

Effects of low and high dose intraarticular tiludronate on synovial fluid and clinical variables in healthy horses - a preliminary investigation

To determine effects of intraarticularly administered tiludronate on articular cartilage in vivo, eight healthy horses were injected once with tiludronate (low dose tiludronate [LDT] 0.017 mg, n=4; high dose tiludronate [HDT] 50 mg, n=4) into one middle carpal joint and with saline into the contralateral joint. Arthrocentesis of both middle carpal joints was performed pre-treatment, and 10 min, 24 h, 48 h, 7 and 14 days after treatment. Synovial nucleated cell counts and total solids, tiludronate, sulfated glycosaminoglycan (sGAG), chondroitin sulfate 846 epitope (CS-846, a measure of aggrecan synthesis), and collagen type II cleavage neoepitope (C2C) concentrations were determined. Histologic analysis of joint tissues and sGAG quantitation in cartilage was performed at 14 days in HDT horses. Data were analyzed by repeated measures non-parametric ANOVA and Wilcoxon signed-rank test. High dose tiludronate administration produced synovial fluid tiludronate concentrations of 2,677,500 ng/mL, exceeding concentrations that were safe for cartilage in vitro, and LDT administration produced synovial fluid concentrations of 1,353 ng/mL, remaining below concentrations considered potentially detrimental to cartilage. With HDT, synovial fluid total solids concentration was higher at 24 h and 7 days and sGAG concentration was higher at 48 h, compared to control joints. Synovial fluid CS-846 concentration was increased over pre-treatment values in HDT control but not in HDT treated joints at 24 and 48 h. All joints (HDT and LDT control and treated) showed a temporary decrease in synovial fluid C2C concentration, compared to pre-treatment values. Histologic features of articular cartilage and synovial membrane did not differ between HDT treated and control joints. High dose tiludronate treatment caused a transient increase in synovial total solids and temporarily

increased proteoglycan degradation in cartilage. Although clinical significance of these changes are questionable, as they did not result in articular cartilage damage, further investigation of the safety of intraarticular HDT in a larger number of horses is warranted.

14 Introduction

15 Tiludronate, a non-nitrogen containing bisphosphonate, slows bone turnover by causing
16 apoptosis in osteoclasts (Rogers et al., 2011). This effect may be useful to treat conditions
17 associated with an increase in bone turnover, such as navicular disease or osteoarthritis. In fact,
18 some horses with navicular disease (Denoix, Thibaud & Riccio, 2003), osteoarthritis of the distal
19 tarsal joints (Gough, Thibaud & Smith, 2010) or the thoracolumbar facet joints (Coudry et al.,
20 2007) exhibited decreased signs of pain associated with their condition after systemic tiludronate
21 treatment. In humans, atypical subtrochanteric and femoral shaft fractures have been reported
22 after years of treatment (Nieves & Cosman, 2010). In horses, only anecdotal reports of side
23 effects are available to date, which have included colic, tachycardia, electrolyte imbalances, and
24 presumed association with renal failure. Concerns regarding side effects and the high cost of
25 systemic treatment constitute possible reasons why veterinarians have begun to administer
26 tiludronate locally via intraarticular injection or regional limb perfusion. However, no
27 information is available concerning safety, efficacy, or appropriate doses of these routes of
28 administration. Based on in-vitro results (Duesterdieck-Zellmer, Driscoll & Ott, 2012), the extra-
29 label use of tiludronate via intraarticular injection or regional limb perfusion, especially in high
30 doses, may result in deleterious effects for articular cartilage. While it is common belief among
31 veterinarians who have been using this drug in an extra-label fashion, that no untoward effects
32 exist, this view is scientifically unfounded. Further, lameness after treatment is likely being
33 attributed to the cause for the original lameness problem and not to negative effects of
34 tiludronate. Thus, it is imperative to investigate possible deleterious effects of extra-label routes
35 of administration for tiludronate in horses.

36 Little is known about tiludronate's effects on joint tissues after intraarticular
37 administration. Concentration-dependent effects of tiludronate on articular cartilage in-vitro

(Duesterdieck-Zellmer, Driscoll & Ott, 2012) raise concerns about the safety of higher doses administered intraarticularly. More specifically, tiludronate concentrations of $\geq 19,000$ ng/mL increased chondrocyte apoptosis and release of glycosaminoglycans from equine articular cartilage explants, suggesting that doses resulting in synovial fluid concentrations of $\geq 19,000$ ng/mL may promote articular cartilage damage (Duesterdieck-Zellmer, Driscoll & Ott, 2012). Anecdotally, the intraarticular dose of tiludronate is 50 mg per joint, which is likely to result in synovial fluid concentrations above 19,000 ng/mL when injected into the middle carpal joint, based on an estimated synovial fluid volume of 15 mL for this joint (Ekman et al., 1981). This dose was chosen as the high dose in this study, whereas the low dose (0.017 mg of tiludronate per joint) was chosen to result in synovial fluid concentrations of about 1,900 ng/mL. The objective of this study was to determine effects of low dose tiludronate (LDT) and high dose tiludronate (HDT) administered intraarticularly to healthy horses. We hypothesized that a single intraarticular injection of HDT, but not of LDT would have a negative impact on clinical, clinicopathologic, and biochemical indicators of joint health, compared to observations in contralateral control joints injected with the same volume of saline. We further hypothesized that these negative effects would result in histologically detectable articular cartilage damage in joints administered HDT.

Materials and methods

Animals

After approval from the Institutional Animal Care and Use Committee, four horses (age 12-15 years, two Thoroughbreds, one Warmblood, one Quarter Horse) were enrolled to receive LDT (ACUP 4034, approved 6/29/10) and a year later, four different horses (age 2-18 years, Quarter Horses) were enrolled to receive HDT. All horses were without front limb lameness and

61 radiographic abnormalities of their carpal joints. They were housed in box stalls and offered free
62 choice grass hay and water during experiments.

63 Study Design

64 Baseline lameness examinations were conducted, followed by sedation with detomidine
65 (Dormosedan, Pfizer) and butorphanol (Torbugesic, Fort Dodge; both 0.01 mg/kg IV) for
66 arthrocentesis of both middle carpal joints (performed by KDZ and LM). After withdrawing up to
67 2 mL joint fluid (used to determine all synovial fluid variables as described below), 0.017 mg
68 tiludronate (Tildren, Ceva) in 1 mL saline was injected into one randomly assigned middle carpal
69 joint of four horses, and 1 mL saline was injected into the contralateral middle carpal joint (year
70 one, LDT). The other four horses (year two, HDT) were treated similarly, using an intraarticular
71 dose of tiludronate of 50 mg in 6 mL saline as treatment and 6 mL saline as control.
72 Randomization was performed via coin toss for each horse and investigators were blinded to
73 treatment allocation by an assistant removing the label from the syringes before injection. Both
74 joints were flexed and extended manually 15 times after injection. Aspiration of 0.5 mL joint
75 fluid (used purely for determination of tiludronate concentrations) was performed after 10 min on
76 both middle carpal joints. This resulted in removal of an estimated reduction of the effective
77 intraarticular dose of tiludronate by 3% for LDT and 2.5% for HDT based on a presumed
78 synovial fluid volume of 15 mL in the middle carpal joints (Ekman et al., 1981) and the
79 assumption that none of the saline used as diluent for tiludronate had been absorbed from the
80 joint space by 10 min post treatment. Repeat arthrocenteses of up to 3 mL joint fluid were
81 performed after 24 and 48 h, 7 and 14 days (used for determination of all synovial fluid variables
82 as described below). All horses treated with HDT were euthanatized on day 14 (Beuthanasia,
83 Merck; 1 mL/4.54 kg IV) and articular cartilage from the radial facet of both third carpal bones

84 and adjacent synovial membrane were collected. Investigators were blinded to treatment
85 allocations for all sample analyses.

86 Clinical variables

87 Horses underwent daily physical and lameness examinations (performed by KDZ and
88 LM), including palpation of both carpi for pain, effusion (none, mild, moderate, severe) and
89 development of edema, measurement of joint circumference of the middle carpal joints at the
90 level of a clipped mark on the lateral aspect of each middle carpal joint, and measurement of the
91 angle of maximum flexion of both carpi (Baseline Plastic Goniometer, Fabrication Enterprises).
92 For the latter, the angle present on the caudal/palmar aspect of the limb was measured. Thus, an
93 increase in angle of maximum flexion would indicate decreased range of motion of the carpal
94 joints. Horses were observed walking and trotting in a straight line, and trotting after flexion of
95 both carpi for 1 min. Lameness was categorized as sound, intermittently lame at the walk or trot,
96 consistently lame at the trot, or consistently lame at the walk. Responses to carpal flexion tests
97 were graded as positive when obvious lameness persisted for more than four strides (Ross, 2011).

98 Synovial fluid analyses

99 Synovial fluid samples were divided into 0.3 ml aliquots, of which one was placed in
100 EDTA containing tubes (Monoject, Covidien) for cytologic analysis. This aliquot was stored at 4
101 °C until cytologic analysis within 12 h of sample collection. All other aliquots were stored at -80
102 °C until sample analyses within 6 months of collection. All samples from year one (LDT) were
103 analyzed as one batch, and all samples from year two (HDT) were analyzed as one separate
104 batch.

105 Total solids concentration was measured via refractometry (E-line Veterinary,
106 Bellingham+Stanley). Total nucleated cell count was determined manually (Leuko-Tic,
107 Bioanalytic). Differential cell counts were obtained manually on Wright's-Giemsa stained
108 cytocentrifuge-prepared slides (CytoSpin* 4 Cytocentrifuge, Thermo Scientific).

109 Synovial fluid sulfated glycosaminoglycan (sGAG) concentration was determined
110 employing the 1,9-dimethylmethylene blue (DMMB) assay as described (Oke et al., 2003), with
111 some modifications. Briefly, samples were added to equal volumes of papain digestion buffer (2
112 mg/mL papain) and mixed at 65 °C for 3 h, followed by an additional 1:3 (v:v) dilution in papain
113 digestion buffer. Each sample was placed in triplicates into wells (5 µL/well) of a 96 well plate
114 (nunc Optical Bottom Plate non-treated, Thermo Scientific). Immediately before measurement of
115 absorbance at 540 nm, 245 µL of DMMB working solution (0.016 mg/mL DMMB) was added to
116 each appropriate well using a multichannel pipette. Sample concentrations were calculated from a
117 standard curve of chondroitin-6-sulfate (31.25-500 µg/mL; Chondroitin 6-sulfate from shark
118 cartilage, Sigma Aldrich).

119 Aggrecan synthesis in articular cartilage was estimated by quantitating chondroitin sulfate
120 846 epitope (CS-846) in synovial fluid by ELISA (IBEX Technologies), according to
121 manufacturer's instructions. Briefly, synovial fluid samples were centrifuged (16,000 x g for 2
122 min) and diluted 1:60 in Buffer III (provided by the manufacturer) and run in duplicates. A color
123 change was measured at 450nm (Multiskan Go, Thermo Scientific) and sample concentrations
124 were calculated from a standard curve of 20-1000 ng/mL CS-846.

Collagen type II degradation was estimated by quantitating collagen type II cleavage neoepitope (C2C) in synovial fluid via ELISA (IBEX Technologies) according to manufacturer's instructions. Briefly, synovial fluid samples were centrifuged (16,000 x g for 2 min) and diluted 1:2 in Buffer III (provided by the manufacturer) were run in duplicates. A color change was measured at 450nm (Multiskan Go, Thermo Scientific). Sample concentrations were calculated from a standard curve of 10-1000 ng/mL C2C.

Tiludronate concentration was determined by high performance liquid chromatography (XBridge phenyl column, Waters) followed by mass spectrometry (Tarcomnicu et al., 2009; Zhu et al., 2006). Tiludronate was methylated using 0.2 M trimethylsilyldiazomethane in acetone. Sample concentrations were calculated from a standard curve of 0.5 – 64 ng/mL tiludronate. Samples with tiludronate concentrations above the range of the standard curve were serial diluted to fall within that range. Positive and negative control samples were run with each batch of samples and deuterated tiludronate (Toronto Research Chemicals) was used as internal control in each sample. The lower level of detection for this assay was 10 ng/mL.

Joint tissue analyses (n=4, HDT)

Cartilage samples from the radial facet of both 3rd carpal bones were digested with papain (1 mL papain digestion buffer as described above per 10 mg cartilage wet weight) for ≥ 24 h until no particulate matter was visible in the sample. Subsequently, sGAG content was determined via DMMB assay as described above.

Histologic analysis on paraffin embedded sections of cartilage and synovial membrane was performed by a board-certified veterinary pathologist (CVL) who was unaware of treatment allocations. Hematoxylin and eosin stained cartilage sections were graded on a scale of 0-4 for

chondrocyte necrosis, chondrocyte clusters, cartilage fibrillation or fissures, and focal cell loss (McIlwraith et al., 2010). Cartilage sections stained with toluidine blue (for proteoglycans) were graded on a scale of 0-4 for loss of staining (McIlwraith et al., 2010). Hematoxylin and eosin stained synovial membrane sections were graded on a scale of 0-4 for cellular infiltration with lymphocytes and plasma cells, and intimal hyperplasia (McIlwraith et al., 2010). Scores were recorded for three independent readings and the median score was determined.

Chondrocyte apoptosis was assessed on cartilage sections using the terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) method (In Situ Cell Death Detection Kit, AP, Roche) as described previously (Duesterdieck-Zellmer, Driscoll & Ott, 2012).

Data Analysis

Data were expressed as median and total range, other than tiludronate concentrations, which were expressed as mean and standard error of the mean. To assess possible negative effects of intraarticular administration of LDT or HDT on normal joints, differences between treated and control joints within the same horse were determined using a two factor factorial model (dose of tiludronate and treatment with saline or tiludronate) with repeated measures via non-parametric ANOVA. To assess effects of LDT or HDT on normal joints over time, differences between measurements prior to experimental treatment (baseline) and time points after experimental treatment within the same joints (LDT control joints, LDT treated joints, HDT control joints, or HDT treated joints) were determined. Comparisons between joints treated with HDT and joints treated with LDT were not performed, as experiments were conducted in two different years and samples were analyzed in different batches. Further, this comparison is of lower importance, as the study did not aim at determining which dose was safer than the other. For variables in which the main effect of time was not significant, median values for each treatment group (LDT control

joints, LDT treated joints, HDT control joints, HDT treated joints) were calculated by pooling all time points. For those variables in which time significantly influenced the outcome, medians were calculated for each time point separately. Data from post-mortem analyses in horses treated with HDT was analyzed using the Wilcoxon signed-rank test. Statistical significance was set at $P=0.05$.

A power analysis performed prior to the experiments estimated an 80% chance of detecting a difference of 30% between treated and control joints within the same horse with a sample size of $n=4$ and $P<0.05$.

Results

All physical examination variables remained within normal limits in all horses. No pain or edema was evident upon palpation of any carpi, and no lameness or positive response to carpal flexion was noted after tiludronate administration at any time. Mild to moderate effusion of the middle carpal joints was common 1-3 days and 8 days after intraarticular injection of saline, LDT and HDT (Table 1). Joints treated with HDT showed a greater degree of effusion than their saline controls 1 day ($P=0.0162$), 3 days ($P=0.0349$), and 8 days ($P=0.0349$) after intraarticular injection. In contrast, in the LDT group, joints treated with saline showed a greater degree of effusion on day eight ($P=0.0349$) than joints treated with LDT. When comparing joint effusion within experimental groups to baseline observations, HDT control joints showed increased effusion 2 days after injection of saline ($P=0.0008$), whereas HDT treated joints showed increased effusion 2 days ($P=0.0264$), 3 days ($P=0.0264$) and 8 days ($P=0.0264$) after treatment. LDT control joints, showed increased joint effusion 1 day ($P=0.0264$), 2 days ($P<0.0001$) and 8 days ($P=0.0008$) after intraarticular injections, whereas LDT treated joints showed increased joint effusion 1 day ($P=0.0264$) and 2 days ($P<0.0001$) after treatment.

Joint circumference did not differ over time ($P=0.7326$) nor between treated and control joints ($P=0.3735$) in horses treated with HDT (28.3 [3.8] cm vs. 28.4 [2.7] cm – median and range pooled over time) or LDT (29.0 [5.9] cm vs. 28.8 [6.5] cm – median and range pooled over time).

Joint angle of maximum flexion was smaller in limbs treated with HDT than controls 10 ($P=0.0135$) and 13 days ($P=0.0219$) after treatment. There was no difference between treated and control joints in horses treated with LDT (all $P>0.3266$) at any time. Joint angle of maximum flexion was decreased at multiple time points compared to baseline measurements in HDT treated, HDT control, LDT treated, and LDT control joints (Table 2). All differences were $<10^\circ$, and are unlikely to be clinically significant (Liljebrink & Bergh, 2010).

Synovial fluid concentrations of tiludronate are illustrated in Fig. 1. Tiludronate was detectable in all joints treated with HDT throughout the study, whereas in joints treated with LDT, tiludronate was not detectable after 24 h. Tiludronate was detectable in two HDT control joints 24 h after treatment, albeit below the lower margin of quantitation for the assay. Tiludronate was not detectable in any other samples from control joints or in any baseline samples.

Synovial total nucleated cell count did not differ between treated and control joints in horses treated with HDT or LDT ($P=0.1165$). Total nucleated cell counts exceeded the reference interval of 0-500 cells/ μ L (Mahaffey, 2002) in three HDT treated joints, including one heavily blood contaminated sample, and in one HDT control joint 7 days after treatment. All other values remained within that reference range. When compared to total nucleated cell counts prior to intraarticular injection, cell counts were increased 24 h, 7 days and 14 days (all $P<0.0001$) after

215 treatment in HDT treated joints and 24 h, 48 h, 7 days and 14 days (all $P < 0.0042$) after treatment
 216 in HDT control joints. Total nucleated cell counts in samples from joints treated with LDT
 217 decreased 7 days after treatment compared to baseline values ($P = 0.0124$), and no change over
 218 time was found for LDT control joints (all $P > 0.7$).

219 The percentage of neutrophils among nucleated cells in synovial fluid samples remained
 220 within the reference interval of $\leq 10\%$ (Mahaffey, 2002) in the majority of samples (79%). The
 221 remaining samples had 12-68% neutrophils, which was considered to be within normal limits due
 222 to the very low total nucleated cell counts in these samples (Mahaffey, 2002). The percentage of
 223 neutrophils among nucleated cells in synovial fluid samples did not differ over time ($P = 0.0871$)
 224 nor between treated and control joints ($P = 0.3386$) in horses treated with HDT (4.5 [68] % vs. 5.5
 225 [55] % – median and range pooled over time) or LDT (2 [20] % vs. 5 [25] % – median and range
 226 pooled over time).

227 Total solids concentration in synovial fluid (Fig. 2) was higher in HDT treated joints than
 228 HDT control joints but there was no difference between LDT treated and LDT control joints.
 229 Compared to baseline values, total solids increased in HDT treated and HDT control joints for the
 230 first 2 days. In LDT treated joints, total solids concentration was decreased at the end of the
 231 study, compared to baseline values and there was no difference compared to baseline in LDT
 232 control joints.

233 Synovial fluid sGAG concentration (Fig. 3) was greater in HDT treated than HDT control
 234 joints on day 2 of the study, but there was no difference between LDT treated and LDT control
 235 joints. Compared to baseline values, sGAG concentration tended to increase ($P = 0.0513$) and then
 236 decreased over time in HDT treated joints, whereas no increase compared to baseline was seen in

the HDT control joints, and instead, values decreased compared to baseline. In LDT treated or control joints, sGAG concentration did not change compared to baseline.

Synovial fluid CS-846 concentration (Fig. 4) was lower in HDT treated joints compared to HDT control joints, whereas there were no differences between LDT treated and LDT control joints. In HDT control joints, synovial fluid CS-846 concentration increased and then returned to not different from baseline levels again and this was not seen in HDT treated joints, as there was no change compared to baseline. In LDT treated and LDT control joints, no change in synovial fluid CS-846 concentration compared to baseline was found.

Synovial fluid C2C concentration (Fig. 5) was lower in HDT treated than control joints, as well as in LDT treated compared to LDT control joints. All joints, HDT treated and HDT control joints as well as LDT treated and LDT control joints showed a temporary decrease in C2C concentration, compared to baseline values.

No significant difference was found between joints treated with HDT and control joints for sGAG content of articular cartilage (308.0 [15.9] $\mu\text{g}/\text{mg}$ vs. 308.6 [46.8] $\mu\text{g}/\text{mg}$ respectively; $P=1.0$) or % of apoptotic chondrocytes (2.2 [1.2] % vs. 1.7 [0.6] %; $P=0.5637$). Histologic scores for joint tissues were not different between joints treated with HDT and control joints (Table 3).

Discussion

The target tissue for tiludronate has traditionally been bone (EMEA, 2001), but tiludronate also exerts direct effects on cartilage and chondrocytes (Duesterdieck-Zellmer, Driscoll & Ott, 2012; Emonds-Alt, Breliere & Roncucci, 1985), especially after extra-label local administration via regional limb perfusion or intraarticular injection, since these routes of

administration potentially result in high synovial fluid concentrations. In-vitro data suggests that synovial fluid tiludronate concentrations of 19,000 ng/mL and above promote chondrocyte apoptosis and release of sGAGs from articular cartilage matrix, whereas concentrations of 1,900 ng/mL and below may ameliorate sGAG release and chondrocyte apoptosis in equine joints (Duesterdieck-Zellmer, Driscoll & Ott, 2012). Subsequently, the dose for the LDT group was chosen to produce synovial fluid tiludronate concentrations approximating 1,900 ng/mL. The dose for HDT was selected based on anecdotal reports of clinical use and was suspected to generate synovial fluid tiludronate concentrations exceeding those considered safe for articular cartilage. As suspected, HDT resulted in synovial fluid concentrations much higher than 1,900 ng/mL for at least 48 h after intraarticular injection. This was accompanied by increased synovial fluid sGAG concentration, resulting either from increased degradation and/or increased turnover of sGAGs in articular cartilage (de Grauw, van de Lest & van Weeren, 2009), which would be associated with an increased sGAG synthesis. To estimate synthesis of sGAGs, synovial CS-846 concentrations were determined, as this epitope has been used as a biomarker for aggrecan synthesis (McIlwraith, 2005; Poole et al., 1994; Rizkalla et al., 1992). Aggrecan synthesis appeared to remain unchanged in joints treated with HDT compared to measurements prior to treatment. Thus, increased synovial sGAG concentrations in joints treated with HDT in the present study were most likely associated with cartilage matrix degradation and not with an increased turnover of sGAGs. Increased concentration of sGAG in synovial fluid has also been reported due to repeated arthrocentesis in horses (van den Boom et al., 2005). However, it is unlikely that the increase in sGAG concentration 48 h after intraarticular injection of HDT was caused by repeated arthrocenteses, as sGAG concentration in contralateral control joints that had undergone the same repeat arthrocentesis protocol as the treated joints were significantly lower than in tiludronate treated joints. Further, repeat arthrocentesis caused a more modest increase in synovial fluid sGAG concentration of about 20 µg/mL (van den Boom et al., 2005) compared to

what was found after HDT in this study (increase in synovial fluid concentration of about 200 $\mu\text{g/mL}$). Nevertheless, sGAG content in articular cartilage was not found to be different between joints treated with HDT and control joints 14 days after treatment, though this may reflect the small number of horses investigated. A power analysis performed prior to the experiments estimated an 80% chance of detecting a difference of 30% between treated and control joints within the same horse with a sample size of $n=4$ and $P<0.05$. Another explanation for the lack of difference in sGAG content between HDT treated and control joints may be that tiludronate concentration in HDT treated joints remained within a range that has been shown to decrease sGAG release from articular cartilage matrix in vitro (Duesterdieck-Zellmer, Driscoll & Ott, 2012) for at least the last seven days of the study. This may have allowed for increased retention of sGAGs, thus ameliorating earlier sGAG losses.

Similar to what was observed in HDT control joints in this study, aggrecan synthesis, measured as CS-846 concentration in synovial fluid, has been reported to increase with repeated arthrocentesis after 24 and 48 h in horses (Lamprecht & Williams, 2012). This increase was ameliorated in joints injected with HDT in our study, suggesting that high synovial fluid concentrations of tiludronate may prevent chondrocytes anabolic response to mild insults such as repeated arthrocenteses. Exercise has also been shown to increase aggrecan synthesis by chondrocytes (Lamprecht & Williams, 2012), but it is impossible to state if intraarticular injection of HDT would ameliorate this response in a similar fashion.

Another major protein of articular cartilage matrix is collagen type II (Vachon et al., 1990), and it is accepted that collagen type II degradation in cartilage is irreversible (Catterall et al., 2010; Jubb & Fell, 1980). The impact of repeat arthrocenteses on synovial fluid C2C concentration appears to be variable over time in young horses (Lucia et al., 2013). After multiple

arthrocenteses over a time period of 12 h, synovial fluid C2C concentration was increased at 24 h, decreased at 7 days and unchanged at 14 days compared to baseline values. In the present study, no increase in C2C was observed in LDT or HDT treated or control joints. Similarly to what was reported in young horses (Lucia et al., 2013), a decrease in C2C was seen in all experimental groups between 24 h and 14 days after treatment. Thus, changes in type II collagen cleavage are likely attributable to the effect of repeat arthrocenteses, as opposed to tiludronate treatment, although these results should be viewed in light of the small sample number used in this study.

Synovial fluid total solids concentration increased at 24 and 48 h in both treated and control joints of HDT horses. While this was likely due to effects from repeated arthrocenteses (Francoz, Desrochers & Latouche, 2007; Jacobsen, Thomsen & Nanni, 2006) and saline injections (Wagner, McIlwraith & Martin, 1982) for the control joints, total solids concentration increased to a much greater extent in HDT treated joints than in control joints. Thus, intraarticular administration of HDT was associated with a significant increase in synovial fluid total solids concentration, most likely due to increased synovial total protein concentration. Increased synovial protein concentration in HDT treated joints was attributed to be most likely caused by synovial inflammation, as these joints were also palpable effused 24 and 48 h after treatment, and in clinical cases, this observation is usually associated with a synovial inflammatory response (Mahaffey, 2002). However, as synovial fluid prostaglandin E₂ concentration was not determined in this study, we are unable to prove this assumption. It is unlikely that the high tiludronate concentration in samples from HDT treated joints increased the total solids readings on the refractometer, as spiking of blank synovial fluid samples with similar concentrations of tiludronate did not change total solids readings (data not shown). Finally, while an increase in sGAG concentration can affect total solids readings on the refractometer (data not shown), the

330 increased total solids concentration 24 h after HDT treatment cannot be explained with this
331 phenomenon, as sGAG concentratin was not elevated at that time point.

332 An unexpected finding was a significant elevation of the total nucleated cell count in both,
333 HDT treated and HDT control joints 7 days after treatment. This is unlikely to be due to repeat
334 arthrocenteses, as no arthrocenteses had been performed for the previous 5 days and elevation of
335 nucleated cell counts in synovial fluid due to repeat arthrocenteses have been reported to occur
336 within 24 – 48 h after initial arthrocentesis in horses (White et al., 1989) and calves (Francoz,
337 Desrochers & Latouche, 2007) and it has been suggested that joints can adapt to repeated
338 arthrocenteses over time, resulting in fewer alterations of total protein concentration and
339 nucleated cell counts after 24 h (Francoz, Desrochers & Latouche, 2007; White et al., 1989).
340 Further, there was no increase in total nucleated cell count 7 days after treatment in horses treated
341 with LDT. Thus, the cause for this increase in total nucleated cell count is unclear.

342 Although LDT resulted in synovial tiludronate concentrations that remained within a
343 range shown to be safe and beneficial for articular cartilage in vitro, these concentrations were
344 maintained only for 24 to 48 h, which may not be sustained enough to provide lasting beneficial
345 effects. However, it is possible that this dose is sufficient to affect subchondral bone remodeling
346 in treated joints if tiludronate diffuses through hyaline and calcified cartilage into adjacent
347 subchondral bone, although it is unknown whether or not this occurs. Investigations to determine
348 tiludronate content in subchondral bone after intraarticular administration are necessary to answer
349 this question.

350 Interestingly, tiludronate was detectable in two control joints of horses treated with HDT,
351 although concentrations were below the linear part of the standard curve for the tiludronate assay.

This finding is most likely explained by absorption of tiludronate from synovial fluid by synovial capillaries, followed by redistribution into peripheral tissues, including distant joints. In support of this, radioactivity from technetium 99 medronate, a radioactively labeled bisphosphonate, was detectable in peripheral plasma within 5 min after intraarticular injection, peaked at about 45 min, and was still detectable 24 h post intraarticular injection (Dulin et al., 2012). Alternatively, contamination of the two samples from HDT control joints may have occurred during sample processing.

The first hypothesis, that a single intraarticular injection of HDT, but not of LDT would have a negative impact on variables of joint health, compared to contralateral control joints was statistically confirmed in this preliminary investigation. However, the observed changes are of questionable clinical significance and further investigation with a greater number of horses is warranted. The second hypothesis that intraarticular injection of HDT would result in histologically detectable articular cartilage damage was rejected, but the low power of this preliminary study has to be taken into consideration when interpreting this result.

Conclusions

This study suggests that intraarticular administration of a high dose of tiludronate (50 mg) may result in temporary elevation of synovial fluid total solids and sGAG concentration. Further, this dose may prevent chondrocytes' short-term anabolic response to mild insults such as repeated arthrocenteses. However, a high dose of tiludronate did not appear to negatively affect cartilage or synovial membrane as assessed via histologic analysis 2 weeks after treatment. Thus, the clinical significance of these findings remains questionable and further study of possible negative

effects of a high dose of tiludronate administered intraarticularly in a larger number of horses is warranted.

Intraarticular administration of a low dose of tiludronate (0.017 mg) did not appear to impact assessed variables of joint health, although this finding has to be interpreted with caution, due to the small number of horses investigated.

4^aHistology was scored on a scale of 0-4, with 0 representing normal histology (McIlwraith et
5al., 2010).

Figure 1

Graph of synovial fluid tiludronate concentration over time.

Fig. 1: Semi-log bar graph of mean synovial fluid tiludronate concentration over time.

Tiludronate was injected at a dose of 0.017 mg in 1 ml saline (A) or at a dose of 50 mg in 6 ml saline (B) into normal middle carpal joints of 4 horses, respectively. The contralateral joints were injected with an equal volume of saline to serve as control joints. Tiludronate concentration was determined using HPLC followed by mass spectrometry. Error bars show +95% confidence interval of measurements from 4 horses.

Figure 2

Box-and-whisker plot of synovial fluid total solids concentration over time.

Fig. 2: Box-and-whisker plot of synovial fluid total solids concentration over time. Tiludronate was injected at a dose of 0.017 mg in 1 ml saline (A) or at a dose of 50 mg in 6 ml saline (B) into normal middle carpal joints of 4 horses, respectively. The contralateral joints were injected with an equal volume of saline to serve as control joints. Total solids concentration was determined via refractometry. The dotted horizontal line represents the upper limit of the normal reference interval (Davidson and Orsini, 2007). Whiskers represent the minimum and maximum values. Asterisks indicate significant difference compared to pre-treatment measurements in the same joints (* $P < 0.05$). The superscript “a” indicates significant difference between treated and control joints ($P < 0.05$).
