A recent interpretation of the fossil remains of the enigmatic, large predatory dinosaur *Spinosaurus aegyptiacus* Stromer 1915 proposed that it was specially adapted for a semi-aquatic mode of life – a first for any predatory dinosaur. To test some aspects of this suggestion, a three-dimensional, digital model of the animal that incorporates regional density variations, lungs and air sacs was generated, and the flotation potential of the model was investigated using specially written software. It was found that *Spinosaurus* would have been able to float with its head clear of the water surface, although it was laterally unstable and would tend to roll onto its side. Similarly detailed models of another spinosaurid *Baryonyx* (*Suchomimus*) *tenerensis* Sereno et al. 1998, along with models of the more distantly related *Tyrannosaurus rex* Osborn 1905, *Allosaurus fragilis* Marsh 1877, *Struthiomimus altus* Lambe 1902 and *Coelophysis bauri* Cope 1887 were also able to float in positions that enabled the animals to breathe freely, showing that there is nothing exceptional about a floating *Spinosaurus*. Validation of the modelling methods was done with floated models of an alligator and an emperor penguin. The software also showed that the centre of mass of *Spinosaurus* was much closer to the hips than previously estimated, similar to that observed in other theropods, implying that this dinosaur would still have been a competent walker on land. With its pneumatized skeleton and a system of air sacs (modelled after birds), the *Spinosaurus* model was found to be unsinkable, even with its lungs deflated by 75%, and this would greatly hinder a semi-aquatic, pursuit predator. The conclusion is that *Spinosaurus* may have been specialized for a shoreline or shallow water mode of life, but would still have been a competent terrestrial animal.

14

15 ABSTRACT

16 A recent interpretation of the fossil remains of the enigmatic, large predatory dinosaur

17 *Spinosaurus aegyptiacus* Stromer 1915 proposed that it was specially adapted for a semi-

18 aquatic mode of life – a first for any predatory dinosaur. To test some aspects of this

19 suggestion, a three-dimensional, digital model of the animal that incorporates regional density

20 variations, lungs and air sacs was generated, and the flotation potential of the model was

21 investigated using specially written software. It was found that *Spinosaurus* would have been

22 able to float with its head clear of the water surface, although it was laterally unstable and

23 would tend to roll onto its side. Similarly detailed models of another spinosaurid *Baryonyx*

24 (*Suchomimus*) *tenerensis* Sereno et al. 1998, along with models of the more distantly related

25 *Tyrannosaurus rex* Osborn 1905, *Allosaurus fragilis* Marsh 1877, *Struthiomimus altus* Lambe

26 1902 and *Coelophysis bauri* Cope 1887 were also able to float in positions that enabled the

27 animals to breathe freely, showing that there is nothing exceptional about a floating

28 *Spinosaurus*. The software also showed that the centre of mass of *Spinosaurus* was much closer

29 to the hips than previously estimated, similar to that observed in other theropods, implying

30 that this dinosaur would still have been a competent walker on land. With its pneumatized

31 skeleton and a system of air sacs (modelled after birds), the *Spinosaurus* model was found to be

32 unsinkable, even with its lungs deflated by 75%, and this would greatly hinder a semi-aquatic,

33 pursuit predator. The conclusion is that *Spinosaurus* may have been specialized for a shoreline

34 or shallow water mode of life, but would still have been a competent terrestrial animal.

35 INTRODUCTION

36 At the time of their initial discoveries in the 19th century, there were conflicting views
37 about the preferred habitats of dinosaurs. The very largest ones, the sauropods, were claimed
38 by some authors to be capable of a fully terrestrial mode of life (eg. Mantell, 1850; Phillips,
39 1871), while others argued for an aquatic one (eg. Owen, 1875; Hatcher, 1901). The relatively
40 smaller hadrosaurs, while still impressively big when compared to most modern terrestrial
41 herbivores, were typically thought to be mainly aquatic. A series of anatomical features that
42 were interpreted to be adaptations for an amphibious life were regularly listed for these
43 animals (eg. Leidy, 1858; Cope, 1883) – webbed hands, deep tails for sculling, *etc.* In contrast,
44 theropods of all sizes were interpreted as fully terrestrial animals that could not swim. In fact,
45 the aquatic adaptations of hadrosaurs were frequently interpreted as a way to escape
46 predatory theropods by having the former dash to safety in the water, while the latter were left
47 frustrated and hungry on land (eg. Jackson, 1972). However, as early as the 1950s it was argued
48 that it was not physically realistic to interpret some dinosaurs as being aquatic, eg. sauropods
49 (Kermack, 1951). Beginning in the 1960s and 1970s with Ostrom’s (1964) re-interpretation of
50 hadrosaurs as fully terrestrial animals, and Bakker’s (1971) arguing for terrestrial sauropods, the
51 interpretation of all dinosaurs as fully terrestrial animals was starting to take hold. During the
52 past 47 years, as our knowledge of dinosaurs has increased exponentially (Wang & Dodson,
53 2006), this “terrestrialization” of dinosaurs has seemed unshakeable.

54 The idea that spinosaurids might have been piscivorous appears to have begun with
55 Taquet (1984). Since then there have been suggestions that *Spinosaurus* and its close relatives

56 might have had a strong association with aquatic environments. Charig and Milner (1987)
57 accepted the idea of the new english spinosaurid *Baryonyx walkeri* as a fish eater, but preferred
58 to keep the animal on shore. Amiot et al. (2010), based on analyses of oxygen isotope ratios
59 ($\delta^{18}\text{O}_p$) from biogenic apatites from a wide range of spinosaurid remains, proposed that
60 spinosaurids spent extended periods in freshwater. They also suggested that they may have fed
61 on both terrestrial and aquatic prey. Despite these suggestions, they did include the following
62 statement in their paper “However, their [spinosaurid] postcranial anatomy differs relatively
63 little from that of usual, large bipedal theropods, and is not particularly suggestive of aquatic
64 habits.” (Amiot et al., 2010, p. 139).

65 Based on a skeletal reconstruction derived from one partial, associated skeleton and
66 several isolated, partial specimens from other localities of the Late Cretaceous dinosaur
67 *Spinosaurus aegyptiacus* (Stromer, 1915), and a functional interpretation of the resulting body
68 form, along with anatomical details, Ibrahim et al. (2014) made a case for this exceptionally
69 long and “sail-finned” dinosaur being a semi-aquatic predator, and particularly well-adapted for
70 pursuing prey in the ancient rivers recorded by the Kem Kem beds rocks exposed in Morocco.
71 This interpretation of an extinct theropod as being semi-aquatic was much more forcefully
72 stated than previous suggestions, and generated much media attention (eg. Tarlach, 2014;
73 Coghlan, 2014).

74 Following after the article of Ibrahim et al. (2014), other authors took up the idea of
75 *Spinosaurus* as a piscivore, or even as an active aquatic predator. Vullo et al. (2016) outlined the
76 convergence in the shapes of the margins of the jaws and of the teeth of *Spinosaurus* and that

77 of the predatory pike conger eels (members of the family Muraenesocidae). These authors
78 cautiously suggested that spinosaurs would have been well adapted to forage in aquatic
79 settings like the eels, but did not say anything about semi-aquatic habits for spinosaurids. A
80 very speculative paper on the swimming abilities of *Spinosaurus* and the function of the dorsal
81 “sail” by Gimsa et al. (2016) employed qualitative comparisons between crocodylians, large,
82 predatory fishes (both chondrichthyan and osteichthyan) and *Spinosaurus*. The authors
83 envisaged *Spinosaurus* as an animal capable of becoming fully immersed and employing lateral
84 undulation in the pursuit of prey. These authors also hoped that more quantitative studies in
85 the form of hydrodynamical and biomechanical analyses would refine our understanding of the
86 functions of the peculiar anatomy spinosaurids.

87 The gross morphological features of extinct dinosaurs do not immediately suggest any
88 capacity for a mode of life that had an aquatic component. Their dorsal, and often their caudal
89 vertebrae as well, were tightly articulated with little capacity for lateral motion that could assist
90 with aquatic locomotion via lateral undulation. In particular, the theropod clade Tetanura
91 (*sensu* Gauthier, 1986) with their stiffened tails, would have been most unlikely to have been
92 tail-propelled. Spinosaurids belong to the latter clade (Carrano et al., 2010). The parasagittal
93 hind limbs of all dinosaurs, being held in place with the head of the femur deeply implanted in
94 the acetabulum, would also seem unlikely to have performed well in an aquatic setting.
95 Modern, semi-aquatic crocodylians evolved from thoroughly terrestrial animals, and show
96 changes in their spines and hips, especially their capacity to switch the hindlimb orientation
97 between a high walk and a semi-sprawl, that make them much better adapted to a semi-
98 aquatic life (Grigg & Kirshner, 2015). There are examples from around the world of dinosaur

99 fossils recovered from marine settings: hadrosaurs – *Eotrachodon orientalis* Prieto-Márquez et
100 al. 2016; theropods – *Scipionyx samniticus* dal Sasso & Signore 1998 and *Nothronychus*
101 *mckinleyi* Kirkland & Wolfe 2001; ankylosaurs – *Kunbarrasaurus ieversi* Leahey et al. 2015.
102 However, these examples are all interpreted as thoroughly terrestrial animals that got washed
103 out to sea.

104 The emphatic claim by Ibrahim et al. (2014) of a semi-aquatic theropod dinosaur
105 inspired further investigation of the aquatic potential of *Spinosaurus*, and some specially
106 written software was used to test the center of mass, buoyancy and equilibrium of an
107 immersed digital model of the animal. To put the results from an analysis of an immersed
108 *Spinosaurus* into context, the floating capabilities of five other theropods, including another
109 spinosaurid were also tested. The collective body masses of these five animals span almost four
110 orders of magnitude, allowing for the investigation of the effects of body size on the potential
111 for flotation and stability of immersed theropods.

112

113 MATERIALS AND METHODS

114 Five theropods, four of which were not closely related to each other or to *Spinosaurus*, were
115 chosen for comparison with the latter. These were *Coelophysis bauri* (Ceratosauria),
116 *Struthiomimus altus* (Ornithomimosauria), *Allosaurus fragilis* (Carnosauria), *Tyrannosaurus rex*
117 (Tyrannosauridae), and the spinosaurid *Baryonyx (Suchomimus) tenerensis* (Fig. 1). It has been
118 suggested that the fossil remains of *Suchomimus* are not distinct enough from *Baryonyx* to
119 merit the erection of a new genus (Holtz, 2012; Sues et al., 2002), and this suggestion is

120 followed here. The two criteria governing these choices of theropod for comparative purposes
121 were that the animals be known from enough skeletal material to produce reliable, whole body
122 reconstructions, and that they span a range of body sizes to enable investigation of the effects
123 of body size on the ability of theropods to float. There are allometric changes in body shapes as
124 theropods increase in size over time, with the trunk region becoming deeper, broader and
125 relatively shorter, and the hind limbs becoming more massive (Henderson & Snively, 2004). It
126 was felt important to check if these changes in body proportions would affect the ability of the
127 animals to float.

128 For all six theropod models, the axial body and limb shapes used in their construction
129 were obtained using the three-dimensional, mathematical slicing method of Henderson (1999).
130 The illustrations used as sources for the models are listed in Table 1. The basic axial body tissue
131 density of the models was set to be the same as that of water – 1000 gm/l. However, this was
132 modified in certain regions to reflect aspects of theropod anatomy. The system of air sacs
133 within the bodies of extant birds represents about 15% of their axial body volume (Proctor &
134 Lynch, 1993), and this observation was used to adjust the basic axial body densities of the
135 models. From fossil evidence of extensive pneumatization of the skeletons of extinct theropod
136 dinosaurs, and the inference that these animals had a system of air sacs similar to those of
137 extant birds (O'Connor & Claessens, 2005), the pre-caudal, axial densities of the models were
138 reduced by 15% to 850 gm/l to incorporate the density reductions associated with the
139 presumed air sacs in the hips, trunk, and neck. Lacking evidence for differences in the sizes and
140 relative proportions of air sacs in extinct theropods, the most parsimonious assumption is that
141 they were all of similar construction and proportions. The presence of pneumatized bones in

142 theropod skulls, along with the nasal and oral cavities, led to the same reduced density value
143 being assumed for the heads. A lung cavity was also produced for each model and located in
144 the antero-dorsal portion of the thorax. For all the models the lung volume was set at
145 approximately 9% of the axial body volume based on observations of living reptiles (Gans &
146 Clark, 1976). The theropods used in the present study are assumed to have been non-flying, so
147 the use of a lung volume scaling seen in living birds (eg. Schmidt-Nielsen, 1989, Table 9.2) was
148 not considered appropriate. The mass deficits represented by the lungs were incorporated into
149 the determination of the buoyant states of the models. Lastly, the limbs with their substantial
150 bone component were assigned a slightly higher density of 1050 gm/l.

151 Among the distinctive features of *Spinosaurus* is the large dorsal “sail” (fig. 1E). Given
152 the size and position of the sail, and its potential to affect the equilibrium of a floating
153 *Spinosaurus*, special attention was given to its construction and mass estimation, and this was
154 guided by the comments on the sail by Ibrahim et al. (2014). Figure 2 presents details of the sail
155 relevant to the construction of its model. Digitizing the outline of the entire sail, and computing
156 its lateral area by the triangular decomposition method outlined in (Henderson, 2002), gives a
157 value of 6.60 m². Digitizing the perimeters of the neural spines associated with the
158 reconstruction of the sail shown in Ibrahim et al. (2014, figure 2), and computing their net area,
159 reveals that the combined lateral areas of these bones, 2.45 m², is equivalent to slightly more
160 than one third of the lateral area of the entire sail. The volume of bone comprising the sail is
161 given by the product of the lateral area of the neural spines multiplied by an assumed
162 transverse thickness of 2.25 cm, giving a value of 0.0550 m³. Lacking information to the
163 contrary, the sail was assumed to be covered with skin to a depth of 1 cm on both sides, giving

164 a total thickness of 4.25 cm. The total volume of the sail is the product of its full lateral area,
165 6.60 m², and its estimated maximum thickness, and this gives a value of 0.281 m³. Subtracting
166 the volume of the bony component of the sail from the total sail volume gives a volume
167 measure for the soft tissue component. The soft and bony tissues of the sail were assumed to
168 have densities of 1,000 and 2,000 gm/l, respectively. With the above volume and density values
169 for the soft and hard components of the sail, the total mass of the sail was estimated to be 335
170 kg. The centroid of the sail was computed during the estimation of its lateral area (Henderson,
171 2002), and taken to be the center of mass (CM) of the sail. The mass of the sail represents
172 approximately 7.5% of the axial body mass, and almost 80% of the mass deficit represented by
173 the lung cavity (Table 2). Assuming a density of 1000 gm/l, the mass of the 1cm thick layer of
174 skin on one side of the sail is 66 kg. Doubling the thickness of the skin on both sides would
175 increase the sail mass fraction to approximately 8.5% of the axial body mass. The mass and CM
176 of the sail were considered necessary components to ensure an accurate determination of the
177 floating state of *Spinosaurus*.

178 The mathematical and computational methods used to simulate the immersion of a
179 model tetrapod, and the analysis of a model's floating characteristics, were developed in
180 Henderson (2003). To ensure that the modelling and the software can replicate the orientation
181 and depth of immersion of a large reptile that can be observed floating today, the software was
182 tested using a model of the semi-aquatic American alligator (*Alligator mississippiensis* Daudin
183 1802) (Henderson, 2003) (Fig. 3). Crocodylians share a common ancestry with theropods as
184 both are members of Archosauria. Additionally, the alligator has an elongate body with a
185 substantial, muscular tail similar to that inferred for theropods. As was done with the theropod

186 models, a lung volume equal to 9% of the axial body volume was generated for the alligator
187 model. Unlike what was done for the theropods, the axial body and limb densities were
188 maintained at 1050 gm/L as crocodylians lack the system of air sacs inferred for theropods.

189 It was suggested by a reviewer that a test of the software and methods should also be
190 done with a living, aquatic, predatory theropod, ie. a diving bird, to see how it would compare
191 to *Spinosaurus*. This was done with a model of an emperor penguin (*Aptenodytes forsteri* Gray
192 1844). The model was derived from frontal and lateral views of an adult using the 3D-slicing
193 technique, and included both the hind and fore limbs. The total body length from the tip of
194 beak to the tip of the tail was 1.25m. The post-cervical axial body density was set to 1000 gm/l,
195 while the neck and head were set to 800 gm/l. Penguins do not have the system of air sacs
196 found in other birds and have denser bones (Simpson 1976), hence the higher axial body
197 density. The limb densities were set to 1050 gm/l. A lung volume was generated using the bird
198 lung scaling relationships of Schmidt-Nielsen (1989).

199 It was suggested by another reviewer to test the lateral stability of the floating
200 *Spinosaurus* model, and it was decided to do the same test on the alligator model as well. As
201 their limbs are denser than the freshwater that the models are floating in, the buoyant force
202 arises in relation to the amount of water displaced by the less density axial body. An elliptical
203 disk representing the average cross-section of the axial body of a model was produced by
204 computing the average dorso-ventral and medio-lateral radii from the two slices defining the
205 axial body immediately posterior and anterior to the longitudinal position of the CM in the
206 floating model. This elliptical shape was done as a “super-ellipse” where the exponent was 2.5

207 instead of the usual 2. This produces cross-sections of slightly flatter tops, bottoms and sides
208 than a normal ellipse, and is more biologically plausible than a regular ellipse (Motani,
209 2001). The disk represents a transverse section of the floating axial body, and the competing
210 forces of gravity and buoyancy were assumed to act in the plane of the disk. The mass of the
211 disk is the product of its area, thickness and density, with the value of the latter being the mean
212 density of the whole model with a full lung. The center of mass of the test disk was taken to be
213 its centroid. An iterative process of analysis involved determining the degree of immersion of
214 the slice to compute the magnitude of the upwards buoyant force and the two-dimensional
215 location of the center of buoyancy. The positively-directed buoyant force was added to the
216 unchanging negatively-directed weight force, and if the result was positive the disk was moved
217 up by an amount proportional to the magnitude of the difference. Conversely, if the result was
218 negative, the disk was moved downwards. Any horizontal separation between the centers of
219 buoyancy and gravity represented a moment arm for the buoyant force and would produce a
220 turning moment on the disk acting about the CM. After adjusting the vertical position and
221 angular orientation of the disk, the process of testing and shifting was repeated. The disk was
222 considered to be in a final, stable equilibrium state when the difference between the gravity
223 and buoyant forces was less than 1% of the weight force and the torque acting on the disk was
224 less than 0.5% of a predefined reference torque. See Henderson (2003) for more complete
225 details on bringing a floating model to equilibrium.

226 As another test of the lateral stability of the alligator and *Spinosaurus* models, the
227 traditional naval architecture parameter of the metacentric height (Comstock, 1967) was
228 computed for the full body models and this required two additional parameters to be extracted

229 from the models. The first is the water plane for a model, and this was taken as the area
230 representing the intersection of the floating model with the water surface. As lateral stability is
231 the topic of interest, the second moment of area of the water plane was computed with
232 respect to the longitudinal (X) axis located in the sagittal plane. The second parameter is the
233 volume of the immersed portion of the body, and this was extracted from a model's geometry
234 by noting the degree of immersion of each of the sets of cylindrical disks forming the axial body.
235 The metacentric height, KM, is usually defined as the distance above the keel of a boat, but in
236 the present situation it was taken as the distance above the ventral surface of the belly at the
237 longitudinal position of the center of mass. KM was computed with the following expression:

$$238 \quad (1) \quad KM = KB + \frac{I_x}{V}$$

239 where KB is the distance of the center of buoyancy from the ventral surface, I_x is second
240 moment of area of the water plane, and V is the volume of the immersed portion.

241 For the present study, all but one of the flotation simulations were done with the
242 assumption that the models were in freshwater with a density of 1000 gm/l. The only exception
243 was with the penguin which was floated in seawater with a density of 1026 gm/l.

244 The potential effects of increased limb bone density on the mass and overall density of a
245 floating theropod were checked using three-dimensional, digital models of the non-pedal bones
246 of the hindlimb of *Allosaurus fragilis*. The bone geometries were taken from illustrations of the
247 femur, tibia, fibula and metatarsals of Madsen (1976), and their digital models were generated
248 using the methods of Henderson (1999). These bones were analyzed in association with the

249 three-dimensional mesh representing the muscles and fleshed out hindlimb of the *Allosaurus*
250 model of figure 1.

251

252 RESULTS

253 The whole body and component masses computed for the six theropod models, the
254 alligator and the penguin are presented in Table 2. The striding, non-floating theropod models
255 of figure 1 all show their centers of mass (CM) located just ahead of the hip sockets, but above
256 and between the leading and trailing feet, demonstrating that the animals are balanced with no
257 tendency to tip forward or back. This same is true for the highly attenuated, restored body
258 form of *Spinosaurus*. Even with its rather short legs, the CM of *Spinosaurus* is still positioned
259 above the leading foot, showing that with appropriate stride lengths, this animal could still walk
260 on land (Gatesy et al., 2009).

261 The upper pair of images of figure 3 presents the basic mesh form of the alligator model
262 in dorsal and lateral views, together with a grey cylinder indicating the size and position of the
263 lung cavity. The estimated total mass of the 3.07 m long model is 122 kg, and these values are
264 similar to those observed for a 2.89 m female alligator that weighed 129 kg. (Woodward et al.,
265 1995). Further demonstrations of the validity of the alligator model and its computed
266 parameters can be found in Henderson (2003). The lower pair of images of figure 3 show the
267 model in stable, floating equilibrium with a fully inflated lung. This final state closely replicates
268 the observed resting positions of both crocodiles and alligators when resting at the water
269 surface (Grigg & Kirshner, 2015, Chapter 4). With the model of a floating alligator successfully

270 replicating aspects of a living one, this provides a level of confidence for what is predicted for
271 the extinct theropods.

272 Figure 4 shows the penguin model with a full lung floating in seawater with a density of 1026
273 gm/l, and exhibiting stable equilibrium at the surface. The mean body density of the model was 968
274 gm/l, and the computed total body mass was 46.3kg. Living emperor penguins with a body length of
275 1.22m are observed to have body masses of up to 45kg (Wikipedia, accessed January 8, 2018). The
276 model body orientation and depth of immersion match observations of living emperor penguins at the
277 surface (Kooyman et al. 1971), and provides another indication of the reliability of the modelling
278 process. Deflating the model penguin lung by 90% resulted in a mean body density of 989 gm/l, which is
279 still not high enough to make the model negatively buoyant and enable sinking. However, emperor
280 penguins have been observed to inhale prior to diving (Kooyman et al. 1971), so the lung deflation test is
281 not particularly relevant. With their highly derived wings and powerful pectoral muscles, penguins are
282 able to overcome the positive buoyancy associated with a full lung and propel themselves downwards
283 underwater (Lovvorn 2001).

284 For the present study, a criterion for judging whether a normally terrestrial animal was
285 unlikely to drown and could maintain a stable body orientation while immersed was that the
286 head, and the nostrils in particular, were clear of the water surface so that the animal could see
287 and breathe. Figure 5 presents the final, equilibrium floating states for the two spinosaurid
288 models with full lungs. In each case, the models float with their heads and nostrils above the
289 water, and their centers of mass and buoyancy are nearly coincident. As postulated by Ibrahim
290 et al. (2014), the sail of *Spinosaurus* does stay visible while the animal is floating. The
291 orientations of the heads and necks of these models were not altered from the basic,

292 “terrestrial” versions shown in figure 1. The mass of the low crest associated with the *Baryonyx*
293 (*Suchomimus*) model represents 2.2% of the axial body mass. This smaller mass, when
294 compared to the larger 7.5% relative mass of the *Spinosaurus* sail, and combined with the fact
295 the center of the crest lies close to the CM of the whole body, leads to the position and mass of
296 the *Baryonyx* (*Suchomimus*) crest having only a very minor effect on the overall, final CM of the
297 model.

298 Figure 6 presents the floating equilibrium states of the four other comparative theropod
299 models. The first thing to notice is that all four animals/models can float, and that their heads
300 are clear of the water surface. The heads of the *Coelophysis* and *Tyrannosaurus* models needed
301 to be dorsiflexed by 20° and 15°, respectively, to elevate them enough so that the tips of their
302 snouts (nostrils) were above the water surface. These head elevations were done via a series
303 small increments applied to the each of the model slices defining the necks, until the sum of the
304 rotations applied to individual slices equaled the required total head lifting angle. An additional
305 feature is that the floating states appear to be independent of body size, with the same
306 proportions of the bodies being exposed above the water line. The only apparent difference is
307 that the *Coelophysis* model floats with body tipped much more forward, when compared to the
308 others. This may be related to two aspects of the body shape of *Coelophysis*. The much more
309 attenuated, and slender axial body, with less of the body mass concentrated about the hips,
310 and the much longer neck, which will not only represent a larger fraction of the total body
311 mass, but in combination with the head, will also exert a stronger turning moment on the body.

312 Figure 7 shows the results of the lateral stability test conducted for the alligator model
313 with the disk representing the transverse section of the body at the longitudinal position of the
314 whole body CM. Although not shown, when this disk was placed in water without any lateral
315 tipping, it came to stable equilibrium with 95.25% of the disk immersed and remained upright.
316 The mass density of the disk is 952 gm/l. For the lateral stability test the model disk was tipped
317 sideways by 20° (figure 7, frame no. 0). This resulted in a small, although not visible, horizontal
318 separation between the CM (grey '+') and the CB (white '◇'). The shape of the whole cross-
319 section and its immersed portion, and the relative positions of the CM and CB, resulted in the
320 disk returning to equilibrium with the original topside uppermost (Figure 7, frame no. 42). The
321 vertical positions of the centers of buoyancy and mass, relative to the water surface in this final
322 state were -0.167 m and -0.159 m, respectively. The lengthy number of cycles needed to return
323 to equilibrium, 42 (also the answer to “life, the universe and everything” (Adams, 1982)), is
324 interpreted to be the result of the CM and CB being almost coincident and the moment arm of
325 the restoring buoyant forces being very small. The final degree of immersion was the same
326 95.25% as before. This capacity for stability and self-righting when floating at the surface is
327 what could be expected for a semi-aquatic animal that habitually spent extended periods at the
328 water surface. Confirmation of this dynamic stability was observed directly in a floating, and
329 occasionally gently paddling and rolling caimans (*Caiman crocodylus*) that remained upright at
330 the Vancouver Aquarium (Graham Amazon Gallery), Stanley Park, Vancouver, British Columbia
331 (pers. obs. January 2, 2018).

332 When not tipped sideways, the disk representing the *Spinosaurus* cross-section
333 remained upright, with 82.8% immersion. The mass density of the disk is 833 gm/l and ideally

334 the disk should have come to equilibrium with 83.3% immersion. The modelled value of 82.8%
335 is only off by 0.6% of the expected value, and this discrepancy is interpreted to arise from
336 modelling process and the asymptotic nature of how the disk is brought to equilibrium. Figure 8
337 shows what happened when the *Spinosaurus* disk was tipped sideways by 20° - the disk quickly
338 rolled over onto its side, with the final, equilibrium vertical positions of its CB and CM being -
339 0.301 m and -0.239 m, respectively. This test demonstrates that the body of a floating
340 *Spinosaurus* would have been liable to tip when nudged, and suggests that *Spinosaurus* must
341 have had to apply constant limb action to maintain an upright posture when in water when
342 subject to any disturbances at the surface. This does not appear to be an attribute of an animal
343 well- adapted for a semi-aquatic life.

344 Further confirmations of the conditions of stable and unstable equilibrium of the
345 alligator and *Spinosaurus*, respectively, were provided by the determinations of their
346 metacentric heights. A metacentric height located below the center of mass of an immersed
347 object indicates an unstable situation. Figure 9 presents graphically the locations of the centers
348 of buoyancy (KB), centers of mass (KG), and the metacentric heights (KM) of these two models.
349 Similar to what was found with the disk version of the alligator body (figure 7), these three
350 quantities in the alligator are all virtually coincident with one another, with just millimeters
351 separating them. Although the KM of the alligator is above the KG, the separation is less than
352 2mm, and this latter distance represents less than 0.5% of the 36cm body depth at the location
353 of the whole body center of mass. The closeness of the three quantities indicates that any
354 moment arms associated with misaligned buoyant and gravitational forces will be extremely
355 small. In contrast, the positions of KB, KM, and KG of the *Spinosaurus* model clearly

356 demonstrate an unstable situation, with the center of gravity located 12cm above the
357 metacentric height.

358 Figure 10 shows the fleshed-out form of the model hindlimb of the *Allosaurus* model
359 from figure 1 along with its larger limb bones. The volume of the hindlimb mesh was found to
360 be 0.1152 m³, and with the assigned density of 1050 kg/m³, it has a mass of 121 kg. The bones
361 have a combined volume of 0.01052 m³, and subtracting this from the total volume leaves a
362 flesh (non-bone) volume of 0.1047 m³. The mass of the leg can be expressed as:

$$363 \quad (2) \quad \text{leg_mass} = \text{flesh_volume} * \text{flesh_density} + \text{bone_volume} * \text{bone_density}$$

364 Given that the total leg mass and the flesh and bone volumes are known, and assuming that the
365 flesh density is 1000 gm/l, one can solve (1) for the bone density. This gives a bone density for
366 the *Allosaurus* leg model of 1547 gm/l, approximately 50% more than that of water. Assuming
367 that compact bone has a density of approximately 2000 gm/l, the reduced bone density is
368 consistent with an open medullary cavity in the bones. The mass of the bones is computed as
369 their volume multiplied by their density, and comes to 16.28 kg. The bones of the single
370 hindlimb represent 1.69% of the total body mass estimated for the *Allosaurus* model of 963 kg
371 (Table 2). With the availability of the bone volumes, the effects of increasing the density of the
372 bones to increase their mass can be analyzed. Assuming that the bones are solid with a density
373 of 2000 gm/l, one gets a heavier bone mass of 21.04 kg which now represents 2.248% of total
374 body mass, an increase of just over half of one percent of total mass. The leg of the new
375 restoration of *Spinosaurus* is estimated to have a mass of 295 kg, more than twice that of the
376 *Allosaurus* model. However, the body mass of the animal is seven times as great as that of

377 *Allosaurus* at 6500 kg, and the hind limb represents just 4.54% of total body mass. Assuming
378 the same bone to flesh proportions in the hindlimbs of *Spinosaurus* and *Allosaurus*, any
379 increase in the mass of the relatively smaller hindlimbs of *Spinosaurus* via solid bones will be an
380 even smaller fraction of total body mass than that estimated for *Allosaurus*. Given the inherent
381 uncertainties of the various densities of the various body regions, and their true volumes,
382 exceptional evidence would be needed to demonstrate that the increase in body mass by a few
383 percent by having denser limb bones would significantly affect the ability of a *Spinosaurus* to
384 immerse itself.

385

386 DISCUSSION

387 Ibrahim et al. (2014) list details of *Spinosaurus aegyptiacus* and its ancient environment that
388 plausibly suggest this dinosaur was specialized for a semi-aquatic mode of life. These details
389 include: highly unusual adaptations such as a higher bone compactness than seen in alligators;
390 peculiar morphology of the pes; extremely retracted position of nares; oxygen isotope analyses
391 strongly suggesting a semiaquatic; presence of abundant giant fishes; very few remains of
392 plant-eating dinosaurs in the Kem Kem beds and other equivalent sequences in North Africa;
393 and seemingly optimal conditions for large, fish-eating tetrapods and fish-based food webs.
394 However, while no amount of evidence can prove the validity of a hypothesis, and it only takes
395 one contradictory observation to potentially falsify it. The three problems with the hypothesis
396 of a semi-aquatic *Spinosaurus* identified in the current work would appear to seriously weaken
397 the hypothesis of Ibrahim et al.

398 Contrary to the claim by Ibrahim et al. (2014) that the CM of *Spinosaurus* was centrally
399 located in the trunk region, this study finds the CM much closer to the hips than previously
400 estimated. In fact, it is less than the relative CM distance determined for the *Tyrannosaurus*
401 model (Table 2 – Horizontal Relative CM Position). This is interpreted to be a consequence of
402 the new restoration of *Spinosaurus* and the associated muscle mass of its substantially longer
403 tail when compared to that of *Tyrannosaurus*. Having a CM closer to its hips indicates that
404 *Spinosaurus* would still be competent as a terrestrial biped since the CM would be above
405 and/or between the supporting feet while walking (Henderson & Nicholls, 2015). A validation of
406 the present method for determination of the CM in theropods comes from an estimate of the
407 CMs of a standing pigeon and ostrich (Henderson, 2010). With densities appropriate for birds
408 assigned to the heads, necks, trunks and limbs of models of the latter two animals, their CMs
409 were found to lie directly above and between the feet enabling the animals to stand in a stable
410 fashion (Henderson, 2010, figure 1), as can be observed in the living forms.

411 In an attempt to replicate the more anteriorly located CM for *Spinosaurus* reported by
412 Ibrahim et al. (2014), two alternate versions of determination the CM were tried. The first
413 attempt involved determining the centroid of the the two-dimensional lateral profile of the
414 axial body. This 2D centroid is located towards the rear of trunk region, and slightly posterior to
415 the ventral bulge associated with the pubis (figure 11A). A second used just the axial body of
416 the three-dimensional model and assumed a uniform density, no pneumatic cavities, and no
417 lung cavity. The resulting 3D CM was again located towards the rear of the trunk region, but
418 just ahead of the ventral bulge associated with the distal end of the pubis (figure 11B). None of

419 the three computed values for the CM for *Spinosaurus* in the present study can match that
420 reported by Ibrahim et al. (2014).

421 *Spinosaurus* is certainly able to float and breathe with the head above water (Figure 5A),
422 However, there is nothing special about the state of the immersed *Spinosaurus*. With the
423 modest 15° upwards tilt of its head relative to that of the basic terrestrial form (figure 1F), the
424 *Tyrannosaurus* is also able to float and breathe (figure 6D). Furthermore, the *Tyrannosaurus*
425 model is 51% heavier and slightly denser than the *Spinosaurus* one (Table 2), yet is able to keep
426 most of the head clear of the water surface. The floating equilibrium states of the four other,
427 lighter models – *Baryonyx* (*Suchomimus*) (figure 5B), *Coelophysis* (figure 6A), *Struthiomimus*
428 (figure 6B), *Allosaurus* (figure 6C) – are consistent with the floating states of the two, heavier,
429 longer animals. These results are not unexpected, as most terrestrial tetrapods can successfully
430 float and swim (see Henderson & Naish, (2010) for review).

431 It was found that the alligator model would sink when the lungs were deflated by 40-
432 50% (Henderson, 2003). However, the lower mean densities of the two spinosaurid models,
433 relative to that of the alligator, immediately suggests that they might not be able to sink and
434 become fully immersed. This was tested by deflating the lung of the *Spinosaurus* model by 75%.
435 This had the effect of increasing the mean density of the model from its basic value of 823 gm/l
436 to 885 gm/l. It should be mentioned that the lung deflation process was associated with an
437 elevation of ventral abdominal region of the model body so that the volume decrease of the
438 axial body was reflecting the volume decrease of the lung. With the increased density, the
439 model reached buoyant equilibrium at the lower depth of 48 cm, compared to the 37 cm when

440 the lung was fully inflated. However, the new density is still less than that of water, 1000 gm/l,
441 indicating that the animal would still be buoyant. Extant semi-aquatic birds and reptiles such as
442 penguins, loons, ducks, cormorants, sea snakes, marine iguanas, crocodilians and both marine
443 and freshwater turtles ALL have the ability, and the apparent need, to become submersed to
444 enable the pursuit of prey, or in the case of the marine iguana, forage on the sea bed. The same
445 is true of semi-aquatic mammals such as otters, musk rats, waters shrews, beavers, hippos and
446 polar bears. Not being able to become fully immersed for any of these taxa listed would be a
447 major impediment. The inability of a *Spinosaurus* to sink underwater would severely limit its
448 ability to effectively capture aquatic prey, and conflicts with the suggestion that *Spinosaurus*
449 was specialized for a semi-aquatic life.

450 As a test of how sensitive the buoyant *Spinosaurus* model was to the assumed presence
451 of avian style air sacs and pneumatized bone, an alternate model lacking these features was
452 tried. This model assigned a uniform axial density of 1000 gm/l from the tip of the tail to the tip
453 of the snout. The limb and sail densities were unchanged, and the same lung was retained. This
454 resulted in a denser (918 gm/l) and heavier (7160 kg) model. Deflating the lungs of this denser
455 model by 75% resulted in an even greater mean body density of 986 gm/l, and deeper depth of
456 immersion for the CM at 0.696 m, but this model was still not able to sink as its density was still
457 less than that of fresh water. If it could be shown that the mass deficit represented by the
458 lungs and air sacs was offset by the increased mass of a denser skeleton that might help the
459 claim of a semi-aquatic *Spinosaurus*.

460 It should not be forgotten that the restoration of *Spinosaurus* by Ibrahim et al. (2014) is
461 based on the composition and scaling of the remains of several animals from different
462 localities, along with missing details supplied from other spinosaurids such as *Baryonyx*
463 (*Suchomimus*), *Irritator* and *Ichthyovenator* (caption for Figure S3, Supplementary Materials,
464 Ibrahim et al., 2014). In particular, the hind limbs of the new restoration, although from a single
465 individual, were not associated with a complete dorsal axial skeleton. The color codings of the
466 vertebrae used in the reconstruction (Ibrahim et al. 2014, Figure S3, Supplementary Materials)
467 clearly show that the majority of the vertebrae come from other animals and locations. The
468 only partially contiguous set of vertebrae are those of the anterior and mid dorsals and the
469 incomplete sacrum from the original specimen described by Stromer (1915). With the axial
470 body providing the majority of the body mass, any systematic errors in the restoration of body
471 length will affect estimates of total body mass and relative limb/body proportions. The restored
472 hindlimb proportions of *Spinosaurus* do appear to be rather small when compared to the rest of
473 the body, and when compared with the hind limb-body proportions seen in other theropods.
474 Figure 12 shows a plot of relative masses of single hind limbs, expressed as a percentage of
475 total body mass for the six animals of the present study. For the computation of the mean and
476 standard deviations shown in figure 12, the values for *Spinosaurus* were not included. The
477 relative hindlimb mass of the restored *Spinosaurus*, 4.88%, is less than half the mean relative
478 mass computed for the other five of 12.6% (stan.dev. = 1.87%). It might be argued that the
479 qualitative reconstructions of the forms of the hindlimbs of the models might be highly
480 subjective, and subject to bias. However, some qualitative aspects of the plot argue for its
481 general plausibility. *Struthiomimus*, interpreted to be highly cursorial (Russell, 1972), and

482 assumed to have extensive hindlimb musculature for running, has the highest relative leg mass
483 with it plotting more than one standard deviation above the mean (the dashed line of figure
484 12). The heaviest animal of the present study, *Tyrannosaurus*, has the second highest relative
485 limb mass, while lightest animal, *Coelophysis*, has a relative leg mass less than the mean value.

486 Modern, semi-aquatic crocodylians have relatively smaller hind *and* forelimbs when
487 compared to their more terrestrial ancestors eg. *Sebecus* (Pol et al., 2012), *Terrestrisuchus*
488 (Crush, 1984). This reduction in limb size is interpreted as an adaptation to reduce drag while
489 swimming, and reflects the dominance of axial musculature for aquatic propulsion (Grigg &
490 Kirshner, 2015). If the reduced hindlimbs of the new restoration of *Spinosaurus* are an
491 indication of a more aquatic mode of life (Ibrahim et al., 2014), one would expect that the
492 forelimbs would also be reduced, similar to what is seen in the crocodylians. However, the
493 forelimbs as restored for *Spinosaurus* are large enough to reach the ground. Complete
494 forelimbs were not found in association with the hindlimbs or the axial body, and the color
495 codings in the supplementary information figure S3 of Ibrahim et al. (2014) clearly
496 demonstrates the disparate origins of the forelimb elements in the new restoration. The only
497 two minor exceptions to the mixed origins of the forelimb elements comes from a manual
498 phalanx 2 and an incomplete base of phalanx 3 from digit II that were found with the new
499 specimen. If isometric scaling based on the dimensions of these two elements was used to set
500 the sizes of the other bones, then it needs to be demonstrated that the assumed scaling
501 relationship is valid. The exceptionally large size of *Spinosaurus* compared to other theropods
502 indicates that non-linear, non-isometric changes in bone sizes and their relative proportions in
503 the forelimbs are a distinct possibility, and this undermines confidence in the new restorations.

504 Despite the above problems with having *Spinosaurus* as an animal that spent substantial
505 amounts of time immersed in water, it is still reasonable to interpret the animal as having some
506 connection with aquatic environments. Charig and Milner (1997) noted the gharial-like aspects
507 of the skull and dentition of another well-known spinosaurid, *Baryonyx walkeri*, and proposed
508 that *Baryonyx* was wading in the shallows snatching fish with its specialized jaws. The very
509 robust arms and manual claws of *Baryonyx* were also suggested as another way for the animal
510 to procure aquatic prey without having to become fully immersed - similar to modern grizzly
511 bears (Charig & Milner, 1997). Amiot et al. (2010) used stable isotope geochemistry analysis of
512 oxygen in the teeth of spinosaurids to show that they must have spent significant time in water
513 and must have included some aquatically derived prey as part of a more generalist diet. Ibrahim
514 et al. (2014) made a series of observations of the skull and teeth of *Spinosaurus* that suggested
515 it was well adapted to sense, pursue, and capture aquatic prey. However, given the findings of
516 the present study, the more conservative, and more terrestrially linked, *Baryonyx* model of
517 Charig and Milner would also seem to be the one for the interpretation of the mode of life of
518 *Spinosaurus aegyptiacus*.

519

520 CONCLUSION

521 The combination of a CM close to the hips that still enabled effective terrestrial locomotion, an
522 inability to become negatively buoyant, and a body (when immersed) with a tendency to roll
523 onto its side unless constantly resisted by limb use, suggests that *Spinosaurus* was not highly
524 specialized for a semi-aquatic mode of life. Furthermore, the floating characteristics of the

525 *Spinosaurus* model were similar to those of models of other predatory dinosaurs, indicating
526 that there was nothing special about the buoyant characteristics of this animal, and that other
527 theropods could have successfully taken to water to the same degree as well. Terrestrial
528 activity would still have been part of its normal life of *Spinosaurus*, similar to the interpretations
529 given for other large predatory dinosaurs. Lastly, the new reconstruction of *Spinosaurus* is
530 based on a composition of remains from multiple individuals of varying sizes and proportions
531 that come from different locations, and were scaled to match the presumed proportions of a
532 single individual. This does not seem like a good platform for building hypotheses about what
533 this animal was like as a once living organism.

534 ACKNOWLEDGEMENTS

535 I thank Jim Gardner (Royal Tyrrell Museum of Palaeontology) for reading an earlier draft of the
536 text. The constructive comments and suggestions of reviewers C. Palmer, V. Allen, and I.M.
537 Anonymous made for a much improved study.

678 FIGURE CAPTIONS

- 679 Figure 1 Dorsal and lateral views of the theropod models used for flotation tests. (A)
680 *Coelophysis bauri*; (B) *Struthiomimus altus*; (C) *Allosaurus fragilis*; (D) *Baryonyx (Suchomimus)*
681 *tenerensis*; (E) *Spinosaurus aegyptiacus*; (F) *Tyrannosaurus rex*. Animals in order of increasing
682 mass. Lung volumes and positions are represented by the dark gray cylinders in the chest

683 regions. Black '+' denotes the computed center of mass. See Tables 1 and 2 for model image
684 sources and model details, respectively.

685 Figure 2 Detailed view of the *Spinosaurus* "sail" and its associated neural spines (after Ibrahim
686 et al. (2014)). These details were used to determine the relative fractions of the bony and soft
687 tissue components of the sail which were then used to compute the mass and center of mass of
688 the sail. These latter two values were components in the final calculations of the mass, center
689 of mass, and buoyant characteristics of the complete *Spinosaurus* model. Small white '+'s are
690 the centroids of the individual spines. Large black '+' is the centroid of the entire sail. See
691 Methods for details of the calculations.

692 Figure 3 Three-dimensional alligator (*Alligator mississippiensis*) model as a validation of the
693 methods. (A) basic model; (B) floating model that has attained buoyant equilibrium with a fully
694 inflated lung. Thin, horizontal black line is the water surface. Light colored dorsal regions are
695 "dry" and exposed to the air. Black '+' denotes the center of mass, while the white '◇' indicates
696 the center of buoyancy. These figures are derived and updated from Henderson (2003). See
697 Tables 1 and 2 for details of the model and its floating state.

698 Figure 4 Dorsal, lateral and anterior views of the floating model of the emperor penguin
699 (*Aptenodytes forsteri*). This example of an extant, aquatic, predatory theropod was done as
700 another test of the validity of the methods employed with the extinct theropods. The model is
701 in its final, equilibrium flotation state with a full lung, and replicates the situation seen in living
702 emperor penguins floating at the water surface. Unlike all the other flotation tests, this one is

703 done with seawater of density 1026 gm/l. Colours and symbols as per figure 3. See Table 2 for
704 details of the model and its floating state.

705 Figure 5 Floating spinosaurids in lateral and dorsal views. (A) *Spinosaurus aegyptiacus*; (B)
706 *Baryonyx (Suchomimus) tenerensis*. Determination of the buoyant state required knowing the
707 masses and centers of mass of the axial body (accounting the presence of a lung), all four limbs,
708 and in both cases, the dorsal “sail”. See Table 2 for model details.

709 Figure 6 Floating theropods with masses ranging from 10.3 kg to 9360 kg. (A) *Coelophysis bauri* ;
710 (B) *Struthiomimus altus*; (C) *Allosaurus fragilis*; (D) *Tyrannosaurus rex*. See figure 3 explanation
711 of symbols. All models floated with full lungs. See Table 2 for model details.

712 Figure 7. A test of the lateral stability of the floating *Alligator* model using a disk representing
713 the transverse section of the immersed axial body at the position of the CM from the floating
714 model of figure 3B. The disk was given a 20° sideways tip, but slowly returned to an upright
715 orientation by passive self-righting. Gray ‘+’ indicates center of mass (centroid) of disk and
716 white ‘∅’ is the center of buoyancy. Green indicates the “dry” area above the waterline, while
717 the blue is the “wet”, immersed portion.

718 Figure 8. A test of lateral stability of the floating *Spinosaurus* model using a disk representing
719 the cross-sectional area of the axial body at the position of the CM from the floating model of
720 figure 5A. The disk was given a 20° sideways tip and subsequently rolled onto its side to a new
721 position of stable equilibrium. Symbols and colors as per figure 7.

722 Figure 9 Graphical views of the metacentric heights (KM '□') determined for the floating
723 alligator and *Spinosaurus* models. A center of gravity above the metacentric height indicates an
724 unstable situation, which is clearly the case for the *Spinosaurus*. Centers of buoyancy and
725 gravity are indicated by KB '◇' and KG '+', respectively. Stated measurements are relative to the
726 water line and are in meters. See Methods and Results sections for more details.

727 Figure 10 Centers of mass determinations for the axial body of *Spinosaurus* using two different
728 methods: (A) two-dimensional silhouette with constant areal density; (B) Three-dimensional
729 mesh without lung cavity or air sacs. In neither case does the CM reside at the midpoint of the
730 trunk region as claimed by Ibrahim et al. (2014). See Discussion section.

731 Figure 11 Isometric views of hindlimb model of *Allosaurus fragilis* using the right limb from
732 figure 1C and three-dimensional models of the large limb bones based on illustrations in
733 Madsen (1976). The volumes of these shapes, combined with the appropriate densities, were
734 used to investigate the effects of higher than normal bone densities on the mass and density of
735 the host animal. See Discussion.

736 Figure 12 Relative mass fractions of the hindlimbs of the theropods in the present study
737 highlighting the small size of the restored *Spinosaurus* hindlimbs. Dashed line represents the
738 mean value of 12.6%. Gray band spans plus and minus one standard deviation about the mean.
739 The *Spinosaurus* limb mass was not used in the calculation of the mean and standard deviation.
740 A.f – *Allosaurus fragilis*, B.t – *Baryonyx (Suchomimus) tenerensis*, C.b – *Coelophysis bauri*, S.a –
741 *Struthiomimus altus*, S.ae – *Spinosaurus aegyptiacus*, T.r – *Tyrannosaurus rex*.

Table 1 (on next page)

1. Axial mass reduced by an equivalent mass of water represented by the lung cavity and excludes the mass of the sail for *Spinosaurus*.
2. Center of Mass: horizontal position expressed as meters from the tip of the tail, vertical position is meters above lowest point of the axial body. For *Alligator* and *Aptenodytes* vertical CM is from floating models and measured relative to water surface.
3. Horizontal Relative CM: distance in front of acetabulum expressed as a percentage of the gleno-acetabular distance.

Figure 1(on next page)

Dorsal and lateral views of the theropod models used for flotation tests.

(A) *Coelophysis bauri* ; (B) *Struthiomimus altus* ; (C) *Allosaurus fragilis* ; (D) *Baryonyx* (*Suchomimus*) *tenerensis* ; (E) *Spinosaurus aegyptiacus* ; (F) *Tyrannosaurus rex* . Animals in order of increasing mass. Lung volumes and positions are represented by the dark gray cylinders in the chest regions. Black '+' denotes the computed center of mass. See Tables 1 and 2 for model image sources and model details, respectively.

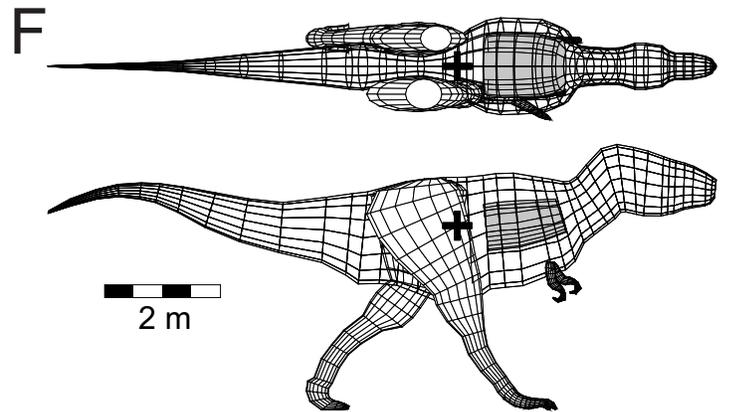

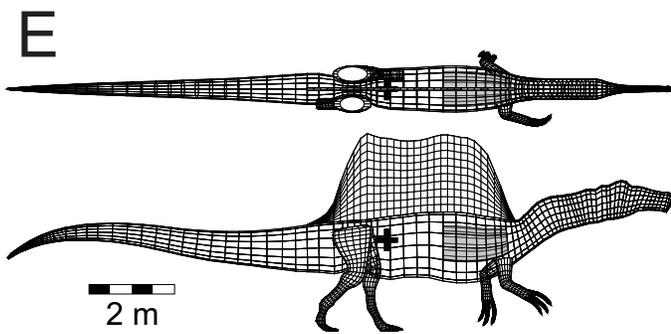

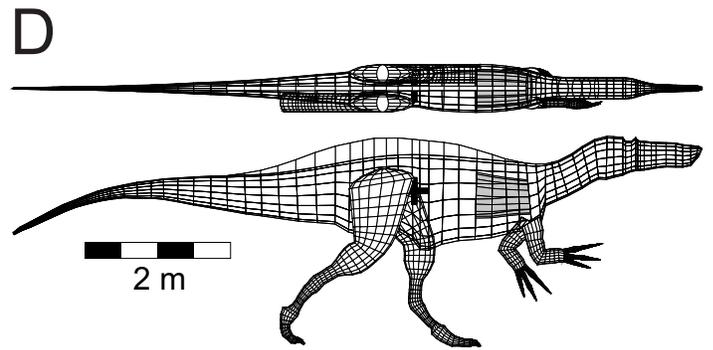

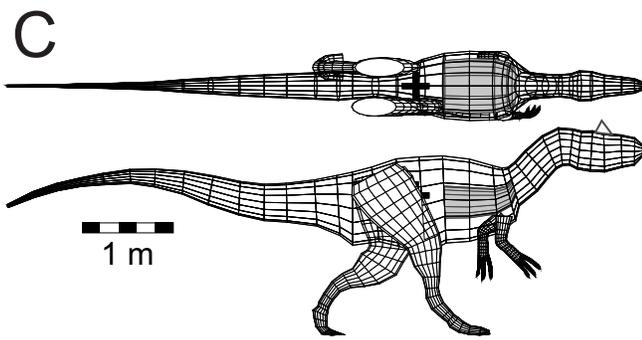

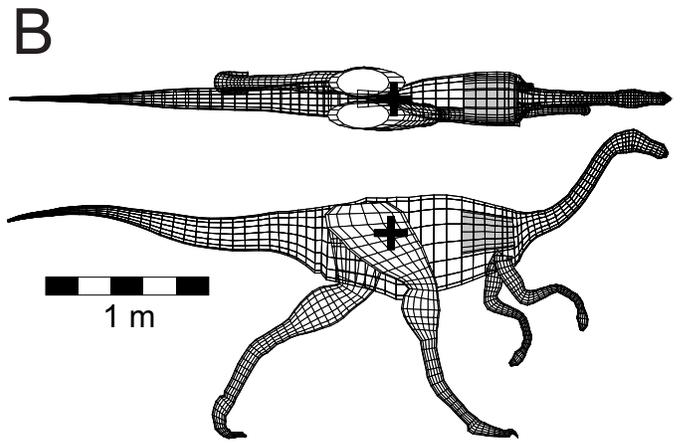

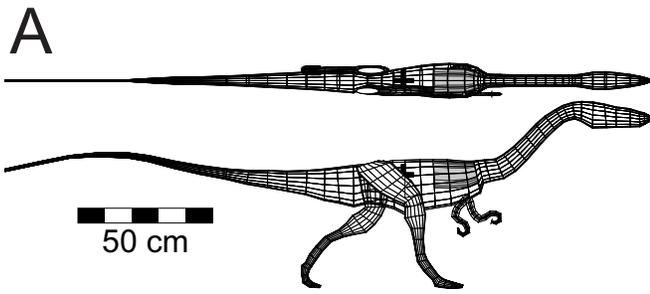

Figure 2(on next page)

Detailed view of the *Spinosaurus* “sail” and its associated neural spines (after Ibrahim et al. (2014)).

These details were used to determine the relative fractions of the bony and soft tissue components of the sail which were then used to compute the mass and center of mass of the sail. These latter two values were components in the final calculations of the mass, center of mass, and buoyant characteristics of the complete *Spinosaurus* model. Small white ‘+’s are the centroids of the individual spines. Large black ‘+’ is the centroid of the entire sail. See Methods for details of the calculations.

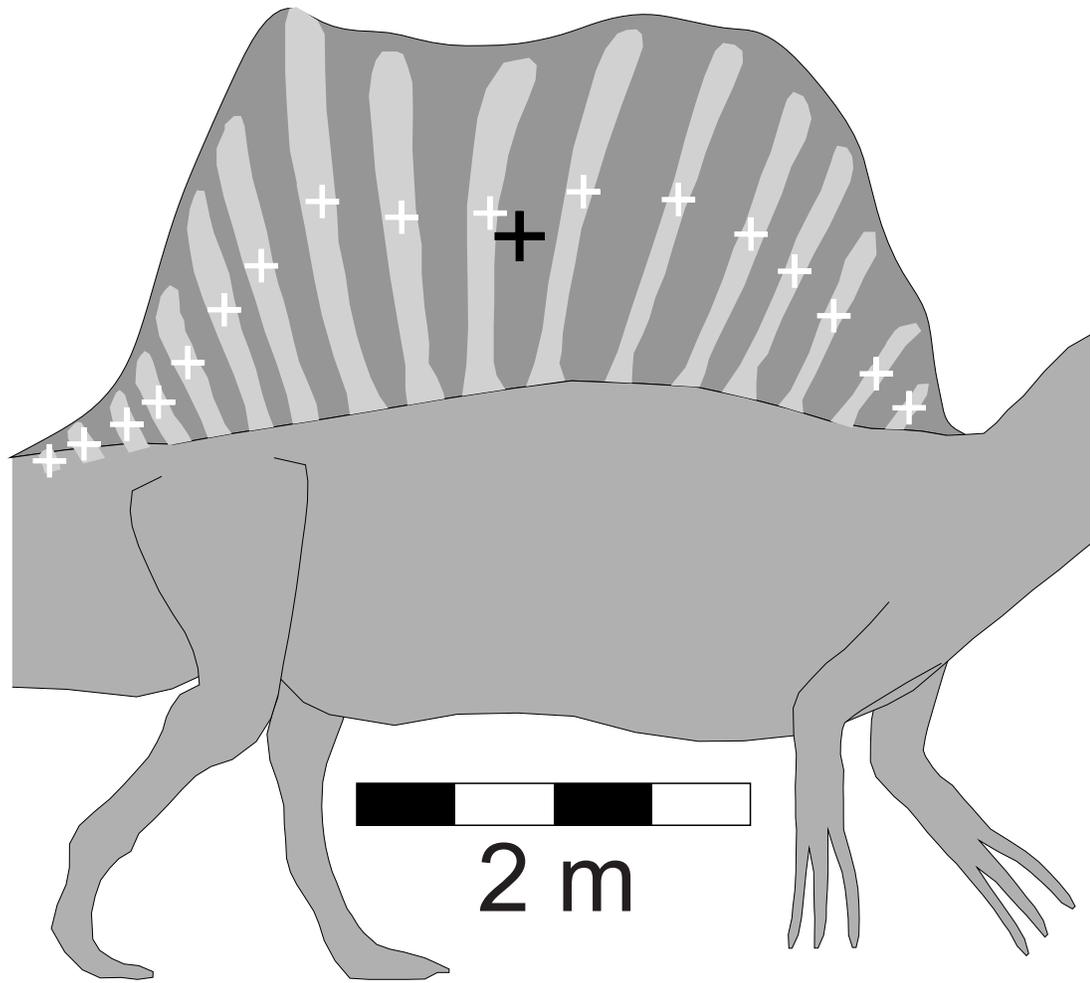

Figure 3(on next page)

Three-dimensional alligator (*Alligator mississippiensis*) model as a validation of the methods.

(A) basic model; (B) floating model that has attained buoyant equilibrium with a fully inflated lung. Thin, horizontal black line is the water surface. Light colored dorsal regions are “dry” and exposed to the air. Black ‘+’ denotes the center of mass, while the white ‘◇’ indicates the center of buoyancy. These figures are derived and updated from Henderson (2003). See Tables 1 and 2 for details of the model and its floating state.

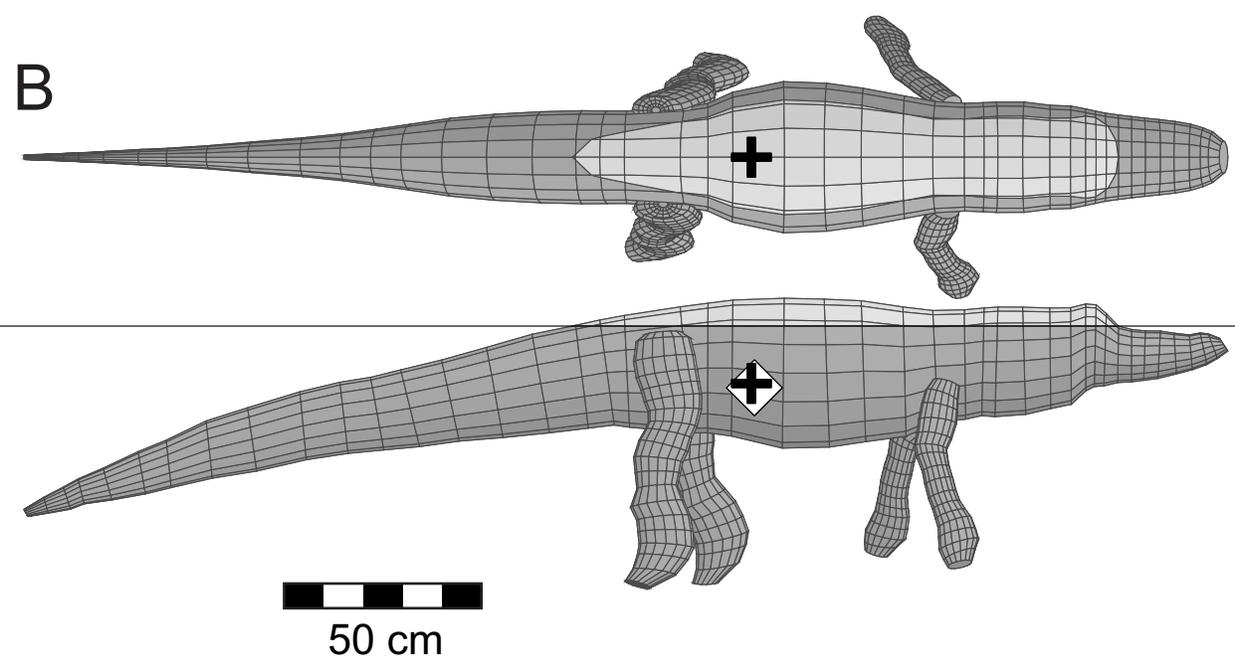

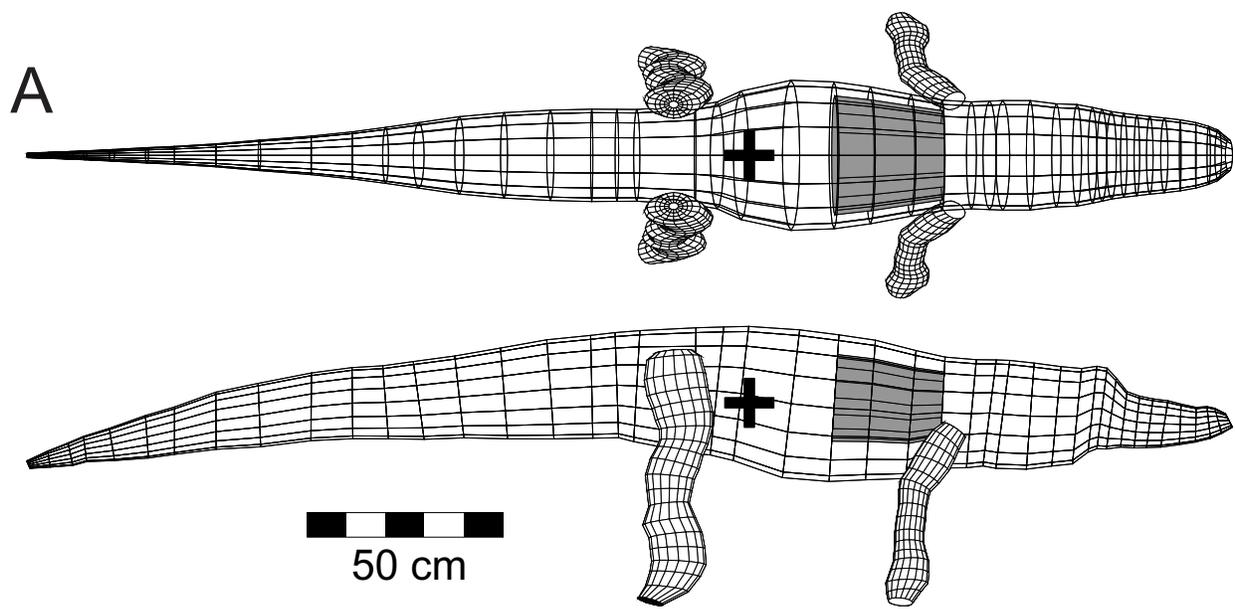

Figure 4(on next page)

Dorsal, lateral and anterior views of the floating model of the emperor penguin (*Aptenodytes forsteri*).

This example of an extant, aquatic, predatory theropod was done as another test of the validity of the methods employed with the extinct theropods. The model is in its final, equilibrium flotation state with a full lung, and replicates the situation seen in living emperor penguins floating at the water surface. Unlike all the other flotation tests, this one is done with seawater of density 1026 gm/l. Colours and symbols as per figure 3. See Table 2 for details of the model and its floating state.

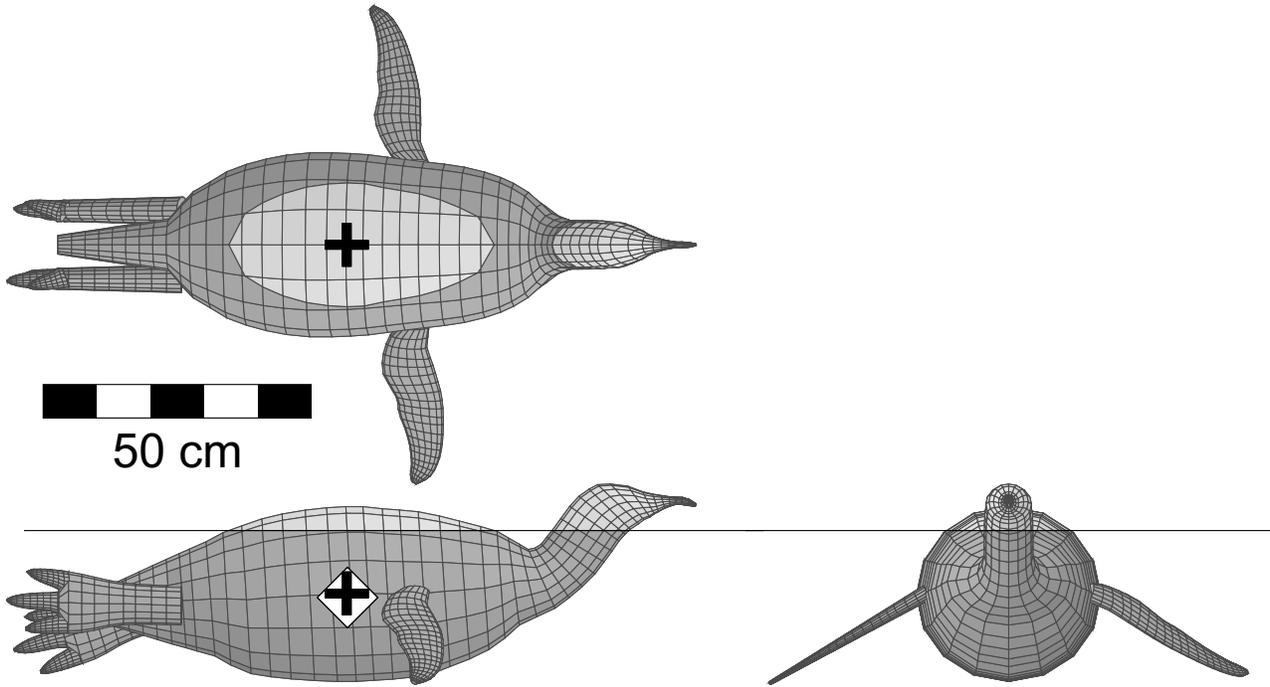

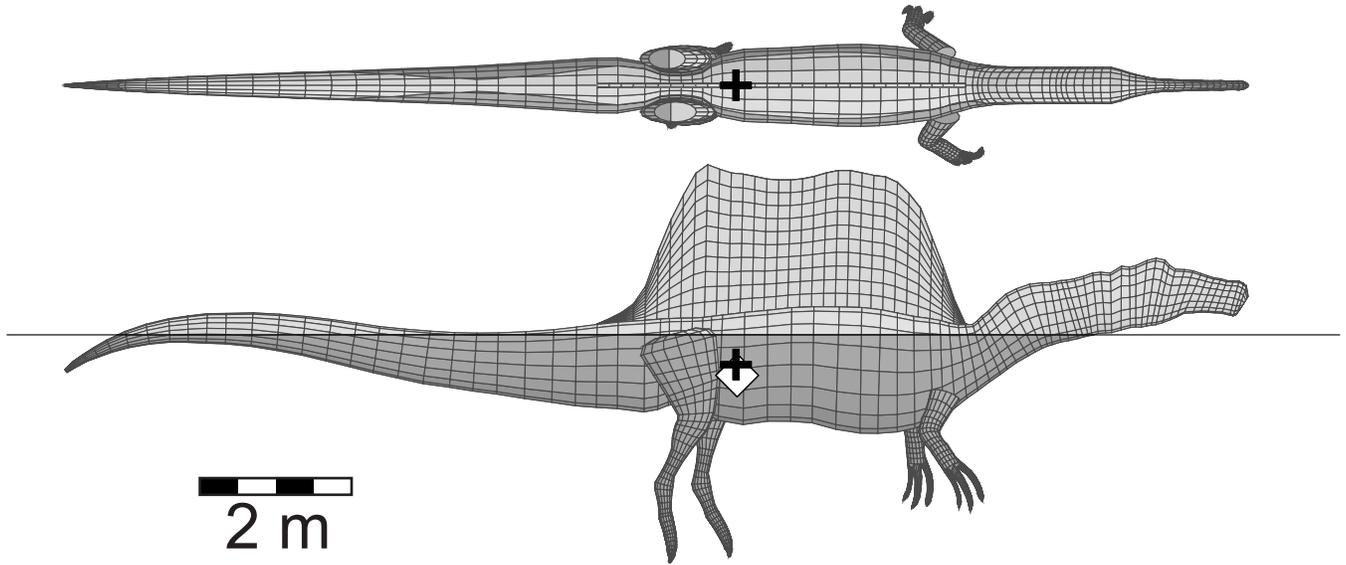

Figure 5(on next page)

Floating spinosaurids in lateral and dorsal views.

(A) *Spinosaurus aegyptiacus* ; (B) *Baryonyx* (*Suchomimus*) *tenerensis* . Determination of the buoyant state required knowing the masses and centers of mass of the axial body (accounting the presence of a lung), all four limbs, and in both cases, the dorsal “sail”. See Table 2 for model details.
