/400 composed of a 390 ml transparent removable flat vessel. On top of the vessel, a stainless lid accommodates different tubes, connectors and sensors. The base of the instrument contains a control unit with analogic and digital electronic circuits. Enlarged the details of the red and blue LEDs installed in the light panel of the reactor, the densitometer and the fluorometer. (B) Red and blue LED spectra of PBR FMT150.2/400.(C) Transmission spectrum of cyanobacterial culture affected by light absorptions, light scattering. The lines and arrows indicate wavelength of the light sources present in the flat panel reactor and the detection range of the detector filter. (D) 3D modelled

1039 geometry of PBR with modelled domains selection: 1-closing, 2-inoculum, 3-sparger, 4-air,
1040 5-sampling, 6-culture, 7-stirring bar, 8-wall of vessel, 9-base of vessel.

1041

1042 **Figure 2: Challenging *Synechocystis* by high light intensity revealed its adaptive**
1043 **capacity.**

1044 *Synechocystis* behaviour was assessed by quantifying the growth rate and the relative
1045 concentration of dissolved oxygen in the medium under increasing photon irradiance. The
1046 turbidostat-controlled cultures were grown at constant temperature (30°C) and pH (8.0) under
1047 orange-red light and acclimated for 24 h at each light intensity. The figure shows
1048 *Synechocystis* ability to fully recover after passing through a complete state of
1049 photoinhibition at 1460 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$. (A) Growth rate of *Synechocystis* evaluated at
1050 each light intensity. (B) Oxygen released in the medium of the PBR by *Synechocystis*. The
1051 blue dots show the mean values derived from three biological replicates and are accompanied
1052 by their respective standard deviation bars. Data were normalized to the values obtained at 50
1053 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$. The orange triangles show the simulated values according to our PBR
1054 model. In both panels (•) stands for point of recovery, which was set at 200 $\mu\text{mol photons m}^{-2}$
1055 s^{-1} , and the asterisk (*) indicates that no steady state could be reached in 24 h at this condition
1056 (as shown by the large error bars).

1057

1058 **Figure 3: Recovery of growth of *Synechocystis* after high light treatment.**

1059 *Synechocystis* quickly recovers from high light (1460 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$, left side) after
1060 reducing light intensity to a non-photoinhibiting intensity (200 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$, right
1061 side). Dissolved oxygen concentration (red line) and growth rate (black squares, calculated
1062 per turbidostat cycle) are shown. The half-life of this recovery is 3 h.

1063

1064 **Figure 4: Relationship of the cell size and growth rate of *Synechocystis* set at different**
 1065 **light intensities.**

1066 The figure displays the relationship between growth rate and cell size at varying light
 1067 intensities. Dot colours reflect the incident light intensity, with the green and red colours
 1068 corresponding to low values and high values, respectively

1069
